### ABSTRACT

In this paper we investigate how consumers respond to the UK nutritional food label Traffic Light System (TLS). Employing a choice experiment (CE) we find that consumers appear to behave in a manner consistent with our expectations regarding the impact of the TLS. We identify a strong preference on the part of respondents to avoid a basket of goods containing a mix of foods with any “Red” lights. In addition, we find that consumers have a hierarchy of importance in terms of perception of the various nutrients examined and there are clear behavioural differences associated with particular socio-economic characteristics confirming early research on the use of nutrition labels. Overall our results indicate significant heterogeneity in the attitudes and responses of consumers to the TLS nutritional food labels within and across socio-economic strata.

### Introduction

There is an ever-growing awareness and understanding of the relationship between food and the role it plays in health and well being. The importance of this relationship is increasing as the health implications of a poor diet in the UK, and elsewhere, have become ever more apparent (HMSO, 2007). In response, there are now a whole raft of policy approaches that attempt to address this issue including various health campaigns such as the Food Standards Agency (FSA) “The eatwell plate” (FSA, 2007), the FSA “6 g per day of salt intake” and the Department of Health “5-a-day campaign” for fruit and vegetable consumption. All of these campaigns have been accompanied by a drive to have food labelled in a manner that provides important dietary information to consumers.

In terms of nutritional food labelling, the UK has voluntarily adopted the Traffic Light System (TLS)<sup>1</sup> which indicates the levels of four key nutrients i.e., fat, sugar, saturates and salt, which are found in processed food. The TLS system is relatively simple. A Red<sup>2</sup> light indicates a very high level of a specific nutrient, Amber a medium amount and Green low. The choice of colour is based on the content of each of the nutrients per 100 g of any food type

that can then be converted into a per portion quantity. Thus, for any food the resulting quantities of these nutrients are measured then compared against the TLS which in turn provides the colour coding on the food packaging. In practice, the TLS is meant to aid consumers in getting the balance of products right in terms of their overall diet. It can be used a means to monitor the amount of food being consumed that is high in one or more of the nutrients identified.

There already exists a large literature that has examined various aspects of the TLS and nutritional labels in general. In comprehensive reviews of the literature on consumer use and response to nutrition information on food labels, Cowburn and Stockley (2005) and Grunert and Wills (2007) observe that it has been established that the use of label information can alter overall food purchase behaviour. Furthermore, research indicates that most consumers are interested in nutrition information and that they use nutrition labels. However, as many researchers note the use of nutrition labels in actual food choice is almost certainly lower than consumers claim in surveys. In addition, it has been observed that when consumers are confronted by complex food choices in terms of food selection they are less able to make informed choices. For example, Black and Rayner (1992) noted that consumers struggle to understand how to process information when they are shown several nutrients simultaneously. Indeed, there is evidence that consumers will employ a heuristic that sees food choices made in terms of a specific nutrient. Evidence from New Zealand reported by Mhurchu and Gorton (2007) indicates that consumers do not understand how to balance the consumption of nutrients in their diet and often make choices based on the fat content of food

<sup>1</sup> If a specific nutritional claim is made it is necessary for producers to adhere to the appropriate EC Directive in terms of label format. Within the UK food labelling is regulated by EC Directive 90/496/EEC.

<sup>2</sup> For interpretation of colour in Figs. 1 and 2, the reader is referred to the web version of this article.

regardless of other nutrient levels. Grunert and Wills (2007) note that in terms of nutrition information interest, calories and/or fat are frequently cited as being of most interest to consumers followed by salt and sugar.

Given these important observations about how consumers cope when making complex food choices as well as preferences for specific nutrients we aim to reveal the relative value that consumers attached to specific nutrients. To do this we examine the TLS from a different perspective to that previously undertaken in the literature. We conduct a choice experiment (CE) to examine consumers' willingness-to-pay (WTP) for reductions in the various nutrients as indicated by the TLS, i.e., fat, saturates, sugar and salt, in terms of a basket of shopping. This analysis allows us to reveal the relative values placed on the reduction of each specific nutrient in terms of going from Red to Amber and from Amber to Green.

The reason why we employ a basket of goods as opposed to specific products is that the TLS is designed to help food purchase choice as part of a healthy diet. Consumers need to consider the mix of all food being purchased and consumed, and assess consumption against ideal dietary requirements. Thus, there is nothing preventing a consumer from eating a bag of crisps, or a piece of cheese, as long as they compensate for these food types with moderation elsewhere in their diet. Importantly previous research on nutrition labels has identified that consumers find it difficult to employ nutritional label information to place a specific food item within an overall dietary plan (Cowburn and Stockley, 2005). Furthermore, Wansink and Chandon (2006) note that consumers who select a healthy food option frequently over compensate with some sort of indulgence, yielding a negative impact in terms of their dietary intake. For these reasons simply focussing on a single food item within a CE could lead to behavioural outcomes that will not capture how the TLS should be used in helping to achieve a healthy diet.

The emphasis here on a basket of goods as opposed to specific product is not without precedent. For example, a basket of goods as a means to assess dietary goals has previously been employed by Jetter and Cassady (2006) who examined the US Department of Agriculture Thrifty Food Plan diet guide that employs a specific basket of food items. Furthermore, most consumers will engage with the TLS as part of the weekly shopping experience and it is within this context that we should examine the impact of the nutrition label.

Given the design of our CE and the statistical methods we employ to analyse the data we make several contributions to the literature on TLS and nutritional labels in general. First, and our main contribution, is that our results provide information about changes in consumer choice in relation to the colours. Specifically, we find that the relative WTP of moving from Red to Amber is much greater than that from moving from Amber to Green. This is an important insight into how consumers respond to the TLS. In particular, it may help to explain and inform the food supply chain industry is responding to the dietary demands of consumers by modifying its processed foods products. Our analysis also reveals the relative importance of each of the nutrients as revealed by our WTP estimates.

Second, the use of CEs to undertake research on nutrition labelling is very limited in the literature to date. To date the only other paper that has employed a CE to examine issues relating to consumer use of nutritional labels is Berning et al. (2008). This study examines preferences for detailed versus summary nutritional information. It reveals that the alternative nutritional label formats appeal to different groups of respondents. Most other CE applications in the literature (e.g., Teratanavat and Hooker, 2006; Bond et al., 2008) examine health claims on food packaging as opposed to nutritional information. They examine presence or absence of claim or the strength of a claim for a specific product. In our CE

the nutritional label represents the amount of each nutrient within a basket of goods using colour.

From a methodological perspective our paper adds to a small literature that having employed a CE to generate stated preference data then estimates the resulting Mixed Logit (MXL) model using Bayesian methods. In addition, the model is estimated in WTP space as opposed to preference space. As Balcombe et al. (2009) report, there are very few examples in the literature adopting this approach which is surprising given the number of important econometric benefits that emerge as a result. Finally, we also employ a model specification that allows respondents to be indifferent to the choices presented. We take this approach because of the observation that many consumers employ a simple heuristic when making food choices with respect to nutrients.

The structure of this paper is as follows. We begin by reviewing the literature on the TLS as well as economic issues related to nutritional labels of specific interest to our study. In Section choice experiment design and data we describe the design and implementation of the survey instrument used in our CE. Then in Section econometric methods we describe the method of analysis we employ in this paper. In Section results we present our survey results and in Section summary and conclusions we provide a summary and conclusions.

## Literature review

### The TLS

The TLS has been the subject of ongoing research and development by the FSA since 2004 (see [www.food.gov.uk](http://www.food.gov.uk) for more details). As noted by Drichoutis et al. (2006) the development of the TLS can partly be explained as a response to difficulties which consumers had with earlier nutrition label systems. However, the emergence of the TLS has not been a simple or cooperative process on the part of the public and private sectors. Lang (2006) describes in detail the struggle that the FSA have had in bringing the TLS into operation. He notes that research has found that consumers find the TLS easy to use, especially when compared to alternative nutritional food label formats. Yet despite the clear public health motivation for implementing the scheme the food industry has at times been less than cooperative. As a result there are a number of alternative nutritional label systems employed in the UK. For example, some in the food industry have advocated the use of a Guideline Daily Amounts (GDA) system that relates food intake to a total daily target.

There have also been ongoing debates about the use of front or back of packaging labels. In comprehensive reviews of the literature, Cowburn and Stockley (2005) and Grunert and Wills (2007) report that research suggests that front-of-label information should be simple with the more complex detailed nutritional information presented on the back. By presenting information in this way consumers are able to make a quick decision at the point of purchase as well as being able to examine in more detail at their leisure specific nutrient details.

Overall there appears to be general support for the use of the TLS amongst many health professionals in the UK. For example, the Children's Food Campaign (2007) supports the use of the TLS. They note that the TLS can be employed by consumers very quickly. Other more complex labelling systems increase the risk of widening existing inequalities in food choice. This is because a large proportion of the UK public finds it difficult to understand what many of the numerical values employed on food labels imply about healthy eating.

However, some researchers are slightly less positive about the TLS. For example, Feunekes et al. (2008) examined front-of-pack

nutrition labelling for various label formats including the TLS. They conducted survey work across four European countries. One of their studies looked at three specific products with each survey participant shown three out of the six nutritional labelling systems being examined. The respondents had to rate each of the label systems based on liking, comprehension, credibility and perceived healthiness. In general the TLS performed very well except in terms of perceived healthiness per product category. In this part of their study Feunekes et al. report that the TLS did not differentiate as well as some of the other nutritional labels with respect to healthier and less healthy products. However, they do conclude by noting that the TLS like several of the other formats examined in the study is understood, liked and considered as credible by consumers.

It also needs to be appreciated that although consumers may prefer simple information presented on the front of packages this does not mean that they react to it in the manner intended (Verbeke, 2005). For example, Grunert and Wills (2007) observe that even though the TLS is a relatively simple nutritional labelling system, consumers can struggle to understand it when attempting to construct a meal. In addition, when it comes to actual use of the TLS not everybody responds to Red as intended because taste can override considerations related to health. However, there is also some indirect evidence that consumers do use the TLS. Several food retailers, including Sainsbury's and Waitrose, have adopted the TLS. Based on this there is some evidence reported by Grunert and Wills (2007) that suggests that by adopting the TLS these retailers have subsequently found it advantageous to reformulate certain products, so as to remove Red lights from various products. This would suggest that consumers are responding to the TLS and retailers have responded as they see a change in the mix of products being purchased.

### *Economics and nutritional labels*

There is a large literature that has examined various economic issues associated with the liking, use, understanding and development of nutritional labels. In addition to the material already cited other examples in the literature include Drichoutis et al. (2005, 2006); Gracia et al. (2007); Kim et al. (2000); Loureiro et al. (2006); Verbeke (2005) and Variyam (2008).<sup>3</sup>

In general it has been established in the literature that consumers are interested in the provision of nutrition information although the extent and detail of this information demanded by consumers varies by product as well as context. In a comprehensive review of the literature Drichoutis et al. (2006) state that nutritional label use does impact purchase behaviour as consumers want to avoid things that are considered bad for them. However, they also find that there is little consistency in research attempting to explain what determines label use in relation to income, age or working status. There is, however, evidence to suggest that being female and being educated are positively related to label use. Furthermore, having time to shop, being concerned about diet for various reasons such as a diet-disease relation and having prior knowledge about nutrition are all positively related to label use. Finally, as might be expected consumers who are price sensitive are less likely to be interested in and use labels.

In terms of actual studies examining nutritional labels Loureiro et al. (2006) employed a survey designed to reveal consumer WTP for a nutritional label on a box of cookies. The WTP values were derived by employing a Contingent Valuation (CV) survey instrument that used a dichotomous choice question format. The

survey was conducted in Spain and the sample size was 400 individuals. The motivation behind this research stems from the fact that the EU have been considering the adoption of mandatory food labels on food much like the Nutritional Labelling and Education Act (NLEA) introduced in the US in 1994. This study found that consumers were WTP 11% more for a product with this information, although this varied by type of consumer. In related research Gracia et al. (2007) examined how consumers value the potential introduction of mandatory nutrition labels. Employing a three-equation multivariate probit model they reveal that individuals with food related health problems know more about nutritional labels, and being knowledgeable makes an individual more likely to use a label and that label users do consider mandatory labels as beneficial.

Berning et al. (2008) employed a CE to examine how consumers respond to detailed versus summary nutritional information. The CE employed a number of nutrition label designs and information sets for a single product, a can of tomato soup. Employing a face-to-face survey method a total of 410 individuals participated. The data was analysed using a MXL model employing Classical methods assuming normal distributions for all random parameters in one model and triangular in another. The main finding is that different nutritional label formats appeal to different groups of shoppers.

In addition to the research that has employed specific consumer surveys to examine issues of nutritional label use, there have also been a number of studies that have examined actual food purchase behaviour (e.g., Kim et al., 2000 and Variyam, 2008). These papers have all made extensive use of the US Department of Agriculture's 1994–1996 Continuing Survey of Food Intakes by Individuals as well as the Diet and Health Knowledge Survey. The reason why this particular part of the literature is relevant to our research is that it provides insights into the relative importance of nutrients being consumed once nutritional labelling has been introduced. For example, Kim et al. report significant effects as a result of label use on the consumption of fats, cholesterol, sodium and fiber. However, Variyam challenges these findings by employing methods of estimation to deal with issues of self-selection in the data. These findings raise doubts about the extent to which the introduction of the NLEA resulted in changes in nutrient intake except for fiber and iron. Thus, these results indicate only a minimal response on the part of the public to nutritional labels.

### **Choice experiment design and data**

#### *Designing and implementing the choice experiment*

Our CE was design and implemented so as to examine consumers' WTP for reductions in the nutrients in the TLS. As we have explained we decided to design our CE around a basket of goods as opposed to specific food items. We did this because the TLS is designed to help consumer food choice as part of achieving a healthy diet. As we will explain the design of the CE we employed allowed us to estimate the WTP for each nutrient in terms of going from Red to Amber and from Amber to Green.

A critical decision was to frame the choices in terms of a basket of goods rather than a specific item. Our rationale was that a specific item would not reflect the purchasing behaviour of the individual in a general enough way. For example, the response of consumers to the nutrients in a meat pie or ready meal would hardly reflect their responses to a range of items. Consumers are obviously ready to tolerate high levels of nutrients in some items but not others. Our piloting suggested that consumers could readily conceptualize a representative basket.

<sup>3</sup> There is related literature that has examined the impact of health claims on food packaging. Examples include Teratanavat and Hooker (2006) and Bond et al. (2008). Both used CE to examine how specific health claims impact consumer choice and the resulting WTP for a product.

We began our CE survey instrument design process by presenting a number of draft choice cards to a small group of participants (i.e., students and staff). From this we developed our set of CE attributes and the associated levels which we then used to conduct a focus group exercise. The nutrients and the associated TLS colours constituted our main CE attributes. In keeping with the TLS we included four nutrients: Salt, Sugar, Fat and Saturates. Next we devised our basket of goods based on the report produced by Synovate (2005) for the FSA. Based on the mix of goods in our hypothetical basket we then referred to the National Statistics (2007) publication, Family Food in 2005–06 to establish the expected cost of this basket of goods for an average UK household. This yielded a value of £20. Having established the status quo price we determined the number of price points used in the survey. We decided to employ five price points with £20 as the mid point. The other price points used in the CE are £15, £18, £25 and £30. Importantly, we allowed the cost of the basket to be lower than the status quo. We considered it important to offer this option because some consumers may well be far more price sensitive than health sensitive, a behaviour observed in previous CE.

In terms of the survey instrument we began by briefly explaining to participants that the government has introduced the TLS to signal the impact of certain nutrients on health. We then described the system using simple language. Next we provided an explanation of the task involved in the CE. This is shown in Fig. 1.

An important facet of the description of the CE task was that we needed to make it clear to all survey participants that although the

choices are hypothetical, we needed them to make their choices as if they are real. Furthermore, we also needed to establish the legitimacy of the cost element in the choice set so that the resulting WTP estimates are meaningful. The development of the information provided in this part of the survey instrument was the result of extensive pre-testing with focus group participants as well as discussions with experts in food marketing.

Having identified our set of attributes (number of attributes by number of levels) we then generated the choice sets employed in the CE. Employing a full factorial design, ensuring balance across all attributes, yielded a total of 24 choice sets. To keep the survey task manageable and to avoid response fatigue we blocked the 24 choice sets into four groups of six. Thus, each respondent only answered six choice sets. Within each choice set the status quo option was always Option 1, with Options 2 and 3 alternative options. We generated the alternative options randomly from the set of 24, always ensuring a balance in terms of attribute levels across the design. We also included a “Don’t Know” as part of the choice set. An example of the choice card used in the CE is presented in Fig. 2.

#### Survey returns

The survey was distributed in the mail to 3000 UK households. It was a single shot survey with participants offered a simple financial incentive to complete the survey. We received 477 useable returns and these are used in our analysis.

**Section C: Survey Description**

We are going to ask you 6 questions concerning food choice.

**You simply indicate the basket you would buy if offered these options in a shop.**

The options presented relate to an individual's weekly basket of food which might include:

- Ready meals
- Chicken burgers/pizzas
- Pasta ready meals/curry ready meals
- Cake/crisps
- Cereal bars/breakfast cereals

We describe the basket of food using the Traffic Light System and cost.

The cost of the basket is for a typical UK consumer for one week's shopping.

This is, on average, about £20.

**In the survey, an option would be described as follows:**

Food Basket	Option A
Salt	Green
Sugar	Green
Fat	Amber
Saturates	Green
Price	£20

This column represents the nutrient content in a basket of goods. We simply call this basket Option A. Using the Traffic Light System we code each nutrient. Finally, £20 is the price for buying this basket of goods

Fig. 1. The choice experiment survey description page.

CHOICE CARD 1				
Food Basket	Option 1	Option2	Option3	Don't Know
Salt	Amber	Red	Green	
Sugar	Amber	Green	Amber	
Fat	Red	Amber	Red	
Saturates	Amber	Amber	Red	
Price of basket	£20	£25	£30	
<b>Tick ONE and only one box</b>				

Fig. 2. Sample choice card.

We begin our analysis of the survey returns by examining various socio-economic descriptive statistics that are reported in Table 1.

Beginning with various socio-economic data the average age of respondents is 48 years. This is slightly higher than the average age in the UK which is 39 in 2007. Also it is slightly higher than reported in related research. For example, Loureiro et al. (2006) have a sample average of 46.8 years and Berning et al. (2008) report 42.4 years. In terms of income our sample average (excluding zero responses which accounted for some 20% of the sample) is £24,500 and was reasonably evenly distributed. In comparison to population data for the UK average income for non-retired households was £37,600 in 2006/07 and the average for all households including retirees £30,000. Thus, the reported levels of income are a little below the UK average.

Next we consider the gender mix of respondents. We had 81% females and 19% males. This is slightly higher than in related surveys that report rates of female participation in the range of 60–70%. To illustrate the effect of this characteristic our analysis we present results that correct for this imbalance where we assume a 50:50 gender mix which is in keeping with current UK demographics.

In terms of children in the household, 67% of respondents did not have children living at home. Currently within the UK there are estimated to be 33% single households and just over 60% of households have no children. Turning to the number of children in the household, our sample has on average 0.6.

**Table 1**  
Survey descriptive statistics.

Socio-economic data	Variable	
Age (years)	Average age in sample	48.34 (13.3)
Income (£ 000's)	Average income in sample	24.5 (21)
Gender	Male	19%
	Female	81%
Marital status	Married	73%
	Single	11%
	Other	16%
Number of children in household children	0	67%
	1	13%
	2	14%
	3	5%
	4	1%
Educational achievement	School to 16	25%
	A Level or equivalent	11%
	Further education	32%
	University Undergraduate	18%
	University postgraduate	12%
	Higher	2%
Employment status	Employed	48%
	Self-employed	12%
	Unemployed	15%
	Other	25%

Finally, we also asked survey respondents a number of questions concerning food and health issues. Some 94% of respondents consider themselves to be health conscious. In terms of food label use the majority claim to read food labels some of the time. We also asked participants to rank the nutrients that appear on the FSA TLS. Ranking, salt, sugar, fat and saturated fats on a scale of 1–4 in terms of most to least important in terms of wellbeing we found the following average scores: salt = 2.4; sugar = 2.9; fat = 2.6; and saturates = 2.1. These indicate that saturates followed by salt are considered the most important in terms of making a negative impact on the wellbeing of respondents.

## Econometric methods

The main objective of this paper is to estimate consumer WTP from a CE designed to avoid high levels of nutrients as indicated by the TLS. To analyse our CE data we employ Bayesian methods to estimate the MXL model following Balcombe et al. (2009).

Formally, let  $x_{j,s,n}$  denote a  $k \times 1$  vector of attributes from the CE presented to the  $j$ th individual ( $j = 1, \dots, J$ ) in the  $s$ th option ( $s = 1, \dots, S$ ) of the  $n$ th choice set ( $n = 1, \dots, N$ ). Next assume that  $U_{j,s,n}$  is the utility that the  $j$ th individual attains from  $x_{j,s,n}$ . In addition, let  $y_{j,s,n}$  be an indicator variable that is equal to one if the  $j$ th individual chooses the  $s$ th option within the  $n$ th choice set, and zero otherwise.

An individual  $j$  is assumed to receive linear utility from the  $s$ th choice in the  $n$ th choice set, although the parameters may be transformed. Consequently, the utility function is of the form

$$U_{j,s,n} = x'_{j,s,n} t(\beta_j) + e_{j,s,n} \quad (1)$$

where  $\beta_j$  is a  $(k \times 1)$  vector describing the preferences of the  $j$ th individual and  $t(\cdot)$  is some transformation of the parameters. The function  $t(\cdot)$  can take a number of forms (see Balcombe et al., 2009). The error term  $e_{j,s,n}$  is assumed to be extreme value (Gumbel) distributed, independent of  $x'_{j,s,n}$  and uncorrelated across individuals or choices.

Specifically, we employ the censored normal distribution for all random parameters, except the price of the basket, such that the preference distribution is censored from below at zero, with a mass point occurring at zero. By censoring the normal distribution from below at zero yields a mass point at zero so that with  $\beta$  normally

distributed with mean  $b$  and variance  $\sigma$  the transformation is  $t = \max(0, \beta)$ . Values of  $b$  and  $\sigma$ , and hence  $t$ , are estimated giving the population proportions massed at zero and above zero. With respect to price we employ a log-normal transformation  $t(\beta) = \exp(\beta)$  with the distribution bounded below at zero and with zero probability mass at zero.

The reason why we employ a bounded distribution is because we consider it necessary to accommodate indifference on the part of respondents in our CE. If we allow a respondent to be indifferent with respect to some attributes this implies that we are allowing marginal utility to be equal to zero for these attributes. The reason for wishing to allow indifference is that we do not believe that respondents are negatively disposed to any particular attributes. But, in the case of food choice based on nutrient content it is highly likely that some individual's will be indifferent to some of the attributes because of health concerns or dietary requirements and/or restrictions. Their choices will be driven by a sub-set of the attributes and there is evidence from the literature to support this view (e.g., Black and Rayner, 1992, and Grunert and Wills, 2007).

Another important feature of the MXL model we employ is that we estimate our model in WTP space. In order to estimate the MXL in WTP space we employed a re-parameterisation of the form:

$$t(\beta_j) = t_1(\beta_{1j})(1, t_2(\beta_{2j}), \dots, t_k(\beta_{kj}))' \tag{2}$$

which means that the quantities  $t_2(\beta_{2j}), \dots, t_k(\beta_{kj})$  are the Marginal Rates of Substitution (MRS) with the numeraire being the first attribute, which will always be the price or cost attribute within the CE. The benefits to be gained by estimating in WTP space are that the MRS are estimated directly and this can significantly reduce the instability associated with WTP estimates derived in preference space. The instability is avoided as the need to derive estimates based on the ratio of random variables, which are by construction volatile, is no longer necessary. The instability of WTP estimates derived in preference space has been found to be particularly problematic when the payment vehicle (price or cost attribute) is variable and not bounded above zero. As a result this has lead researchers to fix the payment coefficient (e.g., Bond et al., 2008) which is an *ad hoc* approach to resolving instability. Indeed, fixing the price coefficient may violate other modelling requirement as well as being behaviourally inappropriate if we assume that individuals' responses vary independently of socio-economic characteristics.

To implement the Bayesian approach to estimation of the MXL we simulate the posterior distribution of the mean and variance/covariance of the preference parameters  $\{\beta_j\}$ . In the Bayesian literature the algorithm used to undertake the simulation is referred to as the "the sampler". A detailed description of the algorithm, in this case Gibbs with a Metropolis–Hastings (M–H) Step which is based on Balcombe et al. (2009) is provided in the Appendix A.

For the analysis we present we have generated all posterior distributions by mapping 10,000 draws from the posterior sampler. We have paid particular attention to the performance of the sampler to ensure convergence has been achieved. To test for convergence we initially observe the values of the parameters sequentially generated by the sampler. If our model is correctly specified and performing appropriately our parameters should move away from their initial starting points and become stable about a mean. To ensure that there is minimal dependence in the sampled values we estimate the autocorrelation coefficients for the sequential values generated by the sampler. To minimise problems of dependence we draw every  $k$ th value (in this model we took very 1 in 500 values) in a sequence generated by the sampler where the number of draws is set so as to minimise the degree of dependence. Following Koop (2003) we formally test for convergence by employing a modified  $t$ -test for which the null

**Table 2**  
MXL results for indifference model.

Attributes	Posterior parameter estimates		
	Mean	Standard deviation	Median
Price	1.720	1.504	1.297
Saturates-A/G	0.437	0.424	0.355
Saturates-R/G	1.727	0.591	1.741
Fat-A/G	0.120	0.197	0.000
Fat-R/G	1.208	0.519	1.207
Sugar-A/G	0.381	0.372	0.311
Sugar-R/G	1.422	0.437	1.438
Salt-A/G	0.263	0.310	0.151
Salt-R/G	1.932	0.540	1.959
SQ	0.366	0.316	0.323

hypothesis is no-difference between the first and second half of the sampled values (with a sub-set of values removed from the middle).<sup>4</sup>

**Results**

Our preferred specification allows for potential heterogeneity in all the parameters characterising preferences. The results we present are for a MXL estimated in WTP space. As previously indicated we allow for the possibility of indifference with respect to the various attributes by employing a censored normal distribution for all parameters except the price of the basket of goods, which we have modelled as a log-normal distribution. The model specification estimated takes the following form

$$U_{j,s,n} = \beta_{1,j}(\text{price}_{j,s,n} + \beta_{2,j}\text{SatAG}_{j,s,n} + \beta_{3,j}\text{SatRG}_{j,s,n} + \beta_{4,j}\text{FatAG}_{j,s,n} + \beta_{5,j}\text{FatRG}_{j,s,n} + \beta_{6,j}\text{SugAG}_{j,s,n} + \beta_{7,j}\text{SugRG}_{j,s,n} + \beta_{8,j}\text{SaltAG}_{j,s,n} + \beta_{9,j}\text{SaltRG}_{j,s,n} + \beta_{10,j}\text{StatusQuo}_{j,s,n}) + e_{j,s,n} \tag{3}$$

where price is the cost of the basket, Sat is saturates, Fat is fat, Sug is sugar and Salt is salt. For each of the nutrients we have estimated the change from Amber to Green (AG) and Red to Green (RG). These parameters provide us with a measure of how much our survey respondents are WTP to reduce their exposure to higher levels of the various nutrients. The StatusQuo captures Option 1 in all choice sets which we devised based on an examination of current consumption activity and the levels of the various nutrients being consumed. Finally, each of the parameters is then conditioned on a set of socio-economic characteristics as discussed in Section choice experiment design and data. In this case each parameter is expressed as follows

$$\beta_{ij} = a_{0,ij} + a_{1,ij}\text{Gender}_j + a_{2,ij}\text{Age}_j + a_{3,ij}\text{Children}_j + a_{4,ij}\text{Education}_j + u_{ij} \tag{4}$$

These estimates can then be used to construct the WTP estimates for groups by Gender, Age, Children and Education. In each case respondents are divided into two groups for each of the characteristics: Male/Female, Young/Old, With/Without Children and Less/More Educated. Importantly, the error terms ( $u_{ij}$  in Eq. (4)) can be correlated. This would be expected because we assume that people that responded more with respect to a particular nutrient (e.g., Salt) would also be more responsive with respect to the other nutrients also (e.g., Fat).

Our results and the resulting WTPs are reported in Table 2.

<sup>4</sup> Details of the likelihood and priors employed in the estimation are provided in an appendix to the paper.

**Table 3**  
Mixed Logit Correlation Matrix.

	Price coefficient	Saturates (Amber)	Saturates (Red)	Fat (Amber)	Fat (Red)	Sugar (Amber)	Sugar (Red)	Salt (Amber)	Salt (Red)	Status quo
Price coefficient	1.000									
Saturates (Amber)	-0.362	1.000								
Saturates (Red)	-0.216	0.288	1.000							
Fat (Amber)	-0.368	0.534	0.193	1.000						
Fat (Red)	-0.414	0.558	0.289	0.725	1.000					
Sugar (Amber)	-0.371	0.524	0.211	0.742	0.768	1.000				
Sugar (Red)	-0.379	0.564	0.228	0.699	0.754	0.764	1.000			
Salt (Amber)	-0.334	0.472	0.143	0.682	0.653	0.658	0.623	1.000		
Salt (Red)	-0.395	0.483	0.327	0.659	0.724	0.687	0.677	0.656	1.000	
Status quo	0.206	-0.276	-0.154	-0.300	-0.329	-0.316	-0.283	-0.341	-0.344	1.000

In Table 2 we report the mean, standard deviation and median of the resulting posterior densities. We report both the mean and median, because for the indifference model these estimates represent quite different aspects of the underlying distribution. If over 50% of consumers are indifferent to an attribute the median might be zero, but the mean may still be (potentially) quite large. As a result Balcombe et al. (2009) advocate that researchers report both the mean as well median. In the resulting analysis we focus on the median, although for this data set the differences are minor.

From the results presented in Table 2 we can see that the change from Red to Green (RG) yields a much larger estimate for all nutrients compared to the change from Amber to Green (AG). This implies that there is a strong aversion to Red for all nutrients, which is in keeping with results reported by Drichoutis et al. (2006). We can also see that the largest mean and median estimates are for Salt and the smallest for Fat. This finding is interesting given the high profile campaign employed by the FSA in the UK to draw attention to salt in the diet and the associated health effects of excessive consumption.<sup>5</sup>

In addition, for Fat (AG) the median is equal to zero indicating that consumers are indifferent to the change in this level of this nutrient. This implies that consumers are concerned about reducing high levels of Fat in their diet but far less concerned about reducing Fat significantly. We can also see that the status quo parameter estimate is positive indicating a positive preference for this option. However, the relative magnitude of the estimate is much smaller than any of the Red to Green changes for all the nutrients.

Overall we note that the resulting WTP estimates are reasonably large. For example, the WTP estimate for moving from Red to Green for Salt is £19. Although this is higher than we anticipated the magnitude of the estimate can be partly linked to the price attached to the basket of goods. It will be important in subsequent research to examine this aspect of the CE design in more detail to see if modifying the price has a significant impact on the choices made and resulting WTP estimates.

Next we report the correlation structure between the regression coefficients. Our estimates are shown in Table 3.

The results in Table 3 show that the regression coefficients for the various food ingredient attributes are all negatively related to price. Furthermore, and as we might expect, all the nutrients are positively correlated. However, there is an interest-

ing pattern for Saturates, especially RG, in that the correlation estimates are much smaller than for all the other nutrients. Thus, reductions in nutrient consumption of Salt, Sugar and Fat are not matched by anywhere near the same reduction in Saturates. Overall, our correlation estimates provide support for our CE in terms of respondents interacting appropriately with the task required.

We next report results for the same model specification including a number of key socio-economic variables in our model which are interacted with each of the parameters in the model as described by Eq. (4). The socio-economic variables we have employed are gender (male or female), age (young (less than 46) or old (more than 46)), children in then household (yes or no), and level of education (school or higher). By including these socio-economic variables we are able to provide estimates of how these various characteristics impact the WTP estimates.

The first thing to note in Table 4 relates to the differences between Men and Women. It is very clear that Men have lower WTP estimates for all nutrients compared to Women. This implies that Women are WTP more to avoid nutrient quantities labelled Red and Amber compared to Green. These differences equate to Men being WTP almost a third less than Women. The second set of results in Table 4, refer to differences associated with Age. On the whole there appears to be only a minimal difference between our Age categories which suggests that this socio-economic characteristic is not important in terms of explaining WTP.

The lower part of Table 4 reports results for differences in WTP depending on if a household includes children or not. Although the differences are not that large there is evidence to suggest that households with children are WTP more to consume food with lower levels of all nutrients compared to those without children. Finally, we examine how the level of education affects WTP. As we might expect from existing results in the literature, those respondents with a higher level of education are WTP more to have lower levels of nutrients.

The final part of our analysis presents results when we take account of the bias in the sample of the high proportion of females (81%). By imposing an equal sample weight of 50% we have recalculated our WTP estimates. These results are reported in Table 5.

The revised results in Table 5 are compared against the original results reproduced from Table 2. As can be seen, by re-weighting the sample to increase/decrease the proportion of males/females we have reduced all the resulting WTP estimates. This result is not that surprising given the results we have previously considered regarding Gender and presented in Table 4. However, these results do indicate that if we wish to extrapolate from our results to those of the general public it will be necessary to ensure that we correctly reflect current socio-economic and demographic characteristics.

<sup>5</sup> The FSA have a stated objective of reducing average salt consumption of adults in the UK to 6g a day by 2010. This objective comes from the Scientific Advisory Committee on Nutrition who were concerned about excessive salt consumption and related health problems such as high blood pressure and the associated increased risk of strokes and cardiovascular disease. To achieve this objective the FSA launched its first Salt Campaign in September 2004, it has engaged with various food organisations asking them to reduce the salt content of food, and in March 2006 it published targets for reductions in salt consumed by consumers backed up by high-profile TV ads.

## Summary and conclusions

In this paper we have developed and analysed a CE to examine how consumers respond to the TLS introduced by the FSA. Overall

our results indicate a very strong preference on the part of UK consumers to reduce the quantity of any nutrient associated with a Red Light. From this response we can conclude that the role of the TLS to inform consumers appears to be understood. We have

also found that consumers are most concerned by Salt and Saturated Fats when it comes to judging nutrient content and much less so by Fat and Sugars. In addition, we have identified that particular parts of the population respond differently to the TLS in a manner that we would expect from previous research on the use of nutrition labels.

Overall we consider these findings provide support for the use of the TLS in terms of consumer understanding and planned shopping behaviour. If the policy agenda is to encourage consumers to move away from purchasing items with very high levels of nutrients, then this is a significant finding. However, it is difficult to know if the hypothetical behaviours identified will be replicated in actual shopping behaviour. This is, of course a problem with all stated preference methods and studies. Currently, anecdotal evidence suggests that this is the case but further research combining revealed and stated preference data (data from actual purchase behaviour and data generated by a hypothetical CE) could significantly enhance our understanding of this issue. In addition, it is unclear if consumers are really responding to the information content associated with the TLS or whether we are simply observing a decision based on the colour scheme used. Further research to examine the extent to which information as opposed to colour of the TLS guides decisions is worthy of further consideration. Indeed, it may well be the case that a key difference between the TLS and other schemes are that the colours not only provide information but convey a strong normative message. This would go some way to explaining the very high WTPs we observe.

**Acknowledgements**

We acknowledge the financial support provided by the Food Standards Agency in helping us to undertake this research. We are appreciate the extensive comments made on earlier versions of this paper by three anonymous referees as well as seminar participants at the University of Kent, University of Portsmouth, University of Bradford La Trobe University, University of Sydney, and participants at the 12th EAAE Congress in Ghent.

**Appendix A. Likelihood and priors**

Following Balcombe et al. (2009) we can assume that the parameters  $\beta_j$  are ordered. Thus, they may contain fixed parameters  $c_j$  as well as random parameters  $b_j|B_j = (c_j|b_j)$ .

Both sets of parameters can be conditioned on appropriate socio-economic variables for any individual where preferences are determined by a vector  $z_j$ , which is a  $(h \times 1)$  vector of variables. Thus, defining  $Z_j = I_k \otimes z_j$ , the components of  $\beta_j$  are defined as:

$$c_j = Z_j' \alpha_c$$

$$b_j = Z_j' \alpha_{b+u_j}$$

where  $u_j$  is a independently and identically normally distributed vector with variance covariance matrix  $\Omega$ .

Next define the set of all stated choices by an individual as  $Y = \{y_{j,s,n}\}_{j,s,n}$ , the set of characteristics describing all respondents by  $Z = \{z_j\}_j$ , the set of options given to the  $j$ th individual is  $X_j = \{x_{j,s,n}\}_{s,n}$ , the set of all option sets given to all respondents is  $X = \{X_j\}_j$  and the set of all data is  $D = \{Y,Z,X\}$ . Finally, we describe the collection of all parameters describing the model as  $\Theta = (\alpha, \Omega)$  the set  $\{b_j\}_j$  denoted as  $B$  refers to  $B$  as latent data. Note, for notational convenience the multiple integral

$$\int_{\beta_n} \dots \int_{\beta_1} db_1 \dots db_n \text{ is expressed as } \int_B dB.$$

Given this notation we can we can define the probability that an individual  $j$  will make a given set of choices. Formally,

$$p_j = \prod_{n=1}^N \prod_{s=1}^{S_n} \left( \frac{e^{t(\beta_j)_{j,s,n}^\alpha}}{\sum_{s=1}^{S_n} e^{t(\beta_n)_{j,s,n}^\alpha}} \right)^{y_{j,s,n}}$$

Therefore, we can express the likelihood function for the choices made (given a selection of a model  $t$ ) as:

$$L(\Theta|D, t) = \int_B \left( \prod_{j=1}^J p_j \right) dF(B|\Theta, Z)$$

Thus, the posterior distribution of the parameters  $\pi(\Theta|D, t)$  (in a Bayesian framework) is:

$$\pi(\Theta|D, t) \propto L(\Theta|D, t)\pi(\Theta)$$

Where  $\pi(\Theta)$  is the prior distribution for the parameters that are independently normal for the parameters  $\alpha_c$  and  $\alpha_b$  and Inverse Wishart (IW) for  $\Omega$ . More specifically for the prior for  $\alpha$  we assume

$$(\alpha_c', \alpha_b')' = \alpha \sim f_N(\alpha|\mu, A_0)$$

where  $\mu$  is the mean and  $A_0$  is a diagonal matrix. With respect to the prior for  $\Omega$

$$\Omega \sim f_{IW}(\Omega|T_0, \nu_0)$$

For the priors we employ, the hyper parameters, which are set *a priori*, are  $\mu, A_0, T_0$  and  $\nu_0$ . Our choice of priors is determined by reference to the literature as well as our own experiments with the data to check for robustness of results generated.
