¹ Utilization of D-glucosamine as a source of nitrogen.

Co-Q: 8 (Suzuki et al. 1994).

Mol% G+C: 34.4, 35.9, 37.8, 37.3, CBS 5214 (*T_m*: Stenderup et al. 1972; *T_m*: Suzuki et al. 1994; BD: Meyer et al. 1984; *T_m*: Meyer, unpublished data, respectively).

Origin of the strains studied: CBS 2751, CBS 5214, CBS 5215, associated with bark beetles and their larvae (*Ernobius* spp.).

Type strain: CBS 5214.

Comments: Suzuki et al. (1994) described a new species, *C. stellimalicola*, that resembles *C. karawaiewii*, *C. diversa* and *C. silvae* in physiological and morphological properties. See Comments for *C. diversa* for more information. Kurtzman and Robnett (unpublished data) found *C. ernobii* and *C. karawaiewii* to have identical sequences in a 600-nucleotide region at the 5' end of large subunit (26S) rDNA, indicating the two taxa to be conspecific. Furthermore, the sequence of *Pichia holstii* differed by only two nucleotides suggesting that it is either the teleomorph or a sibling species.

64.71. *Candida krissii* S. Goto & Iizuka (Goto et al. 1974)**Growth in glucose-yeast extract-peptone broth:**

After 3 days at 25°C, the cells are ovoidal, long oval to cylindrical, (2.0–4.0) × (4.0–7.0) μ m, single and in pairs (Fig. 234).

Fig. 234. *C. krissii*, CBS 6519. After 3 days in glucose-yeast extract-peptone broth at 25°C. Bar = 5 μm.

Dalmu plate culture on corn meal agar: After 7 days at 25°C, abundant development of pseudohyphae consists of branched chains of cylindrical cells with verticils of ovoidal blastoconidia. Aerobic growth is off-white, smooth, shiny, butyrous and with an entire to undulating margin.

Fermentation: absent.

¹ Utilization of D-glucosamine as a source of nitrogen.

Co-Q: 9 (Yamada and Kondo 1972a).

Mol% G + C: 60.0, type strain (*T_m*: Nakase and Komagata 1971d).

Origin of the strains studied: CBS 166, flower of *Magnolia* sp.; CBS 2250, bumble bee's gut; CBS 2800, gut of a bee, Croatia; CBS 2677, concentrated orange juice, South Africa; CBS 5659, larval feed of *Xylocarpa caffra*; CBS 6396, larval pabulum of *Xylocopa scioensis*, South Africa; CBS 6201, beak of a dead tern; CBS 3086, human sputum, Netherlands; CBS 6424, unknown.

Type strain: CBS 166.

Comments: Nakase et al. (1994a) reported on the heterogeneity among strains of *C. magnoliae*. They used mol% G + C, DNA hybridization and electrophoretic comparisons of seven different enzymes to study 10 strains previously identified as *C. magnoliae*. They found five DNA homology groups and four enzyme groups. One enzyme group was split into two DNA groups. These

investigators state that these five DNA groups should be considered distinct species.

64.81. *Candida maltosa* Komagata, Nakase & Katsuya (1964)**Synonyms:**

- Candida cloacae* Komagata, Nakase & Katsuya (1964)
Candida novellus Watanabe, Shimada, Kawaharada, K. Suzuki & Tanaka (1973) nom. nud.
Candida subtropicalis Nakase, Fukazawa & Tsuchiya (1972)

Growth in glucose-yeast extract-peptone broth: After 3 days at 25°C, the cells are subglobose to ovoidal, (3.0–5.0) × (4.0–7.0) μ m, and occur singly or in pairs or small groups (Fig. 240).

Dalmat plate culture on corn meal agar: After 7 days at 25°C, pseudohyphae consist of cylindrical cells with verticils of ovoidal blastoconidia. Aerobic growth is white, creamy, soft, smooth or slightly folded with a fringed margin.

¹ Utilization of D-glucosamine as a source of nitrogen.

Co-Q: 9 (Yamada and Kondo 1972a; Kaneko et al. 1977).

Mol% G+C: 36.3, AJ 4718 (T_m : Nakase and Komagata 1971f); 35.6–36.8, 6 strains (T_m : Meyer et al. 1975); 36.1, CBS 5611; 36.6, ATCC 20184; 37.3, #36 (CBS 6658) and CBS 6465 (T_m : Kaneko et al. 1977); 36.6, CBS 6658; 36.8, CBS 6680 (T_m : Su and Meyer 1991).

Fig. 240. *C. maltosa*, CBS 6680. After 3 days in glucose-yeast extract-peptone broth at 25°C. Bar = 5 μ m.

Origin of the strains studied: CBS 5611, neutralizing tanks for monosodium glutamate; CBS 5612 (type strain of *C. cloacae*), mud; CBS 6465 (type strain of *C. subtropicalis*), atmosphere; CBS 6658 (*C. novellus*), CBS 6680, soil, Japan; CBS 7327, waste water, Germany.

Type strain: CBS 5611.

Comments: Meyer et al. (1975) and Kaneko et al. (1977) employed DNA reassociation to demonstrate that *C. maltosa* is distinct from *C. sake* and *C. tropicalis*. These species are separated on the basis of maximum temperature for growth, assimilation of soluble starch and growth in the presence of cycloheximide.

64.82. *Candida maris* (van Uden & Zobell) S.A. Meyer & Yarrow (Yarrow and Meyer 1978)

Synonym:

Torulopsis maris van Uden & Zobell (1962)

Growth in glucose-yeast extract-peptone broth: After 3 days at 25°C, the cells are subglobose to ovoidal, (2.0–4.0) × (2.5–4.5) μ m, single and in pairs.

Dalmu plate culture on corn meal agar: After 14 days at 25°C, pseudohyphae are not present. Aerobic growth is cream-colored, soft, smooth and entire.

Fermentation: absent.

Assimilation:

Type strain: CBS 5151.

64.83. *Candida maritima* (Siepmann) van Uden & H.R. Buckley ex S.A. Meyer & Ahearn (1983)

Synonyms:

Trichosporon maritimum Siepmann (Siepmann and Höhnk 1962)

Candida maritima (Siepmann) van Uden & H.R. Buckley (1970) nom. inval.

Candida pilmaiquensis C. Ramírez & A. González (1984g)

Growth in glucose-yeast extract-peptone broth: After 3 days at 25°C, the cells are primarily ovoidal, (3.0–5.0) × (3.5–8.0) μ m, single and in pairs; cylindrical cells also are present.

Dalmu plate culture on corn meal agar: After 7 days at 25°C, pseudohyphae consist of branched chains of cylindrical cells with verticils of ovoidal blastoconidia. Aerobic growth is off-white to cream-colored, soft, smooth to wrinkled, and glistening with an irregular or mycelial border.

Fermentation:

¹ Utilization of D-glucosamine as a source of nitrogen.

Co-Q: Not determined.

Mol% G+C: 45.4, type strain (*T_m*: Meyer et al. 1984); 46.8, CBS 8176 (*T_m*: M.Th. Smith, personal communication).

Origin of the strains studied: CBS 1969, CBS 6069, tanning fluid; CBS 4112, tunnel of ambrosia beetle; CBS 4606, beetle; CBS 5107, sea; CBS 8176 (type strain of *C. pilmaiquensis*), rotten wood, Chile.

Type strain: CBS 5107.

64.84. *Candida melibiosica* H.R. Buckley & van Uden (1968)

Synonyms:

Candida parapsilosis (Ashford) Langeron & Talice var. *hokkai* S. Goto & Yokotsuka (1962b)

Torulopsis navarrensis Moriyon & Ramirez (1974)

Candida navarrensis (Moriyon & C. Ramirez) S.A. Meyer & Yarrow (Yarrow and Meyer 1978)

Torulopsis pampelonensis C. Ramirez & A.T. Martinez (1978)

Candida pampelonensis (C. Ramirez & A.T. Martinez) S.A. Meyer & Yarrow (Yarrow and Meyer 1978)

Growth in glucose–yeast extract–peptone broth: After 3 days at 25°C, the cells are subglobose to ovoidal, (2.5–4.5) × (2.5–5.0) μm, single and in pairs.

Dalmau plate culture on corn meal agar: After 7 days at 25°C, primitive pseudohyphae of short, branched chains of cells are present. This type of growth gives a bushy, feathery appearance. Aerobic growth is cream-colored, butyrous, soft, lobated and entire. An occasional tuft of pseudohyphal growth is evident.

Fermentation:

Glucose	+	Lactose	–
Galactose	s	Raffinose	–/s

¹ Utilization of D-glucosamine as a source of nitrogen.

Co-Q: 9 (Yamada and Kondo 1972a).

Mol% G + C: 46.1, 44.3, CBS 2032 (T_m : Nakase and Komagata 1971f; BD: Kurtzman 1990c, respectively).

Origin of the strain studied: CBS 2032, miso.

Type strain: CBS 2032.

Comments: Kurtzman (1990c) employed DNA reassociation studies to demonstrate that the proposed anamorphic/teleomorphic relationship (Yarrow 1984d) between *C. mogii* and *Zygosaccharomyces rouxii* is not justified. No significant DNA relatedness between the *C. mogii* type strain and any of the nine species included in *Zygosaccharomyces* was revealed.

64.90. *Candida montana* S. Goto & Oguri (1983)**Growth in glucose–yeast extract–peptone broth:**

After 3 days at 25°C, the cells are ovoidal, (2.0–3.0) × (4.0–5.5) μ m, single and in pairs.

Dalmou plate culture on corn meal agar: After 7 days at 25°C, short, primitive pseudohyphae are present. Aerobic growth is off-white to cream-colored, butryous, soft and entire.

Fermentation: absent.

Assimilation:

Glucose	+	<i>N</i> -Acetyl-D-glucosamine	-
Galactose	-	Methanol	-

¹ Utilization of D-glucosamine as a source of nitrogen.

Co-Q: 7 (Goto and Oguri 1983).

Mol% G + C: 35.6, CBS 8057 (*T_m*: Goto and Oguri 1983).

Origin of the strain studied: CBS 8057, wild grapes (*Vitis coignetiae*), Japan.

Type strain: CBS 8057.

Comments: The results here differ from the original description. Goto and Oguri (1983) reported weak fermentation of glucose, very weak assimilation of raffinose, melezitose and α -methyl-D-glucoside, assimilation of glucitol and lactate, growth at 37°C and weak growth in vitamin-free medium.

64.91. *Candida multigemmis* (Buhagiar) S.A. Meyer & Yarrow (Yarrow and Meyer 1978)**Synonym:**

Torulopsis multigemmis (as *T. multis-gemmis*) Buhagiar (1975)

Growth in glucose-yeast extract-peptone broth:

After 3 days at 25°C, the cells are spheroidal to ovoidal, (2.5–6.5) × (3.0–6.5) μ m, single and in pairs.

Dalmau plate culture on corn meal agar: After 14 days at 25°C, pseudohyphae are absent or consist of short chains of budding cells. Aerobic growth is white, smooth, creamy, semi-glossy and entire.

Fermentation:

Cadaverine	+	Growth at 30°C	v
Creatinine	-	Growth at 35°C	-

¹ Utilization of D-glucosamine as a source of nitrogen.

Co-Q: Not determined.

Mol% G + C: 35.4, type strain (*T_m*: Meyer et al. 1984).

Origin of the strains studied: CBS 6524, CBS 6525, CBS 8140, raspberries, UK.

Type strain: CBS 6524.

64.92. *Candida musae* (Nakase) S.A. Meyer & Yarrow (Yarrow and Meyer 1978)**Synonym:**

Torulopsis musae Nakase (1971b)

Growth in glucose-yeast extract-peptone broth:

After 3 days at 25°C, the cells are subglobose to ovoidal, (3.0–5.0) × (4.0–8.0) μ m, single and in small groups (Fig. 242).

Dalmau plate culture on corn meal agar:

After 14 days at 25°C, pseudohyphae are not present, but chains of budding cells are sometimes present. Aerobic growth is white, creamy, smooth, soft and entire.

Fermentation:

Glucose	+	Lactose	-
Galactose	-	Raffinose	-
Sucrose	-	Trehalose	s
Maltose	-		

Assimilation:

Glucose	+	<i>N</i> -Acetyl-D-glucosamine	1
Galactose	–	Methanol	–

Creatinine	–	Growth at 35°C	–

¹ Utilization of D-glucosamine as a source of nitrogen.

Co-Q: Not determined.

Mol% G+C: 47.8, 48.0, CBS 6381 (*T_m*: Nakase 1971b; *T_m*: Meyer, unpublished data, respectively).

Origin of the strain studied: CBS 6381, banana, Japan.

Type strain: CBS 6381.

Comments: Kurtzman and Robnett (1997) found *C. fructus* and *C. musae* to have identical sequences in a 600-nucleotide region at the 5' end of large subunit (26S) rDNA, indicating the two taxa to be conspecific.

Fig. 242. *C. musae*, CBS 6381. After 5 days in glucose-yeast extract-peptone broth at 25°C. Bar = 5 μ m.

64.93. *Candida naeodendra* van der Walt, E. Johannsen & Nakase (1973)

Growth in glucose-yeast extract-peptone broth: After 3 days at 25°C, the cells are subglobose to ovoidal, (2.0–3.0) \times (2.0–5.0) μ m, single and in pairs.

Dalmau plate culture on corn meal agar: After 14 days at 25°C, pseudohyphae are essentially absent, however, short chains of cells are sometimes present. Aerobic growth is cream-colored, soft, smooth with an entire or irregular border.

Fermentation:

Glucose	+	Lactose	–
Galactose	1	Raffinose	–
Sucrose	–	Trehalose	+

¹ Utilization of D-glucosamine as a source of nitrogen.

Co-Q: Not determined.

Mol% G+C: 37.4, CBS 2935 (*T_m*: Suzuki and Nakase 1988b); 36.8, AJ 4772 (CCY-29-44-1) (*T_m*: Nakase and Komagata 1971f).

Origin of the strain studied: CBS 2935, soil, South Africa.

Type strain: CBS 2935.

Comments: This species was considered a synonym of *C. sake* (Meyer et al. 1984), but was restored to species status by Suzuki and Nakase (1988b) as the result of DNA hybridization experiments. Also, Fukazawa et al. (1975) showed that *C. natalensis* differed from *C. sake* on the basis of serological analysis and proton magnetic resonance spectra of cell wall mannans, and Montrocher and Claisse (1984) reported that these species differed in antigenic structure as well as the absorption spectra of cytochromes. A new species, *C. fragi*, described by Suzuki et al. (1991) has physiological properties similar to *C. natalensis*, *C. oleophila* and *C. sake*, but is distinguished from these species on the basis of DNA relatedness, electrophoretic enzyme patterns and

proton magnetic resonance (PMR) spectra of the cell wall mannans.

64.96. *Candida nemodendra* (van der Walt, van der Klift & D.B. Scott) S.A. Meyer & Yarrow (Yarrow and Meyer 1978)

Synonym:

Torulopsis nemodendra van der Walt, van der Klift & D.B. Scott (1971b)

Growth in glucose–yeast extract–peptone broth:

After 3 days at 25°C, the cells are globose to subglobose, (2.2–4.3) µm, and occur singly and in pairs.

Dalmou plate culture on corn meal agar: After 14 days at 25°C, pseudohyphae are not present. Aerobic growth is off-white, butyrous, smooth, soft, shiny and entire.

Fermentation: absent.

¹ Utilization of D-glucosamine as a source of nitrogen.

Co-Q: Not determined.

Mol% G+C: 41.7, CBS 4239 (BD: Stenderup et al. 1972); 40.7, CBS 4239 (BD: Meyer et al. 1984); 41.2, CBS 4239 (Tengku Zainal Mulok 1988).

Origin of the strains studied: CBS 2669, bottle-washing machine; CBS 2670, washed bottles; CBS 2874, miso (*Torulopsis wae* var. *miso*); CBS 4027, CBS 4239, sputum; CBS 6575, seawater.

Type strain: CBS 4239.

Comments: Tengku Zainal Mulok (1988) showed by DNA reassociation studies that CBS 1784, a strain from apple must that had been considered a representative of *C. norvegica*, had insignificant DNA relatedness with the type strain of the species. Other strains are under investigation to determine their species identity.

64.99. *Candida odintsovae*² Bab'eva, Reshetova, Blagodatskaya & Galimova (1989)

Growth in glucose–yeast extract–peptone broth:

After 3 days at 25°C, the cells are ovoidal, long ovoidal to cylindroidal, (2.0–4.5) × (2.5–11.0) µm, single and with buds. Some cells are slightly curved while others appear claviform or somewhat triangular or tear-drop shaped.

² The original spelling, *Candida odintsovi*, has been treated as an orthographic error.

Growth in yeast nitrogen base + 0.5% glucose: After 3 days at 25°C, a thick, folded pellicle is present and growth adheres to the walls of the tube.

Dalmu plate culture on corn meal agar: After 7 days at 25°C, abundant, entwined pseudohyphal growth is present. Some cells are curved and some of the growth appears 'bushy' or feathery and does not extend far from the streak. Aerobic growth is white to off-white, smooth, and dull to somewhat chalky with a mycelial margin.

Fermentation:

¹ Utilization of D-glucosamine as a source of nitrogen.

Co-Q: 7 (Bab'eva et al. 1989).

Mol% G+C: 36.0–36.6, 5 strains (HPLC: Bab'eva et al. 1989); 38.3, CBS 6025 (*T_m*: Meyer, unpublished data).

Origin of the strains studied: CBS 6025, CBS 6026, sap of birch (*Betula verrucosa*), Russia.

Type strain: CBS 6026.

Comments: Bab'eva et al. (1989) reported the fermentation of maltose (weak, slow), the assimilation of 5-ketogluconate and the maximum growth temperature of 42°C. They pointed out that the most characteristic feature of this species is its high glucosidase activity.

64.100. *Candida oleophila* Montrocher (1967)

Growth in glucose-yeast extract-peptone broth: After 3 days at 25°C, a few cells are spheroidal, but most are ovoidal or long-ovoidal to elongate, (2.9–4.3) × (4.3–6.5) μ m. They occur singly, in pairs, and in short branched and unbranched chains. Slender cylindrical cells, (1.5–3.6) × (4.3–9.4) μ m, are also present, as well as cells that are slightly curved. A thin, delicately wrinkled pellicle is present (Fig. 245).

Fig. 245. *C. oleophila*, CBS 2219. After 5 days in glucose-yeast extract-peptone broth at 25°C. Bar = 5 μ m.

Dalmu plate culture on corn meal agar: After 7 days at 25°C, pseudohyphae consist of branched chains of cylindrical cells, sometimes with verticils of ovoidal blastoconidia. Aerobic growth is off-white, dull, both smooth and delicately wrinkled, and the margin is usually entire with a few tufts of pseudohyphal growth.

¹ Utilization of D-glucosamine as a source of nitrogen.

Co-Q: 9 (Nakase et al. 1988b).

Mol% G+C: 40.7, CBS 2219; 41.5, CBS 4371 and CBS 6106 (*T_m*: Meyer et al. 1984); 42.2, NRRL Y-2317 (CBS 2219) (*T_m*: Nakase and Komagata 1971f); 43.7, UCD-FST 62-4=CBS 2219 (*T_m*: Meyer and Phaff 1972); 41.7, 40.1, CBS 2219 (*T_m* and HPCL, respectively: Nakase et al. 1988b).

Origin of the strains studied: CBS 2219, olives, Italy; CBS 2220, a flower; CBS 4371, cider, UK; CBS 6106, tonic water.

Type strain: CBS 2219.

Comments: The three strains identified as *C. oleophila* were at one time included in *C. sake*. Meyer and Simione (1978; unpublished data) showed by DNA reassociation that these strains were *C. oleophila*. Fukazawa et al. (1975) demonstrated that *C. oleophila* and *C. sake* differed on the basis of antigenic structure and the proton magnetic resonance spectra of their cell wall mannans. Also, Montrocher (1980) demonstrated that these species are serologically distinct and Montrocher and Claisse (1984) showed that they have different cytochrome absorption spectra as well as antigenic differences. Three species, *C. rignihuensis*, *C. railenensis* and *Apiotrichum oswaldi*, described by Ramírez and González (1984c,g), were thought to be members of *C. oleophila* (Barnett et al. 1990). Tengku Zainal Mulok (1988) showed by DNA reassociation that the latter two species were not representatives of *C. oleophila*, but they themselves are conspecific. *C. railenensis* has priority. *C. rignihuensis* and several strains in the CBS collection considered to be members of *C. oleophila* based on morphological and physiological properties demonstrated different whole cell protein electrophoretic patterns and different nuclear DNA restriction fragment length polymorphisms (Park and Meyer, unpublished data). These strains have been removed from *C. oleophila* for further study. *C. fragi*, a new species described by Suzuki et al. (1991) has physiological properties similar to *C. oleophila*, *C. sake* and *C. natalensis*, but it is distinct from them on the basis of DNA relatedness, electrophoretic enzyme patterns and proton magnetic resonance (PMR) spectra of the cell wall mannans. These investigators noted that *C. fragi* differs from *C. oleophila* by its inability to utilize trehalose,

to ferment galactose and to grow in the presence of 100 ppm cycloheximide.

64.101. *Candida oregonensis* Phaff & do Carmo-Sousa (1962)**Synonym:**

Candida obtusa Dietrichson ex van Uden & H.R. Buckley var. *oregonensis* (Phaff & do Carmo-Sousa) Montrocher (1967)

Growth in glucose-yeast extract-peptone broth: After 3 days at 25°C, the cells are ovoidal, (2.0–3.5) × (2.5–5.0) μm, single and in chains.

Dalmay plate culture on corn meal agar: After 7 days at 25°C, pseudohyphae consist of branched chains of elongate cells, often with dense verticils of ovoidal blastoconidia. Aerobic growth is white to cream-colored, butyrous, smooth, glistening and entire.

¹ Utilization of D-glucosamine as a source of nitrogen.

Co-Q: 7 (Kumamoto et al. 1986).

Mol% G+C: 35.8, CBS 7298 (*T_m*: Kumamoto et al. 1986).

Origin of the strain studied: CBS 7298, soil, Japan.

Type strain: CBS 7298.

64.103. *Candida palmioleophila* Nakase & M. Itoh (Nakase et al. 1988a)

Growth in glucose–yeast extract–peptone broth: After 3 days at 25°C, the cells are primarily globose with some that are slightly ovoidal, (1.5–4.0)×(1.5–5.0) μm, and occur singly, in pairs, short chains and small clusters.

Fig. 246. *C. palmioleophila*, CBS 7418. After 3 days in glucose–yeast extract–peptone broth at 25°C. Bar = 5 μm.

A thin pellicle is present which eventually drops to the bottom of the tube (Fig. 246).

Dalmou plate culture on corn meal agar: After 14 days at 25°C, primitive pseudohyphae consisting of short, branched chains of ovoidal cells are present. Aerobic growth is white, butyrous, smooth, soft and entire.

Fermentation: absent.

Assimilation:

Glucose	+	<i>N</i> -Acetyl-D-glucosamine	+
Galactose	+	Methanol	–

Creatinine	–	Growth at 40°C	+

¹ Utilization of D-glucosamine as a source of nitrogen.

Co-Q: 9 (Nakase et al. 1988a).

Mol% G+C: 39.4, 39.7, CBS 7418 (T_m and HPLC: Nakase et al. 1988a, respectively).

Origin of strain studied: CBS 7418, soil, Japan.

Type strain: CBS 7418.

Comments: Nakase et al. (1988a) pointed out that *C. palmioleophila* has characteristics similar to *C. famata* and *C. saitoana*, but can be differentiated from them on the basis of its high maximum growth temperature. Furthermore, DNA reassociation studies support the separation of these species. Interestingly, these investigators found 40.3% DNA relatedness between *C. palmioleophila* and *C. parapsilosis*, but also revealed that *C. palmioleophila* lacks antigen 13 which is specific for antigenic Group IV of which *C. parapsilosis* is a member.

64.104. *Candida paludigena* Golubev & Blagodatskaya (Golubev et al. 1981)

Growth in glucose–yeast extract–peptone broth:

After 3 days at 25°C, the cells are ovoidal, (2.0–3.5) × (4.0–7.0) µm, single and in pairs (Fig. 247). Pseudohyphae may be present.

Dalmu plate culture on corn meal agar: After 14 days at 25°C, well-developed pseudohyphae and septate hyphae are present. Aerobic growth is white, butyrous, glistening, and smooth with a fringed border.

Fermentation:

Glucose	s/–	Lactose	–
Galactose	–	Raffinose	–

Co-Q: 9 (Yamada and Kondo 1972a).

Mol% G+C: 40.0, CBS 604 (*T_m*: Meyer and Phaff 1969); 40.5, CBS 604 (*T_m*: Meyer and Phaff 1972); 40.8, CBS 604 (*T_m*: Stenderup and Bak 1968); 40.5, CBS 6318 (*T_m*: Meyer, unpublished data); 39.3–40.0, 6 strains (*T_m*: Nakase and Komagata 1971f); 40.5–41.7, 8 strains (*T_m*: Su and Meyer 1991).

Origin of the strains studied: CBS 604, sprue, Puerto Rico; CBS 1954, olives, Italy; CBS 2194, nail (*Blastodendron globosum*); CBS 2196, skin (*Blastodendron intestinale* var. *epidermicum*); CBS 2197, bladder (*Mycotorula vesica*); CBS 2211, toe; CBS 2215, CBS 2216, pickled cucumbers; CBS 2315, nail (*Monilia onychophila*); CBS 2915 (*Saccharomyces vossii*); CBS 2916, patient (*Saccharomyces verticillatus*), Norway; CBS 6318, CBS 8050, unknown; CBS 8181 (type of *C. osornensis*), rotten tree trunk, Chile.

Type strain: CBS 604.

Comments: *Candida osornensis* demonstrated 100% DNA reassociation with the type strain of *C. parapsilosis* (B. Roy and S.A. Meyer, unpublished data). Lin et al. (1995) showed that strains identified as *C. parapsilosis* based on physiological and morphological characteristics fell into three groups. These groups were defined on the basis of electrophoretic profiles of several enzymes and nucleotide sequences of the internally transcribed spacer, ITS1, next to the 5.8S RNA gene. Two groups have been confirmed by DNA reassociation studies (B. Roy and Meyer, unpublished data). In earlier studies, Meyer and Phaff (1972) showed the lack of DNA relatedness between the type strains of *C. parapsilosis* and *Lodderomyces elongisporus* did not support the proposed anamorphic/teleomorphic relationship of these species. Then, Nakase et al. (1979) demonstrated two different forms of *C. parapsilosis* with similar physiological and serological properties and nuclear magnetic resonance profiles of cell wall mannans. Strains designated *C. parapsilosis* Form I were L-arabinose positive and included the type strain, whereas strains designated *C. parapsilosis* Form II were L-arabinose negative and considered imperfect forms of *L. elongisporus*. Later, Yamazaki and

Komagata (1982a) compared *C. parapsilosis* Form I and Form II on the basis of electrophoretic patterns of ten enzymes and supported the conclusions of Nakase and coworkers. Hamajima et al. (1987) employed DNA base composition and DNA reassociation studies to show that the strains designated *C. parapsilosis* Form II were, indeed, anascosporogenous strains of *L. elongisporus*. It is apparent that the criteria presently employed to identify strains of *C. parapsilosis* are inadequate. The molecular studies being conducted in several laboratories around the world will help to define the '*C. parapsilosis* complex' and provide the criteria necessary to identify the species.

Fig. 249. *C. pararugosa*, CBS 1010. After 5 days in glucose-yeast extract-peptone broth at 25°C. Bar = 5 μm.

64.106. *Candida pararugosa* Nakase, Komagata & Fukazawa (1978)

Synonym:

Cryptococcus aggregatus Anderson (1917)

Growth in glucose-yeast extract-peptone broth:

After 3 days at 25°C, the cells are cylindrical, (1.5–3.0) × (6.0–23.0) μm, single, in pairs and short chains (Fig. 249). A white, creeping pellicle composed of tiny, spherical islands like styrofoam discs, covers the entire surface. After one month the pellicle is complete, folded, rough and thick.

Dalmau plate culture on corn meal agar: After 14 days at 25°C, abundant pseudohyphae consist of long, branched chains of cylindrical cells. Aerobic growth is white, raised, and wrinkled to rough with a mycelial border.

Fermentation: absent.

Assimilation:

¹ Utilization of D-glucosamine as a source of nitrogen.

Co-Q: 9 (Yamada and Kondo 1972a).

Mol% G+C: 41.5, CBS 4412 (T_m : Meyer and Phaff 1972); 39.5 (T_m : Nakase and Komagata 1971f); 40.0 (T_m : Su 1990).

Origin of the strain studied: CBS 4412, insect frass on an oak tree.

Type strain: CBS 4412.

Comments: Meyer and Phaff (1972) employed DNA hybridization to show that *C. parapsilosis* var. *querci* was distinct from *C. parapsilosis* and stated that it should be considered a separate species. However, they did not formally name it. Montrocher and Claisse (1984) used cytochrome absorption spectra and serological procedures to compare these two yeasts and came to the same conclusion. They proposed the name *C. quercus* (published as *querci*). However, this is a later homonym of *C. quercuum* Nakase (1971b) and, therefore, invalid under Article 64.2 of the International Code of Botanical Nomenclature. In the previous edition of *The Yeasts, A Taxonomic Study*, the name *C. quercitrusa* was used for this yeast (Meyer et al. 1984). This name was validated by Meyer and Yarrow (1998).

64.117. *Candida quercuum* Nakase (1971b)**Growth in glucose–yeast extract–peptone broth:**

After 3 days at 25°C, the cells are ovoidal to elongate, (1.5–2.5) × (5.0–9.0) μm, single and in pairs (Fig. 253).

Fig. 253. *C. quercuum*, CBS 6422. After 3 days in glucose-yeast extract-peptone broth at 25°C. Bar = 5 µm.

Dalmau plate culture on corn meal agar: After 7 days at 25°C, pseudohyphae consist of branched chains of elongate cells with globose to ovoidal blastoconidia. Aerobic growth is white, butyrous, smooth, dull, dry and entire.

¹ Utilization of D-glucosamine as a source of nitrogen.

Co-Q: 9 (*T_m*: Nakase and Suzuki 1985b).

Mol% G + C: 36.3–37.5, 6 strains (Nakase and Suzuki 1985b).

Origin of strains studied: CBS 940, atmosphere, Japan; CBS 8046, fish food.

Type strain: CBS 940.

Comments: This species is similar to *C. famata*, but differs from it by growing on propane 1,2 diol. Nakase and Suzuki (1985b) distinguished *C. saitoana* from *C. famata* and *C. naganishii* (teleomorph of *Debaryomyces nepalensis*) by proton magnetic resonance spectra of mannans, serological characterization and electrophoretic mobilities of glucose-6-phosphodehydrogenase. As pointed out by these authors, the name *Torula candida* Saito 1922 has priority. However, it cannot be used because the combination *Candida candida* is a tautonym. Therefore, they chose the name *Candida saitoana*, in honor of Dr. Saito who described *Torula candida*. Suzuki and Nakase (1993) described a new species, *C. pseudoglaebosa*, which resembles *C. saitoana* and *C. glaebosa*. See comments for *C. glaebosa*.

64.124. *Candida sake* (Saito & Oda) van Uden & H.R. Buckley ex S.A. Meyer & Ahearn (1983)

Synonyms:

Eutorulopsis sake Saito & Oda (1934)
Torulopsis sake (Saito & Oda) Lodder & Kreger-van Rij (1952)
Candida sake (Saito & Oda) van Uden & H.R. Buckley (1970) nom. inval.
Torula lambica Kufferath (1925)
Mycotorula lambica Harrison (1928)
Candida tropicalis (Castellani) Berkhout var. *lambica* (Harrison) Diddens & Lodder (1942)
Candida vanriji Capriotti (1958f)
Candida salmonicola Komagata & Nakase (1965)
Candida australis S. Goto, Sugiyama & Iizuka (1969)

Growth in glucose-yeast extract-peptone broth:

After 3 days at 25°C, the cells are spheroidal, ovoidal, elongate or cylindrical, (2.5–5.0) × (3.0–6.0) µm, and occur singly, in pairs, short chains and small clusters (Fig. 257). Pseudohyphae may be present. A ring, islets and a thin pellicle may be formed.

Dalmou plate culture on corn meal agar: After 7 days at 25°C, pseudohyphae may consist merely of a few short chains of cells or of long, branched chains of cylindrical cells with well-differentiated blastoconidia. Aerobic growth varies from smooth to lacy and wrinkled, white to off-white, creamy and soft. The margin may be entire or irregular.

¹ Utilization of D-glucosamine as a source of nitrogen.

Co-Q: 9 (Yamada and Kondo 1972a).

Mol% G + C: 37.8–41.0, 10 strains (T_m : Meyer et al. 1975); 39.3, CBS 159; 39.3, CBS 617 (T_m : Kaneko et al. 1977); 40.1, CBS 159; 39.7, JMC 1595 (CBS 5690) (T_m : Suzuki and Nakase 1988b).

Origin of the strains studied: CBS 159, sake-moto; CBS 617, lambic beer (type strain of *Torulula lambica*); CBS 1939, beer conduit in brewery, Sweden; CBS 2282, CBS 2283, egg yolk; CBS 2920 (type strain of *C. varrijiae*), CBS 2921, soil; CBS 5093, grape juice; CBS 5690, frozen salmon (type strain of *C. salmonicola*);

CBS 5740, soil; CBS 5957, water, Antarctica; CBS 6716, CBS 6717, CBS 6718, water, Chesapeake Bay, U.S.A.

Type strain: CBS 159.

Comments: Meyer and Phaff (1972) reported a high degree of DNA relatedness between *C. sake* and *C. salmonicola* type strains. Suzuki and Nakase (1988b) obtained similar results. Also, DNA reassociation studies confirmed the identity of CBS 617, CBS 2920, CBS 6716 and CBS 6717 as *C. sake* (Meyer et al. 1975). This study, as well as another study (Kaneko et al. 1977), showed the lack of significant DNA relatedness between *C. sake*, *C. maltosa* and *C. tropicalis*. Fukazawa et al. (1975) studied fifteen strains of *C. sake* on the basis of their serological properties and proton magnetic resonance spectra and found that the strains could be divided into four groups. Group I included the type strains of *C. sake*, *C. tropicalis* var. *lambica*, *C. salmonicola* and *C. varrijiae*. Group II was represented by the type strains of *C. maltosa*, *C. cloacae* and *C. subtropicalis*. The type strains of *C. oleophila* and *C. natalensis* were members of Group III and Group IV, respectively. Montrocher (1980) found similar results with an immunoelectrophoretic technique. Both of these investigations concur with the DNA studies. The degree of variability exhibited by the strains included in *C. sake* is indicative that heterogeneity still exists and additional molecular studies are needed to determine the identity of these strains. A new species, *C. fragi*, isolated from a fermenting strawberry, has physiological properties similar to *C. sake*, as well as *C. oleophila* and *C. natalensis*, but it is distinct from them on the basis of DNA relatedness, electrophoretic enzyme patterns and proton magnetic resonance spectra of the cell wall mannans (Suzuki et al. 1991). Kurtzman and Robnett (1997) found *C. sake* and *C. austromarina* to have identical sequences in a 600-nucleotide region at the 5' end of large subunit (26S) rDNA, indicating the two taxa to be conspecific.

64.125. *Candida salmanticensis* (Santa Maria) van Uden & H.R. Buckley ex S.A. Meyer & Ahearn (1983)

Synonyms:

Torulopsis salmanticensis Santa Maria (1963a)

Candida salmanticensis (Santa Maria) van Uden & H.R. Buckley (1970) nom. inval.

Growth in glucose-yeast extract-peptone broth:

After 3 days at 25°C, the cells are subglobose to ovoidal, (3.0–5.0) × (4.0–8.0) µm, and occur singly, in pairs and in clusters (Fig. 258).

Dalmou plate culture on corn meal agar: After 7 days at 25°C, pseudohyphae consist of chains of cylindrical cells with verticils of ovoidal blastoconidia. Aerobic growth is white to cream-colored, dull, and smooth with an entire border.

Fig. 258. *C. salmanticensis*, CBS 5121. After 3 days in glucose-yeast extract-peptone broth at 25°C. Bar = 5 µm.

Mol% G+C: 45.5, CBS 5121 (BD: Meyer et al. 1984).

Origin of the strain studied: CBS 5121, alpechin (residue from preparation of olive oil).

Type strain: CBS 5121.

64.126. *Candida santamariae* Montrocher (1967)

Synonym:

Candida krusei (Castellani) Berkhout var. *saccharicola* Santa Maria (1959b)

Growth in glucose-yeast extract-peptone broth:

After 3 days at 25°C, the cells are ovoidal to elongate, (3.5–7.0) × (6.5–12.0) µm. Some single and budding cells are evident, but most of the growth is pseudomycelial. An incomplete pellicle is present.

Dalmau plate culture on corn meal agar:

After 7 days at 25°C, pseudohyphae consist of extensively branched chains of cylindrical cells, sometimes with blastoconidia singly or in short chains. Aerobic growth is off-white to beige, creamy, smooth to irregular, soft, dull, with a mycelial border.

Fermentation:

Glucose	+	Lactose	-
Galactose	-	Raffinose	-
Sucrose	-	Trehalose	+
Maltose	-		

Assimilation:

¹ Utilization of D-glucosamine as a source of nitrogen.

Co-Q: 9 (Yamada and Kondo 1972a).

Mol% G+C: 36.3, 38.8, 37.3, CBS 4515 (*T_m*: Nakase and Komagata 1971f; Meyer et al. 1984; Meyer, unpublished data; respectively).

Origin of strains studied: CBS 4515, sugar, Spain.

Type strain: CBS 4515.

Comments: In the original description of *C. santamariae* (Montrocher 1967), sucrose utilization and galactose

fermentation were recorded as positive. Van Uden and Buckley (1970) determined that these results were negative and attributed the difference to the techniques Montrocher used, which were test periods of up to three months. Also, a strain designated as *C. santamariae* var. *membranifaciens* Montrocher (1967) (isolated from an insect, *Hymenochaete rubiginosa*, in France, CBS 5838) was originally described as differing from the species in sucrose utilization, galactose fermentation and pellicle formation. Without studying this strain, van Uden and Buckley questioned its status as a variety since the type strain of *C. santamariae* failed to utilize sucrose and failed to ferment galactose. Meyer et al. (1984) noted that the mol% G+C was significantly higher (46%) for the varietal strain and stated that more studies needed to be done to identify this strain. (The reported value of 46% was an error. It should have been 44.6%. This was the value reported by Stenderup et al. 1972.) Nevertheless, this value is still significantly higher than that of the *C. santamariae* type strain. Other data (Meyer, unpublished data) places the mol% G+C at 37.3–38.5, based on two T_m determinations. These GC values are closer to that of the type strain of *C. santamariae*. DNA reassociation studies will resolve the relationship of these two strains. Since the taxonomic position of *C. santamariae* var. *membranifaciens* remains uncertain, it is not included as a variety of the species at this time. Kurtzman and Robnett (1997) found *C. beechii* and *C. santamariae* to have identical sequences in a 600-nucleotide region at the 5' end of large subunit (26S) rDNA, indicating the two taxa to be conspecific.

64.127. *Candida santjacobensis* C. Ramírez & A. González (1984i)

Growth in glucose–yeast extract–peptone broth: After 3 days at 25°C, the cells are subglobose to ovoidal, (2.0–3.5)×(2.0–5.0) μm, single and in pairs (Fig. 259).

Dalmou plate culture on corn meal agar: After 14 days at 25°C, a few, short pseudohyphae are formed outside the coverslip. Aerobic growth is creamy, off-white, soft and entire.

Fig. 259. *C. santjacobensis*, CBS 8183. After 5 days in glucose–yeast extract–peptone broth at 25°C. Bar = 5 μm.

Supplementary descriptions of *C. shehatae* varieties:

Variety *insectosa*: L-sorbose, –; L-arabinose, –; erythritol, –; L-arabinitol, –; gelatin liquefaction, w; 0.1% cycloheximide, +; mol% G + C: 44.4, 44.6, 2 strains (Kurtzman 1990b).

Variety *lignosa*: L-sorbose, +; L-arabinose, v; galactitol, v; D-gluconate, –; DL-lactate, w; L-arabinitol, –; 0.1% cycloheximide, +; mol% G + C: 44.1, type strain (Kurtzman 1990b).

Origin of the strains belonging to the variety

***shehatae*:** CBS 5712, rose-hip, Canada; CBS 5813, dead insect-invaded pine tree; CBS 7261, CBS 7263, forest soil, South Africa; CBS 2779, soil, South Africa.

Type strain: CBS 5813.

Origin of the strains belonging to the variety

***insectosa*:** CBS 4286, an insect, *Leptura maculicornis*; CBS 4287, an insect, *Leptura cerambyciformis*.

Type strain: CBS 4286.

Origin of the strain belonging to the variety

***lignosa*:** CBS 4705, wood.

Type strain: CBS 4705.

Comments: Vaughan-Martini (1984) showed by DNA reassociation that *C. shehatae* was not the anamorph of *Pichia stipitis*. This was confirmed by Tengku Zainal Mulok (1988) and by Kurtzman (1990b). Kurtzman's studies not only included DNA reassociation, but ribosomal RNA sequence comparisons. He also found that the strains of *C. shehatae* formed three DNA groups with about 50% DNA reassociation between members of the different groups. He designated three varieties, *C. shehatae* var. *shehatae*, var. *insectosa*, and var. *lignosa*, and found that the physiological properties that separate these varieties are the utilization of galactitol and lactate by var. *lignosa* and the weak liquefaction of gelatin by var. *insectosa*. Our results were variable for the utilization of galactitol by

var. *lignosa* because the tests are terminated after 3 weeks. If they were allowed to run 4 weeks, latent or negative reactions were noted.

64.132. *Candida silvae* Vidal-Leiria & van Uden (1963)**Growth in glucose–yeast extract–peptone broth:**

After 3 days at 25°C, the cells are ovoidal, (2.0–4.0) × (3.0–6.0) μm, single and in pairs (Fig. 262). Islets and a ring may be present.

Dalmau plate culture on corn meal agar:

After 7 days at 25°C, pseudohyphae consist of branched chains of elongate cells with verticils of ovoid blastoconidia. Aerobic growth is white, butyrous, soft, mostly smooth, somewhat glistening and entire.

Fig. 262. *C. silvae*, CBS 5498. After 3 days in glucose–yeast extract–peptone broth at 25°C. Bar = 5 μm.

¹ Utilization of D-glucosamine as a source of nitrogen.

Co-Q: 7 (Suzuki et al. 1994).

Mol% G + C: 39.5, CBS 5498 (*T_m*: Suzuki et al. 1994); 44.0, CBS 5497 (BD: Meyer et al. 1984).

Origin of the strains studied: CBS 988, yeast cake; CBS 1520, vagina; CBS 2832, sputum; CBS 5497, CBS 5498, horse intestine.

Type strain: CBS 5498.

Comments: Suzuki et al. (1994) described a new species, *C. stellimalicola*, that resembles *C. silvae*, *C. diversa* and *C. karawaiewii* in physiological and morphological properties. *C. stellimalicola* is differentiated from *C. silvae* on the basis of a vitamin requirement. See Comments for *C. diversa* for more information.

64.133. *Candida silvanorum* van der Walt, van der Klift & D.B. Scott (van der Walt et al. 1971a)

Growth in glucose–yeast extract–peptone broth:

After 3 days at 25°C, the cells are subglobose to ovoidal, (2.0–3.5) × (2.0–4.0) μm, single, in pairs, small chains and groups.

Dalmou plate culture on corn meal agar: After 7 days at 25°C, well-developed pseudohyphae consist of long chains of slender elongate cells with verticils of usually triangular blastoconidia. Aerobic growth is white to cream-colored, butyrous with a raised, wrinkled central area and an entire or fringed margin.

Fermentation:

Glucose	+	Lactose	–
Galactose	s	Raffinose	s
Sucrose	s	Trehalose	s
Maltose	s

¹ Utilization of D-glucosamine as a source of nitrogen.

Co-Q: Not determined.

Mol% G + C: 39.8, 39.9, 2 strains (*T_m*: Nakase 1971c); 40.7, CBS 2120, CBS 2121 (*T_m*: Meyer, unpublished data).

Origin of the strains studied: CBS 2120, fermenting cacao; CBS 2121, palm wine; CBS 6378, pineapple; CBS 8042, *Euphorbia* species.

Type strain: CBS 6378.

64.141. *Candida spandovensis* (Henninger & Windisch) S.A. Meyer & Yarrow (Yarrow and Meyer 1978)**Synonym:**

Torulopsis spandovensis Henninger & Windisch (1976b)

Growth in glucose-yeast extract-peptone broth:

After 3 days at 25°C, the cells are globose to short-ovoidal, (2.5–3.5) × (3.0–4.5) μm, single and in pairs (Fig. 266).

Dalmou plate culture on corn meal agar: After 14 days at 25°C, pseudohyphae are absent or short chains of budding cells are present. Aerobic growth is white, butyrous, shiny, convex and entire.

Fermentation:

Glucose	+	Lactose	–
Galactose	s	Raffinose	s/–
Sucrose	s	Trehalose	–
Maltose	–		

Fig. 266. *C. spandovensis*, CBS 5511. After 3 days in glucose-yeast extract-peptone broth at 25°C. Bar = 5 μm.

¹ Utilization of D-glucosamine as a source of nitrogen.

Co-Q: 7 (J.-D. Lee and Komagata 1980a); 7 (C.-F. Lee et al. 1994b).

Mol% G+C: 40.9, CBS 8003 (*T_m*: J.-D. Lee and Komagata 1980a); 41.2, CBS 7297 (*T_m*: Kumamoto et al. 1986); 40.0, CBS 8003; 39.5, CBS 7297 (HPLC: C.-F. Lee et al. 1994b).

Origin of the strains studied: CBS 8003, sap of a peach tree, Japan; CBS 7297, oil field, Japan.

Type strain: CBS 8003.

Comments: C.-F. Lee et al. (1994b) found identical chromosomal DNA banding patterns and 90% DNA relatedness between the type strains of *C. methanolophaga* and *C. succiphila* to confirm their conspecificity.

64.144. *Candida suecica* Rodrigues de Miranda & Norkrans (1968)

Growth in glucose–yeast extract–peptone broth:

After 3 days at 25°C, the cells are ovoidal, long ovoidal, ellipsoidal or cylindrical, (2.2–3.6) × (5.8–13.7) µm, single, in pairs and short chains (Fig. 268). Pseudohyphae are present.

Growth in yeast nitrogen base + 0.5% glucose:

After 3 days at 25°C, a delicately wrinkled pellicle is present.

Dalmu plate culture on corn meal agar:

After 7 days at 25°C, abundant pseudohyphae are present and consist of branched chains of cylindrical cells, many with verticils of ovoidal blastoconidia. Aerobic growth is white, smooth and wrinkled, soft, and dry with a lobed margin.

Fermentation:

Glucose	–/l	Lactose	–
Galactose	–	Raffinose	–
Sucrose	–	Trehalose	–
Maltose	–		

Assimilation:

¹ Utilization of D-glucosamine as a source of nitrogen.

Co-Q: Not determined.

Mol% G+C: 42.7, 42.4, CBS 5724 (*T_m*: Meyer et al. 1984; BD: Kurtzman 1987a, respectively).

Origin of the strain studied: CBS 5724, sea water, Sweden.

Type strain: CBS 5724.

Fig. 268. *C. suecica*, CBS 5724. After 5 days in glucose–yeast extract–peptone broth at 25°C. Bar = 5 µm.

64.145. *Candida tanzawaensis* Nakase & M. Itoh (Nakase et al. 1988b)

Growth in glucose–yeast extract–peptone broth:

After 3 days at 25°C, the cells are ovoidal, (1.0–2.0) × (1.5–4.0) µm, and occur singly or in pairs. Short, branched chains of cells are also present. Other cells are long ovoidal or elongate (10 µm and longer), and slender; some are branched. There is abundant pseudohyphal development. A pellicle appears to have dropped from the surface and the liquid is flocculant.

Growth in yeast nitrogen base + 0.5% glucose: After 3 days at 25°C, a wrinkled pellicle is present.

Dalmou plate culture on corn meal agar: After 7 days at 25°C, pseudohyphae consist of long, branched chains of cells with globose to ovoidal blastoconidia occurring singly or in small verticils. Septate hyphae may be present. Aerobic growth is white, dull, and irregular. The margin is fringed.

Fermentation:

Glucose	+	Lactose	–
Galactose	–	Raffinose	–
Sucrose	–	Trehalose	ws
Maltose	–		

Assimilation:

Creatinine	–	Growth at 35°C	–

¹ Utilization of D-glucosamine as a source of nitrogen.

Co-Q: 9 (Nakase et al. 1988b).

Mol% G+C: 45.1, 44.1, CBS 7422 (*T_m* and HPLC, respectively; Nakase et al. 1988b).

Origin of the strains studied: CBS 7422, moss (*Polytrichum commune*), Mt. Tanzawa, Japan.

Type strain: CBS 7422.

Comments: In the original description of *C. tanzawaensis*, Nakase et al. (1988b) reported D-arabinose positive or latent, ribose variable, galactitol, L-rhamnose and soluble starch negative or weakly positive, growth on 50% glucose weakly positive and growth at 35°C positive. These investigators recognized the physiological similarities between *C. tanzawaensis*, *C. kruisii* and *C. oleophila* and found the mol% G+C for *C. oleophila* (41.7%) lower than that of *C. tanzawaensis* (45.1%) and *C. kruisii* (45.4%). DNA reassociation confirmed that these species are distinct.

64.146. *Candida tenuis* Diddens & Lodder (1942)

Synonym:

Mastigomyces philippovii Imshenetskii & Kriss (1933)

Growth in glucose–yeast extract–peptone broth:

After 3 days at 25°C, the cells are ovoidal to cylindrical or elongate, (1.5–3.5) × (2.0–7.0) µm, single, in pairs, chains and clusters (Fig. 269). Pseudohyphae may be present.

Dalmou plate culture on corn meal agar: After 7 days at 25°C, pseudohyphae consist of branched chains of cylindrical cells, sometimes with verticils of ovoidal

Fig. 269. *C. tenuis*, CBS 615. After 3 days in glucose–yeast extract–peptone broth at 25°C. Bar = 5 µm.

blastoconidia. Septate hyphae may be present. Aerobic growth is off-white, creamy, lacy to wrinkled, with a fringed border.

Growth in glucose–yeast extract–peptone broth: After 3 days at 25°C the cells are subglobose to ovoidal, (3.5–7.0) × (5.5–10.0) µm, single and in pairs.

Dalmau plate culture on corn meal agar: After 7 days at 25°C, pseudohyphae consist of branched chains of cylindrical cells with blastoconidia formed singly or in verticils; septate hyphae are usually present. Aerobic growth is white, smooth, butyrous, and soft with a fringed border.

¹ Utilization of D-glucosamine as a source of nitrogen.

Co-Q: 9 (Yamada and Kondo 1972a).

Mol% G+C: 45.4–46.6, 3 strains (T_m : Nakase and Komagata 1971d); 53.7, CBS 1752 (T_m : Meyer et al. 1984); 47.5, type strain of *C. manniotfaciens* (BD: Meyer et al. 1984); 46.4, one strain of *Debaryomyces tamaritii* (BD: Price et al. 1978); 45.0, type strain; 46.2, type strain of *C. manniotfaciens*; 44.1, type strain of *C. halophila*; 45.4, JCM 5957 and JCM 5974; 46.0, JCM 5958 (T_m : Suzuki et al. 1992).

Origin of the strains studied: Fermenting cucumber brines in U.S.A. (8, including CBS 1731, type strain of *Torulopsis anomala*; CBS 1752, type strain of *C. versatilis*); CBS 5007, sugar, Mauritius; soy mash (3, including CBS 5981, type strain of *C. manniotfaciens*; CBS 4019, type strain of *C. halophila*; CBS 4333, type strain of *Debaryomyces tamaritii*).

Type strain: CBS 1752.

Comments: Suzuki et al. (1992) demonstrated the conspecificity of *C. versatilis*, *C. manniotfaciens*, *C. halophila*, *Debaryomyces tamaritii* and two strains designated '*C. rhodohalophila*' in studies that included DNA base compositions and reassociations, electrophoretic patterns of enzymes, and proton magnetic resonance (PMR) spectra of cell wall mannans. F.-L. Lee et al. (1992) performed DNA reassociations on these same species and also reported their conspecificity. The proper identification of *D. tamaritii* is welcomed since this yeast did not fit well in *Debaryomyces*. Previously, it was noted that it had a higher mol% G+C than the other species in *Debaryomyces* (Nakase and Komagata 1971a, Price et al. 1978) and that it was widely separated from other species of *Debaryomyces* by ribosomal RNA comparisons (Kurtzman and Robnett 1991, Yamada et al. 1991a). Although *D. tamaritii* was described as having spherical warty-walled ascospores, no one has been able to confirm this claim. [The mol% G+C value, 53.7%, previously reported for the type strain of *C. versatilis* (Meyer et al. 1984) is most likely an error; possibly a culture mix-up with strains of *C. etchellsii* (52.6%) that have similar CBS numbers.]

64.158. *Candida vinaria* Y. Ohara, Nonomura & Yunome ex M.Th. Smith (1973)

Growth in glucose-yeast extract-peptone broth:

After 3 days at 25°C, the cells are ovoidal, (1.5–2.5) × (3.0–7.0) µm, single and in pairs.

Dalmau plate culture on corn meal agar: After 14 days at 25°C, pseudohyphae consist of branched chains of elongate cells, sometimes with a few ovoidal blastoconidia. Aerobic growth is off-white, shiny, butyrous, smooth and entire.

Fermentation: absent.

Mol% G+C: 57.6, CBS 619 (*T_m*: Stenderup and Bak 1968); 54.5,

2 strains (*T_m*: Nakase and Komagata 1968a); 55.9, ATCC 7351 (CBS 619); 54.7, AJ 4741 (*T_m*: Nakase and Komagata 1971f).

Origin of the strains studied: CBS 619, blastomycotic macroglossia, Sri Lanka; CBS 641, CBS 2328, chilled beef, Australia; CBS 947, throat; CBS 1922, unknown; CBS 2000, sputum, Norway; CBS 2326, dog's skin; CBS 2329, probably human; CBS 4909, sea water; CBS 5122, skin; CBS 5262, dolphin's skin; CBS 5446, 5447, salami, Yugoslavia; CBS 5718, red clover, Canada; CBS 6134, 6135, feces, Finland; 6165, probably human; CBS 6391, 6408, 6409, 6410, 6411, sausages, Spain.

Type strain: CBS 619 (neotype, Diddens and Lodder 1942, p. 304).

Comments: Kurtzman and Robnett (1997) found *C. krissii* and *C. zeylanoides* to have identical sequences in a 600-nucleotide region at the 5' end of large subunit (26S) rDNA, indicating the two taxa to be conspecific.

Comments on the genus

Viljoen and Kock (1989b) presented a chronological account of the history of the genus *Candida* Berkhout with the rationale of various investigators for the changes that took place until the delimitation of the genus to anamorphs with only ascomycetous affinity. Several investigators (von Arx and Weijman 1979, Moore 1980, Golubev 1981, Weijman and Rodrigues de Miranda 1988) reclassified the basidiomycetous *Candida* species and transferred them to other genera. Van der Walt (1987) made the necessary changes to separate the ascomycetous and basidiomycetous anamorphic yeasts into appropriate families. He reinstated the family name Candidaceae for the ascomycetous anamorphic yeasts (to which *Candida* was assigned) and restricted the family Cryptococcaceae to basidiomycetous anamorphs and the family Sporobolomycetaceae to anamorphs termed ustomycetous. Weijman and Rodrigues de Miranda (1988) compared members of the genus *Candida* on the basis of carbohydrate patterns of intact whole cell hydrolyzates. They found three groups. The first group represented ascomycetous yeasts where mannose dominated, and rhamnose, fucose and xylose were absent. The basidiomycetous yeasts were distributed in the other two groups; one characterized by the presence of xylose and low mannose and the other by the presence of fucose and/or rhamnose with significant amounts of mannose. Then, Weijman et al. (1988) redefined the genus *Candida*, emended *Cryptococcus* and *Rhodotorula*, and transferred the basidiomycetous '*Candida*' species to the appropriate emended genera.

Although the species with a basidiomycetous affinity have been removed from the genus, *Candida* still remains heterogeneous. The mol% G+C ranges from 30–62.7%, Co-Q 6, 7, 8 and 9 are present, fermentation may be absent to strong, cells vary in shape and size, and assimilatory properties vary. *Candida* species that were found to sporulate have teleomorphic states in eleven different genera. The taxonomic boundaries of *Candida* still remain

broad and essentially any asexual yeast that does not fit the criteria of some other genus will find its way into *Candida*. In particular, *Candida* acts as a depository for all the asexual yeasts with ascomycetous affinity except those with: (a) acetic acid production (*Brettanomyces*), (b) bipolar budding on a broad base (*Kloeckera* and *Schizoblastosporion*), (c) triangular cells (*Trigonopsis*), (d) blastoconidia formed on sympodulae (*Sympodiomyces*) or on pedicels or denticles (*Blastobotrys*), (e) dichotomously branched terminal pseudohyphal cells (*Botryozyma*), (f) needle-shaped terminal conidia (*Aciculoconidium*), and (g) arthroconidia (*Arxula*, *Geotrichum*), (h) carotenoid pigments (*Lalaria*, *Oosporidium*, *Saitoella*), (i) extracellular starch-like compounds (*Myxozyma*). In some instances, *Candida* is a temporary repository for a species until ascosporeulation is observed and it can be placed in a teleomorphic genus. Some species are represented by only a single strain. A number of *Candida* species have been found to sporulate, either independently or when strains are mixed and mating types are revealed. The list of *Candida* species presented here includes some species that have teleomorphic counterparts. Some are often isolated as single mating types, such as *C. guilliermondii* and *C. lusitanae*, or others are well-known species whose relationship to the teleomorph was established by DNA reassociation (*C. krusei*, *C. sorbosa*). In addition, there are other species that were at one time included in *Candida*, but because they were found to sporulate are not listed in *Candida*, but in the appropriate ascomycetous genera. These species (anamorph/teleomorph) are cross-referenced in the index. When sporulation is elusive, molecular techniques can be used to resolve relationships. DNA-DNA reassociation and ribosomal RNA gene sequencing are techniques that have been employed to determine anamorphic/teleomorphic relationships, as well as conspecificity of *Candida* species and proper identity of strains within a species. These techniques have been particularly useful in resolving the correct status of a number of *Candida* species.

Some species that were published while this chapter was being prepared are not included, namely: *C. fragi* Suzuki, Nakase & Kukazawa (1991), *C. pseudoglebosa* Suzuki & Nakase (1993), *C. sojae* Nakase, Suzuki, Takashima, Miyakawa, Kagaya, Fukazawa & Komagata (1994b), *C. stellimalicola* Suzuki, Nakase & Komagata (1994), *C. cellulolytica* and *C. fukuyamaensis* Nakase, Suzuki, Takashima, Hamamoto, Hatano & Fukui (1994c), and *C. dubliniensis* Sullivan, Westerneng, Haynes, Bennett & Coleman (1995). *C. fragi* has physiological properties similar to *C. sake*, *C. oleophila* and *C. natalensis*, but it is distinct from them on the basis of DNA relatedness, electrophoretic enzyme patterns and proton magnetic

resonance (PMR) spectra of the cell wall mannans. *C. sojae*, a species isolated from an extraction process of water-soluble substances of defatted soybean flakes, has some similarity to *C. albicans* and *C. tropicalis*. However, it is distinguished from these species on mol% G+C, electrophoretic enzyme patterns and the PMR spectra of cell wall mannans. *C. stellimalicola*, a species isolated from Ma-Fueng (star apple) in Thailand, shows some similarity to *C. diversa*, *C. silvae* and *C. karawaiewii*. It was distinguished from these species by DNA reassociation, proton magnetic resonance spectra of the cell wall mannans and serological characteristics of cell surface antigens. *C. cellulolytica* and *C. fukuyamaensis* are both cellulolytic yeasts isolated from natural habitats by enrichment techniques. The latter species has some similarities with *C. famata*, *C. guilliermondii* and *C. salmanticensis*, but can be differentiated from them on various criteria. *C. dubliniensis* was recently described for a number of strains isolated from HIV-infected patients and uninfected persons. It has characteristics that resemble *C. albicans*. It is germ-tube positive and produces chlamydo-spores in abundance. Its physiological profile is nearly identical to that of *C. albicans*. Sullivan et al. (1995) employed several molecular biological techniques to compare strains of this species with *C. albicans* strains. *C. albicans* serotype A and serotype B strains and the type strain and one other strain of *C. stellatoidea* were included in the study. The results showed that the strains of *C. dubliniensis* were distinct from the *C. albicans* strains. See the comments section of *C. albicans* for more information.

Species of uncertain affiliation: *C. santamariae* var. *membranifaciens* and *C. rignihuensis* were previously included in *C. santamariae* and *C. oleophila*, respectively. *C. molischiana* was previously considered the anamorph of *Pichia capsulata*. However, this relationship is not supported by ribosomal RNA gene sequence comparisons (Kurtzman, personal communication). Also, the status of *Saccharomyces pleomorphus*, a strain previously considered a synonym of *C. lodderae*, is questioned because the type strain of *C. lodderae* was found to be conspecific with *C. viswanathii*.

Species complexes: Some species are heterogeneous. They include unrelated strains whose relationships have not been resolved. *C. sake* and *C. oleophila* are excellent examples. *C. intermedia*, *C. rugosa*, *C. tenuis* and *C. zeylanoides* show much variability and are possibly heterogeneous. Others, such as *C. parapsilosis* and *C. haemulonii* have been shown to have two or more distinct genomic types (refer to the comments section of the species descriptions for more information).

65. *Geotrichum* Link:Fries

G.S. de Hoog, M.Th. Smith and E. Guého

Diagnosis of the genus

Colonies are white, farinose or hairy, usually dry, and consist of true hyphae which disarticulate into rectangular arthroconidia. Additionally, mostly sympodially produced conidia may be present. Budding is absent. Chlamydospores and endoconidia may be present. Septa have micropores.

Fermentation is mostly absent. Nitrate is not assimilated. Extracellular starch is not produced. Diazonium blue B reaction is negative.

Teleomorph genera: *Dipodascus*, *Galactomyces*.

Type species

Geotrichum candidum Link:Fries

Species accepted

1. *Geotrichum candidum* Link:Fries (1832): see *Galactomyces geotrichum*, p. 210

^a Abbreviations: Sor, L-sorbose; Suc, sucrose; Mal, maltose; Cel, cellobiose; Xyl, D-xylose; Rbl, ribitol; Mtl, D-mannitol; Glt, D-glucitol; Sal, salicin; Cit, citrate.

^b Abbreviations: Vfree, in vitamin-free medium; 37°C, at 37°C.

^c Culture produces a strong fruity odor.

^d Hyphae are markedly constricted at the septa.

Systematic discussion of the species

65.1. *Geotrichum candidum* Link:Fries (1832)

See under teleomorph *Galactomyces geotrichum*: p. 210.

65.2. *Geotrichum capitatum* (Diddens & Lodder) von Arx (1977a)

See under teleomorph *Dipodascus capitatus*: p. 186.

65.3. *Geotrichum citri-aurantii* (Ferraris) E.E. Butler (Butler et al. 1988)

See under teleomorph *Galactomyces citri-aurantii*: p. 209.

65.4. *Geotrichum clavatum* de Hoog, M.Th. Smith & Guého (1986)

Growth on 4% malt extract/0.5% yeast extract agar: After 10 days at 20–22°C, colonies are 15–17 mm in diameter, glassy-white, flat, smooth and tough. Expanding hyphae are in loose bundles and break up into rectangular cells of variable size, (2.8–4.0)×(6–20) μm. Terminal parts of hyphae may swell and become thick-walled; the widest cell at the apex measures 8×11 μm (Fig. 274).

Fig. 274. *G. clavatum*, CBS 576.82, 425.71. MEYA, 22°C. Branching pattern arthroconidia and swollen terminal cells.

Fermentation: absent.

Arbutin	+		

Co-Q: Not determined.

Mol% G+C: 31.1–33.2, CBS 425.71, CBS 576.82 (T_m : de Hoog et al. 1986).

Origin of the strains studied: CBS 425.71, from human lung tissue, Ahearn, Atlanta, U.S.A.; CBS 576.82

(CBS 2465), from human patient with asthma, Orië, Netherlands.

Type strain: CBS 425.71.

Comments: This is one of the arthroconidial opportunists involved in human systemic mycoses, particularly in connection with pulmonary disorders. For a discussion on emerging systemic opportunists, see under *Dipodascus capitatus*.

65.5. *Geotrichum decipiens* (L. Tulasne & R. Tulasne) W. Gams (1983)

See under teleomorph *Dipodascus armillariae*: p. 184.

65.6. *Geotrichum fermentans* (Diddens & Lodder) von Arx (1977a)

Synonyms:

Trichosporon fermentans Diddens & Lodder (1942)

Fermentotrichon fermentans (Diddens & Lodder) Novák & Zsolt (1961)

Growth on 4% malt extract/0.5% yeast extract agar: After 10 days at 20–22°C, colonies are 35–40 mm in diameter, whitish, moist and somewhat raised, with straight and sharp margins that later become fimbriate margins. Expanding hyphae are straight, initially remotely septate, later every 20–60 µm; main branches are 5–7 µm wide, lateral branches are 2.5–4.0 µm wide, and disarticulate into arthroconidia, (2.8–4.0) × (8–30) µm. Hyphae that form later often remain intact and develop short grape-like branches composed of ellipsoidal cells (Fig. 275).

Fermentation:

2-Keto-D-gluconate	-	Growth at 37°C	v
Arbutin	+		

Co-Q: Not determined.

Mol% G+C: 42, CBS 439.83 (T_m : Guého 1979), 46.1–46.2, CBS 409.34, CBS 439.83 (BD: Guého et al. 1984).

Fig. 275. *G. fermentans*, CBS 2529. MEYA, 22°C. Expanding hyphae, blasto- and arthroconidia.

Origin of the strains studied: CBS 439.83 (CBS 2529, NRRL Y-1492, ATCC 10675) from wood pulp, Rennerfelt, Sweden; from wood pulp mill (1); from tanned sheep skin (1).

Type strain: CBS 439.83.

Comments: One of the main characteristics of this species is the relatively long and narrow conidia which do not inflate after detachment, and the local, grape-like lateral branchlets.

65.7. *Geotrichum fragrans* (Berkhout) Morenz ex Morenz (1964)

Synonyms:

Oospora fragrans Berkhout (1923)

Cylindrium fragrans (Berkhout) Burns (1933)

Endomyces lactis (Fresenius) Windisch var. *fragrans* (Berkhout) Windisch (1951)

Oidium suaveolens Krzemecki (1913)

Oospora gigas Smit & Meyers (1928)

Geotrichum magnum Saëz (1968a)

Geotrichum fici S. Goto, Yamakawa & Yokotsuka (1975b)

Geotrichum rectangulatum S. Goto, Yamakawa & Yokotsuka (1975b)

Growth on 4% malt extract/0.5% yeast extract agar:

After 10 days at 20–22°C, colonies are 25–30 mm in diameter, whitish, tough, hispid with creeping hyphal fascicles, and produce a strong fruity odor. Expanding hyphae are straight and stiff, unilaterally branched at acute angles, main branches are 7–12 μm wide, lateral branches are

4–7 μm wide, and mostly without secondary branching. Hyphae disarticulate into rectangular arthroconidia, (4–7) × (10–18) μm, often with some annellations at one or both ends, and they are intermingled with smaller conidia from lateral branches. Endoconidia, chlamydoconidia and rhizoids may be present (Fig. 276).

Fermentation:

2-Keto-D-gluconate	–	Growth at 37°C	v
Arbutin	–		

Co-Q: Not determined.

Mol% G + C: 42.2–44.3, 5 strains (T_m : de Hoog et al. 1986).

Origin of the strains studied: CBS 140.25, type strain of *Oospora gigas*, from fruit juice of *Arenga*, Smit; CBS 152.25, type strain of *Oidium suaveolens*, from water, Krzemecki; CBS 126.76, type strain of *Geotrichum rectangulatum*, from oily debris, Goto, Japan; CBS 127.76, type strain of *G. fici*, from fig (*Ficus* sp.) Goto, Japan; palm wine (1); mash of maize (1); from human pulmonary infections (2).

Type strain: CBS 152.25.

Comments: *Oidium suaveolens* is the oldest epithet available for this taxon, but the combination *Geotrichum suaveolens* had already been made for a species now known as *Moniliella suaveolens*. The well-known name *Geotrichum fragrans* can therefore be maintained. De Hoog et al. (1986) found that several strains of the species show a very low degree of DNA/DNA reassociation, which would point to taxonomic heterogeneity. Thus far no usable key features are available to distinguish these sibling taxa. The species is regularly found in nutrient-rich, liquid substrates, particularly in industrial waste water.

Fig. 276. *G. fragrans*, various CBS strains. MEYA, 22°C. Expanding hyphae with penicillate arthroconidia and conidia with annellated zones.

Fig. 277. *G. klebahnii*, various CBS strains. MEYA, 22°C. Expanding hyphae and arthroconidia.

65.8. *Geotrichum ingens* (van der Walt & van Kerken) de Hoog, M.Th. Smith & Guého (1997a)

See under teleomorph *Dipodascus ingens*: p. 188.

65.9. *Geotrichum klebahnii* (Stautz) Morenz (1964)

Synonyms:

Trichosporon klebahnii Stautz (1931)

Endomyces lactis (Fresenius) Windisch var. *klebahnii* (Stautz) Windisch (1951)

Trichosporon penicillatum do Carmo-Sousa (1965)

Geotrichum penicillatum (do Carmo-Sousa) von Arx (1977a)

Growth on 4% malt extract/0.5% yeast extract agar: After 10 days at 20–22°C, colonies are 25–30 mm in diameter, glassy-white, moist, somewhat raised and slightly veined, with margins that are fimbriate, and finally hairy. Expanding hyphae are septate every 40–80 µm, 3.5–5.0 µm in width, with slight differentiation of main and lateral branches. Hyphae locally disarticulate into cubic arthroconidia measuring (2.8–3.2) × (4.5–9.0) µm (Fig. 277).

Fermentation:

Glucose	+	Lactose	–
Galactose	w/–	Raffinose	–
Sucrose	–	Trehalose	n
Maltose	–		

Assimilation:

Glucose	+	<i>N</i> -Acetyl-D-glucosamine	–
Galactose	+	Methanol	n
L-Sorbose	+	Ethanol	+
Sucrose	–	Glycerol	+
Maltose	–	Erythritol	–
Cellobiose	–	Ribitol	v
Trehalose	–	Galactitol	–
Lactose	–	D-Mannitol	+
Melibiose	–	D-Glucitol	+
Raffinose	–	α-Methyl-D-glucoside	–
Melezitose	–	Salicin	–
Inulin	–	D-Gluconate	–
Soluble starch	–	DL-Lactate	+
D-Xylose	+	Succinate	+
L-Arabinose	–	Citrate	v
D-Arabinose	–	Inositol	–
D-Ribose	–	Hexadecane	n
L-Rhamnose	–	Nitrate	–
D-Glucosamine	–	Vitamin-free	+

Additional assimilation tests and other growth characteristics:

2-Keto-D-gluconate	–	Growth at 37°C	–
Arbutin	–		

Co-Q: Not determined.

Mol% G+C: 40.1–40.7, CBS 179.30, CBS 627.74 (BD: Guého et al. 1984).

Origin of the strains studied: CBS 179.30, from slime flux of yew (*Taxus baccata*), Stautz; CBS 627.74 (CBS 5586, ATCC 18019), type strain of *T. penicillatum*, from

slime flux of elm (*Ulmus* sp.), Phaff; from wood pulp (1); from sewage filter (1).

Type strain: CBS 179.30.

Comments: The occurrence of this species in slime flux of trees is striking. It is probably selected by high concentrations of sugars. It was also reported from corn pulp (Glanser and Ban 1983) and sugar cane bagasse (Pou et al. 1985). *G. klebahnii* is close to *G. clavatum*, but differs in growth with D-xylose. The ecological preferences of the two species are markedly different; *G. clavatum* is a human pathogen. An additional species that can be found in tree exudates is the *Geotrichum*

anamorph of *Dipodascus australiensis*. The latter species is non-fermentative and cannot grow without vitamins. *G. ludwigii* from oak slime flux has a much larger micromorphology.

65.10. *Geotrichum ludwigii* (E.C. Hansen) Fang, Cheng & Chu (1966)

See under teleomorph *Dipodascus magnusii*: p. 189.

65.11. *Geotrichum sericeum* (Stautz) de Hoog, M.Th. Smith & Guého (1986)

See under teleomorph *Dipodascus ovetensis*: p. 190.

66. *Kloeckera* Janke

M.Th. Smith

Diagnosis of the genus

Asexual reproduction is by bipolar budding in basipetal succession on a narrow base. Cells are apiculate, ovoidal to long-ovoidal or elongate. Pseudohyphae are absent, or if present, rarely well-developed. Ascospores are not produced.

Glucose is fermented. Nitrate is not assimilated. Inositol and pantothenate are required for growth. Acetic acid is not produced. Diazonium blue B reaction is negative.

The teleomorphic genus is *Hanseniaspora*.

Type species

Kloeckera apiculata (Reess emend. Klöcker) Janke

Species accepted

1. *Kloeckera africana* (Klöcker) Janke (1928): see *Hanseniaspora vineae*, p. 219
2. *Kloeckera apiculata* (Reess emend. Klöcker) Janke (1928): see *Hanseniaspora uwarum*, p. 217

66.6. *Kloeckera javanica* (Klöcker) Janke (1928)

See teleomorph *Hanseniaspora occidentalis* M.Th. Smith: p. 215.

66.7. *Kloeckera lindneri* (Klöcker) Janke (1928)**Synonym:**

Pseudosaccharomyces lindneri Klöcker (1912b)

Growth in glucose–yeast extract–peptone water:

After 2 days at 25°C, cells are apiculate, ovoidal or elongate, (2.0–4.5)×(4.0–9.5)µm, single or in pairs. Reproduction is by bipolar budding. Sediment is present. After one month a thin ring is formed.

Growth on glucose–yeast extract–peptone agar:

After one month the streak culture is white to cream-colored, and smooth and glossy; in cross section there is a raised center and a flat periphery.

Dalmou plate cultures on potato agar: Pseudomycelium is absent.

Fermentation:

Glucose	+	Lactose	–
Galactose	–	Raffinose	–
Sucrose	–	Trehalose	–
Maltose	–		

Assimilation:

Glucose	+	<i>N</i> -Acetyl-D-glucosamine	n
Galactose	–	Methanol	–
L-Sorbose	–	Ethanol	–
Sucrose	–	Glycerol	–
Maltose	–	Erythritol	–
Cellobiose	+	Ribitol	–
Trehalose	–	Galactitol	–
Lactose	–	D-Mannitol	–
Melibiose	–	D-Glucitol	–
Raffinose	–	α-Methyl-D-glucoside	–
Melezitose	–	Salicin	+
Inulin	–	D-Gluconate	v
Soluble starch	–	DL-Lactate	v
D-Xylose	–	Succinate	–
L-Arabinose	–	Citrate	–
D-Arabinose	–	Inositol	–
D-Ribose	–	Hexadecane	n
L-Rhamnose	–	Nitrate	–
D-Glucosamine	–	Vitamin-free	–

Additional assimilation tests and other growth characteristics:

2-Keto-D-gluconate	–	0.01% Cycloheximide	+
Starch formation	–	Growth at 34°C	–

Co-Q: Not determined.

Mol% G+C: Not determined.

Origin of the strain studied: CBS 285, soil, Java, Kufferath.

Type strain: CBS 285, isolated by Kufferath.

Comments: *Kloeckera lindneri* shows poor growth in the media used for growth tests. However, growth is stimulated by the addition of yeast autolyzate to the media.

Comments on the genus

In 1978, Meyer et al. correlated the six anamorphic *Kloeckera* species with six teleomorphic species in *Hanseniaspora* from comparisons of DNA relatedness. The status of *K. lindneri* was not settled by these authors since the type strain was not available during their study. However, from the physiology, this species does not appear to be a synonym of any of the known species of *Hanseniaspora*. This possibility is supported by the rDNA sequence data obtained by Boekhout et al. (1994) in a study on the phylogenetic relationships of *Hanseniaspora*, *Kloeckera* and other genera. These authors suggested that *K. lindneri* may represent an anamorph of a *Hanseniaspora* species closely related to *H. uwarum*, *H. guilliermondii* and *H. valbyensis*. Yamada et al. (1993) determined the phylogenetic relationships of species of the apiculate yeast genera *Wickerhamia* and *Kloeckera* on the basis of the partial sequences of 18S and 26S ribosomal RNAs. The single species *Wickerhamia fluorescens* was found to be phylogenetically separate from species of *Kloeckera* and *Hanseniaspora*.

67. *Lalaria* R.T. Moore

R.T. Moore

Introduction

The order Taphrinales is dimorphic: the teleomorphic phase is mycelial and obligately parasitic on a variety of plant hosts while the anamorphic phase is saprobic and yeastlike. The holomorphic biosystematics of these fungi – the development of biological species concepts for them – has been impeded by the lack of anamorph names for their yeast phases. Only three of the seven genera are available from major commercial culture collections: *Protomyces*, *Protomyopsis* and *Taphrina*. Most of the *Taphrina* species were isolated by Mix in the course of his many years of study of the genus. Mix (1954) examined 74 isolates, representing 26 species and 55 host forms for their ability to use 32 different carbon compounds. All isolates gave a common response to 12 compounds. All but the two isolates of *T. polystichi* used xylose and all but the isolates of *T. polystichi* and the isolate of *T. nana* used succinic acid. The isolates exhibited various responses to 18 other compounds. In an earlier paper, Mix (1953) examined the ability of these isolates to utilize nitrogen compounds and found that they could all utilize urea and asparagine. Little serious attention has been given subsequently to the systematic characterization of these yeast forms, and to providing them with standard descriptions. Despite their economic importance they have been largely ignored by plant pathology and although Mix (1935) said that the yeast-phase should be common on plant surfaces and probably in the soil, there is no mention of these species in this literature (e.g., do Carmo-Sousa 1969a, Last and Price 1969, Preece and Dickinson 1971, Phaff and Starmer 1987).

Moore (1990), recognizing that part of the problem was the lack of a name to identify the anamorph phase, proposed the name *Lalaria* as an *omnium gatherum* for all the form-species in the order. He recast Mix's data, originally set out in paragraph style, in tabular form. Despite the datedness and, by current standards, incompleteness of these data, they are still the only comprehensive information that we have on these forms. Consequently, the recognized species of *Lalaria* are, at present, all anamorphs of species of *Taphrina*. Although they are defined strictly on the basis of small differences on a limited number of physiological tests, they do parallel the respective teleomorphs, indicating that they probably are taxonomically distinct.

Diagnosis of the genus

Colonies are pinkish or sometimes yellowish due to carotenoid pigments; budding is holoblastic. The species are diazonium blue B and urease negative; species assimilate glucose, maltose, sucrose, trehalose, melezitose, inulin, urea and asparagine, but not lactose, L-rhamnose, erythritol, inositol, or ammonium acetate. They do not ferment glucose, form extracellular starch-like compounds and do not require thiamine. They have Co-Q 10, and a temperature maximum of 28°C, though many isolates grow poorly above about 20°C.

Type species

Lalaria populina R.T. Moore

Species accepted

1. *Lalaria americana* R.T. Moore (1990)
Teleomorph: *Taphrina americana* Mix
Host: *Betula fontinalis* Sargent
Origin: Mix (1954), no. 1 (CBS 331.55)
2. *Lalaria caerulescens* R.T. Moore (1990)
Teleomorph: *Taphrina caerulescens* (Montagne & Desmazières) Tulasne
Host: *Quercus alba* L.
Origin: Mix (1954), no. 5 (CBS 351.35)
3. *Lalaria carnea* R.T. Moore (1990)
Teleomorph: *Taphrina carnea* Johanson
Host: *Betula intermedia* Thomas
Origin: Mix (1954), no. 21 (CBS 332.55, MUCL 30956)
4. *Lalaria cerasi* R.T. Moore (1990)
Teleomorph: *Taphrina cerasi* (Fuckel) Sadebeck
Host: *Prunus avium* L.
Origin: Mix (1954), nos. 22, 23, 24 (CBS 275.28)

5. *Lalaria coccinea* R.T. Moore (1990)
Teleomorph: *Taphrina caerulescens* (Montagne & Desmazières) Tulasne
Host: *Quercus coccinea* Münch
Origin: Mix (1954), no. 7 (CBS 333.55)
6. *Lalaria communis* R.T. Moore (1990)
Teleomorph: *Taphrina communis* (Sadebeck) Giesenhag
Host: *Prunus americana* Marsh
Origin: Mix (1954), nos. 27, 28, 29 (CBS 352.35)
7. *Lalaria confusa* R.T. Moore (1990)
Teleomorph: *Taphrina confusa* (Atkinson) Giesenhag
Host: *Prunus virginiana* L.; *P. v.* var. *demissa* Torrey
Origin: Mix (1954), no. 39 (CBS 375.39)
8. *Lalaria dearnessii* R.T. Moore (1990)
Teleomorph: *Taphrina dearnessii* Jenkins
Host: *Acer rubrum* L.
Origin: Mix (1954), no. 40 (CBS 334.55)
9. *Lalaria deformans* R.T. Moore (1990)
Teleomorph: *Taphrina deformans* (Berkeley) Tulasne
Host: *Prunus communis* L.; *P. persica* L.
Origin: Mix (1954), nos. 41, 42 (CBS 356.35, MUCL 30957)
10. *Lalaria farlowii* R.T. Moore (1990)
Teleomorph: *Taphrina farlowii* Sadebeck
Host: *Prunus serotina* Ehrhart
Origin: Mix (1954), nos. 45, 46 (CBS 376.39)
11. *Lalaria flavorubra* R.T. Moore (1990)
Teleomorph: *Taphrina flavorubra* Ray
Host: *Prunus besseyi* Bailey
Origin: Mix (1954), nos. 47, 48 (CBS 377.39)
12. *Lalaria johansonii* R.T. Moore (1990)
Teleomorph: *Taphrina johansonii* Sadebeck
Host: *Populus tremuloides* Michaux
Origin: Mix (1954), nos. 49, 50 (CBS 378.39)
13. *Lalaria letifera* R.T. Moore (1990)
Teleomorph: *Taphrina letifera* (Peck) Saccardo
Host: *Acer spicatum* Lamarck
Origin: Mix (1954), no. 51 (CBS 335.55)
14. *Lalaria nana* R.T. Moore (1990)
Teleomorph: *Taphrina nana* Johanson
Host: *Betula nana* L.
Origin: Mix (1954), no. 52 (CBS 336.55)
15. *Lalaria polystichi* R.T. Moore (1990)
Teleomorph: *Taphrina polystichi* Mix
Host: *Polystichum acrostichoides* (Michaux) Schott
Origin: Mix (1954), nos. 53, 54 (CBS 379.39)
16. *Lalaria populi-salicis* R.T. Moore (1990)
Teleomorph: *Taphrina populi-salicis* Mix
Host: *Populus trichocarpa* Torrey & Gray
Origin: Mix (1954), no. 58 (CBS 419.54)
17. *Lalaria populina* R.T. Moore (1990)
Teleomorph: *Taphrina populina* Fries
Host: *Populus nigra* L.
Origin: Mix (1954), nos. 55, 56 (CBS 337.55, MUCL 30958)
18. *Lalaria pruni-subcordatae* R.T. Moore (1990)
Teleomorph: *Taphrina pruni-subcordatae* (Zeller) Mix
Host: *Prunus subcordata* Bentham
Origin: Mix (1954), no. 62 (CBS 381.39)

19. *Lalaria purpurascens* R.T. Moore (1990)
Teleomorph: *Taphrina purpurascens* Robinson
Host: *Rhus copallina* L.
Origin: Mix (1954), no. 63 (CBS 338.55)
20. *Lalaria robinsoniana* R.T. Moore (1990)
Teleomorph: *Taphrina robinsoniana* Giesenhag
Host: *Alnus rugosa* (Du Roi) Sprengel; *A. serrulata* (Aiton) Willdenow
Origin: Mix (1954), nos. 64, 67, 69 (CBS 382.39, CBS 383.39)
21. *Lalaria tosquinetii* R.T. Moore (1990)
Teleomorph: *Taphrina tosquinetii* (Westendorp) Tulasne
Host: *Alnus glutinosa* Gaertner
Origin: Mix (1954), nos. 74, 75 (CBS 276.28)
22. *Lalaria ulmi* R.T. Moore (1990)
Teleomorph: *Taphrina ulmi* (Fuckel) Johanson
Host: *Ulmus rubra* Muhlenberg
Origin: Mix (1954), nos. 77, 78 (CBS 420.54)
23. *Lalaria virginica* R.T. Moore (1990)
Teleomorph: *Taphrina virginica* Sadebeck
Host: *Ostrya virginiana* (Miller) K. Koch
Origin: Mix (1954), no. 79 (CBS 340.55)

Key to isolates

The following key is to all isolates studied by Mix (some of which have been recognized in *Lalaria*). This key points up the fact that several hosts have species complexes, particularly *Quercus* and *Betula*. The three isolates identified as *T. betulina* Rostrup (nos. 2–4) were originally separate species of *Taphrina*: respectively, *T. betulina* and *T. lapponica* Juel on *Betula intermedia* Thomas (one of which is CBS 417.54) and *T. turgida* on *B. pendula* Roth; the original classification is supported by the fact that they key out separately. The 16 isolates of *T. caerulescens* on *Quercus* (nos. 5–20) key out to 14 taxa. In the traditional practice of yeast taxonomy, each terminal entry might be considered a separate species. Only the two species for which cultures are available (*L. coccinea* and *L. caerulescens*) have been accepted in *Lalaria* (Moore 1990). This key has been constructed using Mix's (1954) data.

Key to the anamorphs of *Taphrina* and species of *Lalaria*: {Host} species and numbers are from Mix (1954). See Table 64.

Comments on the genus

67.1. The teleomorph phase

The order Taphrinales Gaumann comprises two families (see Kurtzman 1993a; p. 172):

- The Protomycetaceae (*Burenia* Reddy & Kramer, 2 spp.; *Protomyces* Unger, 10+ spp., *Protomycopsis* Magnus, 5 spp., *Taphridium* de Lagerheim & Juel, 2 spp., and *Volkartia* Maire, 1 sp.).
- The monotypic Taphrinaceae (*Taphrina* Fries, ~95 spp.).

Mixia osmundae (Nishida) Kramer, a fern parasite, was originally described in *Taphrina* before being given generic status in the Protomycetaceae (Kramer 1958) on the basis of the apparent similarity in spore formation and of the multinucleate condition of both the mycelium and the young fruiting structures; *T. higginsii* Mix, a similar parasite on a different species of *Osmunda*, was considered a synonym. *Mixia* was subsequently placed in its own family (Kramer 1987) because, unlike the rest of the Protomycetaceae, but like *Taphrina*, it formed a thin-walled sporocarp and the “asci” were subtended by empty stalk cells; Reddy and Kramer (1975) excluded it from the family and, in a dendrogram of possible phylogenetic relationships, placed it tentatively between *Volkartia* and the Mucorales. Nishida et al. (1995) have presented convincing evidence that the species is a basidiomycete: electron micrographs show ellipsoidal to fusiform sporogenous cells producing a number of stalk cells on their surface that generate spores blastically and not from within; consequently, the previously identified endospores (as ascospores and blastospores) are, in fact, formed externally. The 18S rRNA gene sequence also supports the basidiomycete interpretation.

The general life-cycle of the Protomycetaceae is shown in Fig. 278b. The mycelium is multinucleate, apparently diploid, and develops thick-walled, multinucleate ascogenous cells which either spread through the host tissue or form a continuous subepidermal layer (Reddy and Kramer 1975). Meiosis in the indurated cells, the asci, produces ascospores which initiate the saprobic, yeast haplophase; only diploid cells, resulting from cell and nuclear fusion, are capable of infection; host range is restricted to Umbelliferae and Compositae.

The only comprehensive monograph of *Taphrina* is that by Mix (1949). The approximately 95 species are classified entirely by teleomorphic characters: ascus morphology, location of the mycelium within the host tissue, histological effects on the host, and the host species. There are, however, many examples where morphological criteria overlap and host specificity is inconsistent. These fungi are all highly specialized plant parasites of limited

host range and are found naturally only on their respective host plants where they cause malformations of the tissues attacked, producing such disease symptoms as leaf curl, puckering, pockets, blisters, and witches’ broom. Ascospores are formed only in nature and bud readily, either within the ascus or after spore discharge. There is reason to believe (Mix 1935) that propagation by budding in the anamorphic phase may continue indefinitely, the cells surviving in this fashion on various plant surfaces and probably also in the soil.

Fig. 278. Generalized life cycles in (a) the Taphrinaceae and (b) the Protomycetaceae. The mycelial parasitic phase is outlined; see the text for a full explanation. Abbreviations: K, karyogamy; Mei, meiosis; Mit, mitosis; P, plasmogamy.

The general life-cycle of the Taphrinaceae is shown in Fig. 278a. The parasitic, more or less coenocytic, dikaryotic mycelium grows and branches, penetrating the various cells and tissues of the host. Hyphal strands eventually break up into binucleate ascogenous cells that are often incorrectly called chlamydospores because of their somatic origin. It should also be noted that this dikaryon is more comparable to fruitbody-less ascogenous hyphae than to typical basidiomycete dikaryotic mycelia (Blanz and Unseld 1987). Karyogamy occurs within each cell and about this time the cells begin to elongate. The diploid nucleus divides mitotically while this elongation is proceeding, one daughter nucleus remaining near the base of the cell while the other moves towards the growing tip. A septum forms between the two diploid nuclei, dividing the cell into a stalk cell – whose protoplast disintegrates and leaves it empty – and an upper, ascus cell that forms eight primary ascospores (see Kramer 1960). The asci form a palisade layer above the epidermis and it is their presence which gives the surface its waxy bloom. The ascospores, or their buds, are projected from the unitunicate asci which often open by a characteristic slit. Ascospores occasionally undergo yeastlike budding while still in the ascus. Budding usually starts, however, after

spore discharge, producing numerous uninucleate, thin-walled, secondary spores. During summer and autumn, some secondary spores form yeastlike colonies on the twigs of the host. These colonies overwinter in crevices of the bark or between bud scales. The spores germinate on the young leaves, infecting them as the buds open. Most species are homothallic but *T. epiphylla* Sadebeck, at least, is strictly heterothallic; a few species, e.g., *T. deformans* and *T. pruni* Tulasne, may behave as heterothallics but are usually homothallic (see Gäumann 1952). The single haploid nucleus divides once and the paired daughter nuclei then pass into the germ tube which, on penetration of the host, gives rise to the more or less coenocytic, dikaryotic mycelium.

There are three types of mycelial habit (Mix 1949): (1) intercellular forms (e.g., *T. deformans*) develop abundant mycelium between the interior cells of leaf, stem, or fruit and subsequently form a subcuticular layer of ascogenous cells; (2) subcuticular forms (e.g., *T. betulina*) in which the mycelium and ascogenous cells grow only beneath the cuticle; (3) wall-inhabiting forms (e.g., *T. laurencia* Mix) that live entirely within the outer epidermal wall of the host.

The Taphrinales are usually interpreted as simple ascomycetes and have, as a rule, been classified in the Saccharomycetes (Hemiascomycetes), which mainly comprise the ascus-forming yeasts. More recently, the Taphrinales and similar species, termed archiascomycetes, have been found to form a lineage distinct from that of euascomycetes and hemiascomycetes (Nishida and Sugiyama 1994). Historically, some authors, however, have suggested that the Taphrinales are related to the basidiomycetes. Savile (1955, 1968) asserted that ancient parasitic fungi developed on primitive plants, e.g., ferns, and he therefore considered *Taphrina* to be close to primitive rusts, suggesting that they had a common ancestor, which he referred to as *Prototaphrina* (nom. nud.). Von Arx in 1967 (see von Arx et al. 1982) classified the Taphrinales, Exobasidiales, and Ustilaginales, all of which are dimorphic and have yeastlike states, with the Saccharomycetales (Endomycetales), later (von Arx 1979b, p. 567) he stated that he "... would prefer to classify the Taphrinales next to the Sporobolomycetales and the Ustilaginales in the Ustomycetes." Raper (1968) found Savile's (1968) hypothesis attractive, saying that various characteristics of the basidiomycetes could be rationalized from such an ancestor far more easily than from more highly differentiated ascomycetous forms. Syrop and Beckett (1972) tended to agree with Savile's (1955) interpretation that *Taphrina* was an "ancient organism" because the ascospore-delimiting membranes appeared to arise individually from the plasmalemma rather than by the invagination of an ascus sac; but, in as much as the spindle pole bodies were not preserved in potassium permanganate prepared material, it is not possible to critically compare *Taphrina* ascospore formation with, respectively, holocarpic and ascocarpic

ascomycetes (see Moore 1987b). Prillinger et al. (1990c) state that the "Molecular and biochemical data (cell wall carbohydrate, 5S rRNA, ubiquinone (Q-9, Q-10), urease activity) position the Schizosaccharomycetaceae, the Protomycetaceae, and Taphrinales in the phylogenetic vicinity of the Basidiomycetes (e.g., genera of the *Microbotryum* [*Ustilago*]-type) and of the fruit-body forming Ascomycetes (e.g., *Ophiostoma* species)." Donk (1973b), while recognizing that some features of *Taphrina* were more common to the basidiomycetes, nevertheless rejected Savile's (1968) interpretation because the spores were produced endogenously.

The other genera in the order (see Reddy and Kramer 1975) are poorly understood and only a few of their species are in culture.

67.2. The anamorph phase

Lalaria, as presently circumscribed (Moore 1990), is the ordinal repository for the anamorphs of the Taphrinales Gäumann and the Protomycetaceae Gray. Although there are some 115 species in the order, only those 23 species included in the genus have available cultures, have been systematically studied, and conform to the generic description. There is a critical need for new cultures of all species, particularly those not presently in culture; these should be initiated from single ascospore isolates. I anticipate that future studies of these yeasts will find general characters suitable for establishing additional genera paralleling the teleomorphs. *Protomyces inundatus* Dangeard (Valadon et al. 1962), for example, has been found by Trinci and Gull (1973) to be sensitive to griseofulvin and by Ahmad (1973) to require thiamine for growth and to have the ability to assimilate ammonium acetate.

There have been a number of physiological and molecular biological studies of these yeasts, some of which present conflicting evidence as to whether the isolates are more like ascomycetes or basidiomycetes. Much of this equivocal data, undoubtedly, is in the nature of the fungi themselves but some of it, at least, is a consequence of accidentally isolating basidiomycetous yeasts from host substrates and erroneously labeling them as taphrinalean anamorphs. A brief synopsis of the available data follows, in alphabetical order, under the following headings: 1. Assimilation and morphology, 2. Auxins and cytokinins, 3. Budding, 4. Buffer-soluble proteins, 5. Cell walls, 6. Fatty acid ratios, 7. Mitosis morphology, 8. Pigmentation, 9. Polyols, 10. 5S rRNA nucleotide sequences, 11. Sterols, 12. Ubiquinones, and 13. Urease.

Assimilation and morphology: Verona and Rambelli (1962a,b) studied 21 isolates of *Taphrina* from the CBS Collection at Baarn, most of which were deposited by Mix. All of these isolates were non-fermentative and were able to assimilate glucose but not lactose. Most of the isolates were also able to assimilate xylose, maltose,

or mannitol. Among the isolates they identified one, which was labeled *T. californica* Mix, as *Cryptococcus laurentii*. Von Arx et al. (1982) reported that the *T. californica* isolate (CBS 374.39) had morphological characters that were slightly different from other *Taphrina* isolates; see the subsection on sterols. All of the other 19 isolates formed starch-like compounds, grew slowly, and would not grow at temperatures above 28°C; most of these isolates could assimilate nitrate. Verona and Rambelli (1962c) reported another *Taphrina* isolate to be a *Candida* sp. They proposed *Saprotaphrina* nom. nud. for the anamorphs of *Taphrina* (Verona and Rambelli 1962a). Unfortunately, they did not designate a type species and the isolates chosen were not identified by their CBS numbers.

Auxins and cytokinins: Kern and Naef-Roth (1975) examined ten species and found that all synthesized indole-3-acetic acid (IAA) and indole-lactic-acid (ILA) from tryptophan; traces of tryptophol were formed only by *T. betulae* and *T. betulina*. All culture filtrates lacked tryptamin and were high in cytokinin activity due to the presence of zeatin, IPA, and a third, unidentified substance.

Budding: Von Arx and Weijman (1979) comment, without documentation, that basipetal, enteroblastic budding was observed in *T. californica*, *T. deformans*, *T. polystichi* and *Protomyces macrosporus* as well as *Symbiotaphrina buchneri* and *S. kochii* (see section 67.3). Von Arx et al. (1982) interpreted budding in *Taphrina* to be rather similar to that of the apiculate yeasts and concluded that the genera *Taphrina*, *Mixia*, and *Protomyces* were correctly classified as hemiascomycetes. Electron micrographs of *T. californica* (CBS 374.39) bud scars by Heath et al. (1982) clearly show the flared multiple wall layers characteristic of basidiomycete budding.

Buffer-soluble proteins: Snider and Kramer (1974a,b) analysed 31 isolates of *Taphrina* by polyacrylamide gel electrophoresis (PAGE). They found that no one band occurred in all samples, although some fractions appeared to be characteristic of the genus in both mobility and concentration of the proteins. When isolates were grouped on the basis of host families, seven of the eight host families had percentages of mean homology. Only one family, the Polypodiaceae, was lower than the norm. When isolates were grouped according to the ascus morphologies, one out of six, which contained the species of family Polypodiaceae, was lower than the norm. These findings tend to support the concepts of conventional taxonomy, except possibly for the *Taphrina* species grouped in the host family Polypodiaceae.

Cell walls: Petit and Schneider (1983) analysed a strain of *T. deformans* that they isolated from spores of a single ascus on a peach leaf using a micromanipulator. Their results showed that there was a heteropolysaccharide fraction that, in four-day-old cultures, contained 54% mannose,

31% galactose, and 15% rhamnose; that chitin, if present, formed no more than 2% of the total wall composition; and that glucosamine was the only amino sugar. They stated that the biochemical profile they obtained was most like that of *Schizosaccharomyces*.

Fatty acid ratios: Watson and Kramer (1974) analysed 19 isolates of *Taphrina* grouped according to host family and host genera. They found no significant patterns indicative of phylogenetic relationships. *Taphrina* does, however, have relatively slow growth rates and the fatty acid ratios may change during maturation.

Mitosis morphology: The potential of mitotic analysis to help explain relationships among hypothetically primitive basidiomycetes was demonstrated by Heath and Heath (1976) who showed that the cowpea rust has a mitotic apparatus that shares characteristics with those of some ascomycetes. Heath et al. (1982) similarly studied isolates identified as from five species of *Taphrina*. They concluded that those of three species – *T. cerasi*, *T. faulliana* Mix, and *T. polystichi* – were typical ascomycetes. Each of two isolates of the fourth species, *T. deformans*, was apparently a mixed culture because, although ascomycete-type mitosis occurred in cells of both isolates, one isolate also had cells with another kind of ascomycete mitotic system characterized by elaborate and unique nucleus-associated organelles, whereas the second isolate had, in addition, cells that contained a basidiomycetous mitotic apparatus. The isolate from the fifth species, *T. californica*, contained a typical basidiomycetous mitotic system as well as basidiomycete-type bud scars; both of these traits indicate that the isolate (CBS 374.39) is misidentified. The detailed differences that they found among the mitotic systems of the true *Taphrina* isolates suggests that the genus as a whole may be polyphyletic but that it is undoubtedly ascomycetous. For three of the isolates, they found a previously unreported pattern of spindle formation otherwise known only in the red algae, a finding that could be used to support the hypothesis of a red algal ancestry for the ascomycetes (see Moore 1989a). Heath et al. (1987) extended the previous study showing that the isolate of *T. maculans* Butler had the basidiomycete pattern whereas three species of *Protomyces* (*P. inouyci* P. Hennings, *P. lactucae-debilis* Sawada, and *P. pachydermus* Thuem.) collectively had a mitotic apparatus that was clearly similar to the typical ascomycete type.

Pigmentation: Tubaki (1957) made ethanol extracts of isolates of *Taphrina* and *Protomyces* and examined them spectrophotometrically; his results showed that "... members of the two genera resemble each other closely as to pigmentation. Though colonies of these fungi are pinkish in color, none of them produced the carotenoid pigments which are characteristic of *Rhodotorula*." Valadon (1964) using improved techniques found, however, that isolates of *Protomyces* did contain carotenoids whereas those of *Taphrina* did not, and he

suggested that pigment characteristics of certain fungi may be an aid in elucidating their taxonomic affinities. Van Eijk and Roeymans (1982) screened isolates of *Taphrina* and *Protomyces* for the presence of carotenoid pigments and the sterols ergosterol and brassicasterol. They concluded that the two genera cannot be separated on the basis of the presence or absence of carotenoids. All the *Taphrina* isolates were found to produce carotenoids though in a lower concentration than those of *Protomyces*.

Polyols: Rast's group has extensively investigated these acyclic sugar alcohols. On the basis of their studies, which included species of *Taphrina*, they recommended that the Endomycetales be assigned a rank adequate to its distinction (Rast and Pfyffer 1989). They also reported (Pfyffer et al. 1990) that *Taphrina*, in accumulating mannitol, behaves perfectly as a euascomycete (all of which are the P₂-type) and stated: "The P₂-type of *Taphrina* thus supports the hypotheses that the Taphrinales are among the oldest true Ascomycetes, ... and, in possessing the largest combination of common characteristics, befit also a likely ancestor of the Basidiomycetes ...".

5S rRNA nucleotide sequences: Walker and Doolittle (1982) showed that sequences in the smut fungi have uridine in the 107 position but that this position is vacant in other Basidiomycota. Walker and Doolittle (1983) subsequently identified five clusters. Clusters 1 and 2 had a type A molecule with a "U" in the 107 position while clusters 3–5 had the type B molecule with an empty 107 position. Gottschalk and Blanz (1985) produced a dendrogram showing the relationships between the basidiomycetous fungi based on the 5S rRNA sequences. They stated that the 5S rRNA from *T. deformans* corresponded best with those sequences found in the basidiomycetes and placed it on its own next to Cluster 1 which contains a number of smut-like species (see Moore 1988a); but it was also starred to indicate that it corresponded "with the type A/type B bifurcation only in part." In an addendum at the end of the paper they cited a recent paper by Walker (1985a) which contained an analysis of *Protomyces inundatus* that showed it had 5S rRNA very close to that of *T. deformans*. In a subsequent paper (Blanz and Gottschalk 1986) the diagram appeared without *T. deformans*, but it is reinstated by Blanz and Unsel (1987). They also reported a dichotomy that has been found in 28S rRNA: an insertion of 27 nucleotides that occurs between positions 603 and 604 in *Exobasidium vaccinii* (Fuckel) Woronin, *Rhodospidium toruloides*, *Septobasidium cretianum* Bresadola, and *Ustilago hordei* (Persoon:Persoon) de Lagerheim, but that is absent from *Saccharomyces carlsbergensis*, *Schizosaccharomyces pombe*, *T. deformans*, and *T. vestergrenii* Gies.

Sterols: Van Eijk and Roeymans (1982) screened isolates of *Taphrina* and *Protomyces* for the presence of ergosterol and brassicasterol. They found that 30 strains (24 spp.) of *Taphrina* produced brassicasterol as the principal sterol,

whereas in four isolates (4 spp.), no brassicasterol could be detected (*T. californica*, *T. cerasi*, *T. farlowii* and *T. maculans*). In these latter isolates ergosterol was found to be the major component, while it was missing or only slightly present in the remaining *Taphrina* species. These authors concluded that there was no reason to doubt the identification of the four *Taphrina* isolates which did not form brassicasterol (but see the subsections on budding and on mitosis morphology). The effects of sterol inhibitors on *T. deformans* have been reported by Weete et al. (1985) and Sancholle et al. (1988).

Ubiquinones: The ubiquinone Q-10 system, otherwise generally restricted to basidiomycete yeasts, has been reported from isolates of *Protomyces inouyei*, *P. lactucae-debilis*, *P. pachydermus*, *T. caerulescens*, *T. californica*, *T. carnea*, *T. deformans*, *T. maculans*, *T. populina*, *T. tormentillae* Rostrop, and *T. wiesneri* (Rathay) Mix (Yamada et al. 1983, 1987b, Sugiyama et al. 1985, Moore and Flinn 1991).

Urease: Moore and Flinn (1991) reported positive results for *T. californica*, *T. maculans*, *T. tormentillae*, *Symbiotaphrina buchneri*, and *S. kochii* (weak) and negative results for *Lalaria carnea*, *L. deformans*, and *L. populina*.

67.3. *Saitoella*, *Neolecta* and *Symbiotaphrina*

The genus *Saitoella* (Goto et al. 1987a, Sugiyama et al. 1993) is represented by the single species *S. complicata*, an anamorph species that was described to accommodate two isolates of Himalayan soil yeasts that had been identified as *Rhodotorula glutinis*. Its basidiomycetous characters include enteroblastic budding (confirmed by electron micrographs), Co-Q 10, colonies that are yellow orange because of carotenoid pigments, and a positive urease reaction. The authors classified it in the Cryptococcaceae but considered it to be ascomycetous because they found it to be DBB negative and to lack xylose in the cell walls. They also said that they believed the genus had a probable close relationship with the Taphrinales because of the colony pigmentation and the cell wall biochemistry. Nishida and Sugiyama (1994), using 18S rRNA, found *Saitoella* to group with *Protomyces*, *Schizosaccharomyces* and *Taphrina*. *Saitoella* differs from *Lalaria* in not forming starch-like compounds, being urease positive, and in having enteroblastic budding.

The genus *Symbiotaphrina* Khlwein & Jurzitza ex Gams & von Arx (1980) has been attributed to the Taphrinales because it only "... differs from *Taphrina* [anamorphs] by its symbiotic mode of life." There are two species, both of which occur in intestinal mycetomata of Anobiid beetles (Jurzitza 1979): the type, *S. buchneri* Grabner ex Gams & von Arx from *Stegobium paniceum* (L.) Jacobson (= *Sitodrepa panicea* (L.) Leconte) and *S. kochii* Jurzitza ex Gams & von Arx from *Lasioderma serricorne* F. The extensive studies of endosymbiosis (Buchner 1965) show the insect hosts to be

dependent on the yeasts for essential growth factors and to have evolved very sophisticated behavior patterns to assure the generational transfer of the yeasts. Both species of *Symbiotaphrina* are exceptional in their inability to assimilate urea (Kühlwein and Jurzitza 1961, Jurzitza 1964, Bismanis 1976) and they further differ generically from the species of *Lalaria* in being able to assimilate erythritol and L-rhamnose (but see Bismanis 1976), and in lacking any known teleomorph. Noda and Kodama (1996), using small-subunit rRNA, found the two species to be distinct from each other and to form a distinct line close

to the discomycetes. There are also yeastlike symbiotes in the fat bodies of three genera of rice planthoppers; Noda et al. (1995), using 18S rRNA, found these fungi to be monophyletic and related to the pyrenomycetes.

The teleomorph genus *Neolecta* (Landvik 1996), on the basis of rDNA analyses, is believed to be close to the basal ascomycetes; it clusters with the Schizosaccharomycetales, Taphrinales (Taphrinaceae and Protomycetaceae), and Pneumocystidales and with these is thought to constitute a sister group to the Saccharomycetales and to all other ascomatous ascomycetes.

68. *Myxozyma* van der Walt, Weijman & von Arx

C.P. Kurtzman

Diagnosis of the genus

Vegetative reproduction is by multilateral budding on a narrow base. Cells are spheroidal or ellipsoidal. Rudimentary pseudohyphae may be present but true hyphae are not formed.

Sugars are not fermented. Nitrate is not assimilated. Cultures are often quite mucoid. Extracellular starch-like compounds are produced. Diazonium blue B reaction is negative.

Type species

Myxozyma melibiosi (Shifrine & Phaff) van der Walt, Weijman & von Arx

Species accepted

1. *Myxozyma geophila* van der Walt, Y. Yamada & Nakase (1987)
2. *Myxozyma kluyveri* van der Walt, Spencer-Martins & Y. Yamada (1989)
3. *Myxozyma lipomycooides* van der Walt, Y. Yamada & Nakase (1987)
4. *Myxozyma melibiosi* (Shifrine & Phaff) van der Walt, Weijman & von Arx (1981)
5. *Myxozyma monticola* Pretorius & Spaaij (1993)
6. *Myxozyma mucilagina* (Phaff, Starmer, Miranda & M.W. Miller) van der Walt, Weijman & von Arx (1981)
7. *Myxozyma udenii* Spaaij, Weber, Oberwinkler & van der Walt (1990)
8. *Myxozyma vanderwaltii* Spaaij, Weber & M.Th. Smith (1993)

Key to species

Systematic discussion of the species

68.1. *Myxozyma geophila* van der Walt, Y. Yamada & Nakase (van der Walt et al. 1987c)

Growth on 5% malt extract agar: After 3 days at 25°C, the cells are spheroidal to ovoidal, (2.2–5.1) × (2.4–5.6) µm, and single or in pairs. Growth is mucoid, glistening and tannish-white in color.

Growth on the surface of assimilation media: Pellicles are not formed.

Dalmau plate culture on morphology agar: After 7 days at 25°C, growth under the coverglass is devoid of pseudohyphae and true hyphae. A few outgrowths of undifferentiated cells are occasionally seen. Aerobic growth is mucoid, glistening, with entire margins, and tannish-white in color. A faint acidic, musky odor is present.

Fermentation: absent.

Assimilation:

Glucose	+	<i>N</i> -Acetyl-D-glucosamine	–
Galactose	+	Methanol	–
L-Sorbose	+	Ethanol	+
Sucrose	+/w	Glycerol	+
Maltose	–	Erythritol	–

5-Keto-D-gluconate	+	Gelatin liquefaction	+
Saccharate	–	Growth at 37°C	–
10% NaCl/5% glucose	–		

Co-Q: 8 (van der Walt et al. 1987c).

Mol% G+C: 46.0, 46.8, CBS 7219, CBS 7037, respectively (T_m : van der Walt et al. 1987c).

Origin of the strains studied: CBS 7219 (NRRL Y-17252), CBS 7037 (NRRL Y-17246), soil, Transvaal, South Africa.

Type strain: CBS 7219.

Comments: Results from the present study are in agreement with the original description of this species (van der Walt et al. 1987c), except that sucrose assimilation was found to be weak or positive rather than negative.

68.2. *Myxozyma kluyveri* van der Walt, Spencer-Martins & Y. Yamada (van der Walt et al. 1989e)

Growth on 5% malt extract agar: After 3 days at

Fig. 279. *M. kluyveri*, CBS 7332. Budding cells after 3 days on 5% malt extract agar at 25°C. Bar = 5 µm.

25°C, the cells are spheroidal to ovoidal, (2.0–4.1) × (2.1–5.1) µm, and single or in pairs (Fig. 279). Growth is mucoid, glistening and tannish-white in color.

Growth on the surface of assimilation media: Pellicles are not formed.

Dalmau plate culture on morphology agar: After 7 days at 25°C, neither pseudohyphae nor true hyphae are formed under the coverglass. Aerobic growth is mucoid, glistening, with an entire margin, and tannish-white in color. There is a faint acidic, musky odor.

Fermentation: absent.

Assimilation:

Glucose	+	<i>N</i> -Acetyl-D-glucosamine	–
Galactose	+	Methanol	–
L-Sorbose	+	Ethanol	s
Sucrose	+	Glycerol	+
Maltose	–	Erythritol	–

2-Keto-D-gluconate	+	Starch formation	+/w
5-Keto-D-gluconate	+	Gelatin liquefaction	–
Saccharate	–	Growth at 37°C	–
10% NaCl/5% glucose	–		

Co-Q: 8 (van der Walt et al. 1987c).

Mol% G+C: 39.5, CBS 7332 (T_m : van der Walt et al. 1989e).

Origin of the strains studied: CBS 7332 (NRRL Y-17277), CBS 7405 (NRRL Y-17359), soil, Transvaal, South Africa.

Type strain: CBS 7332.

Comments: Results from the present study are in generally good agreement with the original description of this species (van der Walt et al. 1989e).

68.3. *Myxozyma lipomycooides* van der Walt, Y. Yamada & Nakase (1987c)

Growth on 5% malt extract agar: After 3 days at 25°C, the cells are spheroidal to ovoidal, (2.1–6.0)×(2.5–6.0)µm, and single or in pairs. Growth is mucoid, glistening and tannish-white in color.

Growth on the surface of assimilation media: Pellicles are not formed.

Dalmau plate culture on morphology agar: After 7 days at 25°C, neither pseudohyphae nor true hyphae are formed under the coverglass. Aerobic growth is mucoid, glistening, and with entire to scalloped margins. The growth is tannish-white in color. A faintly acid, “metallic” odor is present.

Fermentation: absent.

Assimilation:

Glucose	+	<i>N</i> -Acetyl-D-glucosamine	–
Galactose	+	Methanol	–
L-Sorbose	+	Ethanol	+
Sucrose	–	Glycerol	+
Maltose	–	Erythritol	–

L-Arabinose	+	Citrate	s
D-Arabinose	s	Inositol	–
D-Ribose	s	Hexadecane	–
L-Rhamnose	+	Nitrate	–
D-Glucosamine	–	Vitamin-free	–

Additional assimilation tests and other growth characteristics:

2-Keto-D-gluconate	+	Starch formation	w
5-Keto-D-gluconate	–	Gelatin liquefaction	–
Saccharate	–	Growth at 37°C	–
10% NaCl/5% glucose	–		

Co-Q: 9, CBS 7038 (van der Walt et al. 1987c).

Mol% G+C: 40.9, CBS 7038 (*T_m*: van der Walt et al. 1987c).

Origin of the strain studied: CBS 7038 (NRRL Y-17253), from a tree-inhabiting lichen, Transvaal, South Africa.

Type strain: CBS 7038.

Comments: Several differences in assimilation of carbon compounds were found between the present study and the original description (van der Walt et al. 1987c). In the present study, D-mannitol was not assimilated, whereas growth occurred with D-ribose, cellobiose and citrate.

68.4. *Myxozyma melibiosi* (Shifrine & Phaff) van der Walt, Weijman & von Arx (1981)

Synonyms:

Torulopsis melibiosum Shifrine & Phaff (1956)

Paratorulopsis melibiosi (Shifrine & Phaff) Novák & Zsolt (1961)

Cryptococcus melibiosum (Shifrine & Phaff) Phaff & Fell (1970)

Candida melibiosophila Golubev (1981)

Growth on 5% malt extract agar: After 3 days at 25°C, the cells are spheroidal to ellipsoidal, (2.2–6.9)×(2.7–6.9)µm, and single, in pairs, or occasionally in small clusters (Fig. 280). Growth is mucoid, glistening and tannish-white in color.

Fig. 280. *M. melibiosi*, CBS 2102. Budding cells, after 3 days on 5% malt extract agar at 25°C. Bar = 5 µm.

Growth on the surface of assimilation media: Pellicles are not formed.

Dalmau plate culture on morphology agar: After 7 days at 25°C, neither pseudohyphae nor true hyphae are formed under the coverglass. Aerobic growth is mucoid, glistening, with entire to scalloped margins, and a tannish-white color. A faintly acidic odor with a trace of esters is present.

Fermentation: absent.

Assimilation:

Glucose	+	<i>N</i> -Acetyl-D-glucosamine	–
Galactose	+	Methanol	–
L-Sorbose	v	Ethanol	+
Sucrose	–	Glycerol	+

Co-Q: 8, CBS 2102 (Yamada 1986a).

Mol% G + C: 50.3, CBS 2102 (T_m : van der Walt et al. 1987c).

Origin of the strains studied: CBS 2102 (NRRL Y-11781), CBS 2667 (NRRL Y-17360), both from the beetle *Dendroctonus monticolae* in ponderosa pine (*Pinus ponderosa*), California, U.S.A.

Type strain: CBS 2102.

68.5. *Myxozyma monticola* Pretorius & Spaaij (Pretorius et al. 1993)

Growth on 5% malt extract agar: After 3 days at 25°C, the cells are spheroidal to ovoidal, (2.0–5.0) × (2.5–5.0) μm, and single or in pairs. Growth is mucoid, glistening and light tan in color.

Growth on the surface of assimilation media: Pellicles are not formed.

Dalmu plate culture on morphology agar: After 7 days at 25°C, neither pseudohyphae nor true hyphae are formed under the coverglass. Aerobic growth is glistening, mucoid, with entire colony margins, and tannish-white in color. A faintly acidic odor is present.

Fermentation: absent.

Co-Q: 8 (Pretorius et al. 1993).

Mol% G + C: 45.2 (T_m : Pretorius et al. 1993).

Origin of the strains studied: CBS 7790 (NRRL Y-17725), from flux of an oak (*Quercus* sp.), South Africa; CBS 7806 (NRRL Y-17726), soil, South Africa.

Type strain: CBS 7806.

Comments: Results from the present study are in generally good agreement with the original description (Pretorius et al. 1993). Exceptions are growth on cellobiose, negative in the present study, and 5-keto-D-gluconate, positive in the present study.

68.6. *Myxozyma mucilagina* (Phaff, Starmer, Miranda & M.W. Miller) van der Walt, Weijman & von Arx (1981)**Synonym:**

Candida mucilagina Phaff, Starmer, Miranda & M.W. Miller (1980)

Growth on 5% malt extract agar: After 3 days at 25°C, the cells are spheroidal to ellipsoidal, (1.9–6.8) × (2.1–6.8) μm, and single, in pairs, or occasionally in clusters (Fig. 281). Growth is mucoid, glistening and tannish-white in color.

Growth on the surface of assimilation media: Pellicles are not formed.

Dalmu plate culture on morphology agar: After 7 days at 25°C, neither hyphae nor pseudohyphae are formed under the coverglass. Aerobic growth is mucoid, glistening, with entire colony margins, and tannish-white in color. A faintly acidic odor is present.

Fermentation: absent.

Co-Q: 8 (Spaaij et al. 1990).

Mol% G + C: 49.2, CBS 7439 (T_m : Spaaij et al. 1990).

Origin of the strain studied: CBS 7439 (NRRL Y-17387), from soil around the roots of a mango tree (*Mangifera indica*), Miami, Florida, U.S.A.

Type strain: CBS 7439.

Comments: Results from the present study are in agreement with those of the original description (Spaaij et al. 1990).

68.8. *Myxozyma vanderwaltii* Spaaij, Weber & M.Th. Smith (1993b)

Growth on 5% malt extract agar: After 3 days at 25°C, the cells are spheroidal to ovoidal, (3.5–6.5) × (4.0–6.5) µm, and single or in pairs. Growth is mucoid, glistening and light tan in color.

Growth on the surface of assimilation media: Pellicles are not formed.

Dalmat plate culture on morphology agar: After 7 days at 25°C, neither hyphae nor pseudohyphae are evident under the coverglass. Aerobic growth is mucoid, glistening, with colony margins entire, and tannish-white in color. A faintly acidic, buttery odor is present.

Fermentation: absent.

Assimilation:

Glucose	+	<i>N</i> -Acetyl-D-glucosamine	–

Co-Q: 8 (Spaaij et al. 1993b).

Mol% G + C: 44.8 (T_m : Spaaij et al. 1993b).

Origin of the strains studied: CBS 7793 (NRRL Y-17727), from a flower of *Protea repens* (L.) L., South Africa; CBS 7794 (NRRL Y-17728), from the flux of an oak (*Quercus* sp.), South Africa.

Representative strain: CBS 7793, a living ex-type strain is not available.

Comments: Results from the present study are in generally good agreement with the original description

(Spaaij et al. 1993b). Growth reactions on 2-keto-D-gluconate and 5-keto-D-gluconate were exceptions and found to be positive in the present study.

Comments on the genus

The genus *Myxozyma* was described by van der Walt et al. (1981) for anamorphic ascomycetous yeasts with physiological and cultural properties similar to *Lipomyces*, i.e., formation of extracellular starch-like compounds and growth on imidazol and imidazol-4-carboxylic acid as sole sources of nitrogen. The proposed close relatedness of *Myxozyma* and *Lipomyces* was confirmed by Kurtzman and Liu (1990) from analysis of partial sequences of small and large subunit rRNAs. However, with the exception of *M. kluyveri*, which clustered with *Lipomyces* species, the two genera appear as closely related but distinct groups. The rRNA comparisons indicated that the five species (*M. geophila*, *M. kluyveri*, *M. lipomycoides*, *M. melibiosi* and *M. mucilagina*) included in the study were genetically isolated from one another as proposed by Yamazaki and Goto (1985) and Yamada and Aizawa (1987) from analysis

of isoenzyme mobilities. In addition to the preceding, various physiological and electrokaryotypic studies of the Lipomycetaceae have been reported by Botha and Kock (1993), Cottrell and Kock (1989, 1990), Kock et al. (1992), van der Walt (1992) and van der Walt et al. (1990a).

Validly described species not examined because of unavailability of living cultures: The following three species of *Myxozyma* were validly described by virtue of deposit of dried, dead holotypes in herbaria, but the authors, in contradiction to the intent of the Botanical Code (Greuter et al. 1994), did not distribute the living cultures characterized in their publications, thus preventing verification of physiological and genetic properties:

- *Myxozyma neotropica* Spaaij & Weber (Spaaij et al. 1992b);
- *Myxozyma nipponensis* Spaaij & Weber (Spaaij et al. 1993a);
- *Myxozyma sirexii* Spaaij & Weber (Spaaij et al. 1992a).

69. *Oosporidium* Stautz

M.Th. Smith

Diagnosis of the genus

Vegetative reproduction is by multilateral budding on a broad base combined with septation. Cells vary in shape and usually remain attached to each other, forming long chains. True septa are sometimes present and independent from the broad base budding. Arthrospores are absent. Asexual endospores are formed by protoplasmic cleavage.

Sexual reproduction absent.

Fermentation is absent. Nitrate is assimilated. Pink or orange-yellow pigments of a non-carotenoid nature are produced. Diazonium blue B reaction is negative.

Type species

Oosporidium margaritifera Stautz

Species accepted

1. *Oosporidium margaritifera* Stautz (1931)

Systematic discussion of the species

69.1. *Oosporidium margaritifera* Stautz (1931)

Synonym:

Trichosporon margaritifera (Stautz) Buchwald (1939)

Growth in glucose–yeast extract–peptone water:

After 3 days at 25°C, there is no visible growth. After one week, a granular or flocculent sediment is formed. Cells are globose and ovoidal or elongate, (5.0–12.0) × (6.0–12.5) μm. Vegetative reproduction is multilateral, usually by budding on a broad base combined with septation. Cells usually remain attached to each other and form long branched chains (Fig. 282). After one month a sediment is present.

Growth on glucose–yeast extract–peptone agar:

After one month at 25°C, the streak culture is light pink to light orange, dull, rugose, raised, and with a fragile surface.

Dalmat plate culture on corn meal agar:

Pseudomycelium is present. It consists of branched chains of ovoid, globose or elongate cells. At the periphery of the colony, cells tend to become progressively more elongated (Fig. 283). True septa are sometimes formed.

Formation of asexual spores: Asexual endospores are formed by protoplasmic cleavage (Fig. 284). Cells are of variable size and shape and contain one to ten endospores

Fig. 282. *O. margaritifera*, CBS 2531. Budding cells in glucose–yeast extract–peptone water after 1 week at 25°C. Bar = 10 μm.

Fig. 283. *O. margaritifera*, CBS 2531. Filaments in Dalmat plate culture on corn meal agar after 10 days at 25°C. Bar = 10 μm.

of various sizes that are globose or ellipsoidal in shape. Germination of endospores often starts inside the parent cell. Endospores were observed on YM and Gorodkova agar slants and slide cultures after 4–6 weeks at 18–20°C and in slide cultures on corn meal and potato–dextrose agars. The slants had been inoculated with cultures grown in 15% liquid malt extract for 5–6 days at 25°C on a shaker (do Carmo-Sousa 1970b).

Fermentation: absent.

Additional assimilation tests and other growth characteristics:

50% Glucose –
Maximum growth temperature 32–34°C.

Co-Q: Not determined.

Mol% G+C: Not determined.

Origin of the strains studied: CBS 2531, slime flux,

Stautz; CBS 6177, slime flux of elm tree, California, U.S.A., do Carmo-Sousa.

Type strain: CBS 2531, isolated by Stautz.

Fig. 284. *O. margaritifera*, CBS 2531. Endospores on YM agar after 5 weeks at 25°C. Bar = 10 μ m.

Comments: Strains of this species do not grow in the liquid media used for growth tests. Assimilation of carbon compounds was tested on agar slants of Yeast Nitrogen Base. Assimilation of nitrate was tested on agar slants of Yeast Carbon Base. Even on these solid media, growth was very slow.

The occurrence of broad-based budding and formation of pink to orange pigments are unusual characters for ascomycetous yeasts. A phylogenetic analysis of rDNA sequences placed *O. margaritifera* among the euascomycetes (Kurtzman and Robnett 1995).

70. *Saitoella* S. Goto, Sugiyama, Hamamoto & Komagata

D.G. Ahearn, J. Sugiyama and R.B. Simmons

Diagnosis of the genus

Asexual reproduction is mainly by multipolar enteroblastic budding. Vegetative cells are ovoidal to ellipsoidal and occur singly or in pairs. True mycelium and pseudomycelium are normally absent. Ascospores, teliospores, and ballistospores are not formed.

Sugars are not fermented. Nitrate is assimilated. Starch-like compounds are not synthesized. Carotenoid pigments are formed. Xylose is absent in the cell walls. Diazonium blue B reaction is negative. The major ubiquinone system is Q-10.

Type species

Saitoella complicata S. Goto, Sugiyama, Hamamoto & Komagata

Species accepted

1. *Saitoella complicata* S. Goto, Sugiyama, Hamamoto & Komagata (1987)

Systematic discussion of the species

70.1. *Saitoella complicata* S. Goto, Sugiyama, Hamamoto & Komagata (1987a)

Growth in morphology broth: After 3 days at 20°C, the cells are mainly ovoidal to ellipsoidal, (2.5–8.0) × (3.0–14.0) μm; elongate pseudohyphal-type cells are occasionally present (Fig. 285A). Budding is mainly enteroblastic; the primary bud is holoblastic and the secondary, and probably successive buds, are enteroblastic. The cell wall is of the ascomycetous type (Fig. 285B,C). There is an orange-red ring and sediment. Pellicles are not formed.

Growth on morphology agar: After one month at 20°C, the streak culture is yellowish-orange to orangish-red, the surface is smooth and shiny, and the margin is entire.

Dalmeu plate culture on potato dextrose and morphology agars: After 7 days at 25°C, growth under the coverslip is hyaline and consists mostly of single budding cells. Well-developed pseudohyphae or true hyphae are not formed. In aged cultures (>3 weeks)

in dilute (1:3) potato dextrose agar, elongated cells and short hyphal elements are sparsely produced.

Fermentation: absent.

Assimilation:

Co-Q: 10.

Mol% G+C: 51.5, IAM 12963 (holotype) (HPLC: Hamamoto et al. 1986b), 52.9 (Sugiyama et al. 1985); 50.9 IAM 12964 (CBS 7427, JCM 7359), HPLC: Hamamoto et al. 1986b).

Origin of strains studied: Soil from Laya, Bhutan; soil, Nepal (Goto and Sugiyama 1970).

Type strain: IAM 12963 (CBS 7301, JCM 7358) designated by Goto et al. (1987a).

Comments: *Saitoella complicata* was originally identified as a strain of *Rhodotorula glutinis* because both of these species have carotenoid pigmentation, lack

fermentation, possess similar assimilatory spectra, and ascospores, ballistospores and teliospores were not observed. Subsequently, the two species were shown to differ in their cellular carbohydrate composition, ubiquinone systems, diazonium blue B color reactions (Sugiyama et al. 1985), DNA base composition (Hamamoto et al. 1987) and in their cell wall types (Goto et al. 1987a). Goto et al. (1987a) indicated similarities between *Saitoella* and the ascomycetous genera *Protomyces* and *Taphrina*. Analysis of DNA sequences from 18S rRNA coding regions for *T. wiesneri* and *S. complicata* indicated these species form an evolutionary lineage separate from the hemiascomycetes and euascomycetes (Nishida and Sugiyama 1993).

71. *Schizoblastosporion* Ciferri

M.Th. Smith

Diagnosis of the genus

Asexual reproduction is by bipolar budding in basipetal succession on a broad base.

Sexual reproduction is absent.

Fermentation is absent. Acetic acid is not produced. Nitrate is not assimilated. Diazonium blue B reaction is negative.

Type species

Schizoblastosporion starkeyi-henricii Ciferri

Species accepted

1. *Schizoblastosporion starkeyi-henricii* Ciferri (1930)

Systematic discussion of the species

71.1. *Schizoblastosporion starkeyi-henricii* Ciferri (1930a)

Growth on malt extract: After 3 days at 25°C, the cells are ellipsoidal, long-ellipsoidal or cylindroidal, (2.5–6.8) × (4.5–20) µm, single or in pairs. Buds are formed on a broad base at the poles (Fig. 286). A thin sediment is formed. After one month at 17°C, a sediment, a ring and, occasionally, some islets are present, but a pellicle is not formed.

Growth on malt agar: After one month at 17°C, the streak is grayish-brown, soft, dull, and flat.

Dalmu plate cultures on potato- and corn meal agars: Pseudomycelium is absent or consists of small chains of cells that sometimes have side branches.

Fermentation: absent.

Type strain: CBS 2159, isolated by Lund.

Comments on the genus

The genus *Schizoblastosporion* exhibits bipolar budding in common with the genus *Kloeckera* and some species of the genus *Brettanomyces*, as well as with the teleomorphic genera *Hanseniaspora*, *Nadsonia*, *Saccharomyces* and *Wickerhamia*. *Schizoblastosporion* can be distinguished from the latter genera by the absence of ascospores. It differs from *Kloeckera* by lack of fermentation and from *Brettanomyces* by absence of acetic acid production.

Schizoblastosporion chiloense Ramírez & González (1984j) is excluded from the present treatment because it shows multipolar budding and produces septate hyphae in addition to pseudomycelium. This species resembles *Dipodascus ingens* or *D. ovetensis*. Comparisons of LSU rDNA place *S. starkeyi-henricii* within the genus *Nadsonia* and *S. chiloense* near *Dipodascus ingens* (C.P. Kurtzman and C.J. Robnett, manuscript in preparation).

72. *Sympodiomyces* Fell & Statzell

A. Statzell-Tallman and J.W. Fell

Diagnosis of the genus

The streak culture on malt agar is dull cream, the surface is smooth, the texture soft but not mucoid. Yeastlike cells are present. A conidiophore develops directly from a yeast cell, producing a terminal conidium. Subsequent conidia are produced sympodially, i.e., at the side of the conidium a new growing tip of the conidiophore develops, forming a new terminal conidium resulting in an elongate conidiophore with successively formed conidia. As a result of conidial detachment the conidiophores possess several scars. Conidial formation is irregular, both in distance between conidia and location on the conidiophore. Branched true mycelium is inconspicuous and restricted in development. Conidia on the mycelium are single on a short peg or sympodial on an elongate conidiophore. Diazonium blue B, urease and fermentation tests are negative. Coenzyme Q-9 is present.

Type species

Sympodiomyces parvus Fell & Statzell

Species accepted

1. *Sympodiomyces parvus* Fell & Statzell (1971)

Systematic discussion of the species

72.1. *Sympodiomyces parvus* Fell & Statzell (1971)

Growth in 5% malt extract: After 5 days at 12°C, the single cells are polymorphic (Fig. 287); they are round, ovoid and subglobose, (1.0–1.3) × (1.3–3.4) μm. The cells are single, in pairs and short branched chains. The cells in chains are generally larger, (2.6–3.4) × (4.7–5.4) μm and ovoid in shape. The conidiophores at this age are short (which gives the appearance of typical budding yeast cells) or they are elongate to 4 μm. There is a moderate sediment. After one month, the conidiophores

have elongated to 11 μm with numerous bud scars and one or more conidia.

Growth on 5% malt agar: After one month at 12°C, the streak culture is dull cream, the surface is smooth, the texture is soft but not mucoid. The growth is convex and the periphery is entire, apart from tufts of non-aerial mycelium at the edges (Fig. 288).

Dalmau plate culture on corn meal agar: After one month at 12°C, there is true mycelium with distinct septa and clusters of conidia. The latter form in the same manner as single cells, i.e., the new bud forms terminally on a conidiophore that elongates sympodially to produce new conidia. The hyphae are approximately 2 μm in width; there are often spheroidal intercalary cells in the range of 5 × 7 μm. The mycelium formed is inconspicuous, and somewhat more extensive on malt agar than on corn meal agar.

Fig. 287. *S. parvus*, CBS 6147. Yeast phase with the sympodial formation of conidia from culture grown for one to four weeks in malt extract at 12°C. Bar = 10 μm. *Camera lucida* drawings.

Fig. 288. *S. parvus*, CBS 6147. Hyphal formation after one week on malt agar at 12°C. Bar = 10 μm. *Camera lucida* drawings.

Fermentation: absent.

Cellular carbohydrate composition (mol%): glucose, 45.9; mannose, 40.6; galactose, 7.2; fucose, 4.2; ribose, 1.5; arabinose, 1.2 (Sugiyama et al. 1991).

Origin of the strains studied: 52 isolates from the open waters of the southern Indian and Pacific Oceans (Fell and Statzell 1971, Fell 1976).

Type strain: CBS 6147.

Comments on the genus

Sympodiomyces is an ascomycetous yeast; the diazonium blue B and urease test results are negative. Additionally, van der Walt and Hopsu-Havu (1976) and Kreger-van Rij (personal communication) report that the cell wall is typically ascomycetous. Sugiyama et al. (1991) state that the low mol% G + C content is typical of ascomycetous yeasts. The genus may be endemic to marine waters; the only reported occurrences (Fell and Statzell 1971, Fell 1976) have been from waters of Antarctic origin in the southern Pacific and Indian Oceans in the Antarctic Intermediate, Sub Antarctic, and South Pacific Central water masses from approximately 100°W westward to 118°E and 62°S northward to 42°S. Isolations were from depths of 16 to 748 meters where water temperatures ranged from 3.07–10.55°C and salinities were 33.94–34.85‰. Cell concentrations ranged from 1–5 per liter of sea water.

Information on the genus is limited. In addition to the original reports (Fell and Statzell 1971, Fell 1976), the genus has been studied by van der Walt and Hopsu-Havu (1976) who reported on the diazonium blue B reaction and cell wall structure and by Sugiyama et al. (1991) who compared the genus with *Sympodiomycesopsis*. Kurtzman and Robnett (1995) demonstrated from comparisons of nucleotide sequences from the 5' end of large subunit rDNAs that *Sympodiomyces*, *Blastobotrys*, *Arxula* and *Stephanoascus* are closely related and may be congeneric (Fig. 170, p. 385).

73. *Trigonopsis* Schachner

D. Yarrow

Diagnosis of the genus

Cells are triangular or ellipsoidal; tetrahedral and rhomboidal cells are sometimes present. Reproduction is by budding from the projecting angles on triangular and tetrahedral cells, and multilaterally on ellipsoidal cells. Neither hyphae nor pseudohyphae are formed.

Fermentation is absent. Nitrate is not assimilated. The cell wall is ascomycetous, comprising two layers. Diazonium blue B reaction is negative. Urea is not hydrolyzed.

Type species

Trigonopsis variabilis Schachner

Species accepted

1. *Trigonopsis variabilis* Schachner (1929)

Systematic discussion of the species

73.1. *Trigonopsis variabilis* Schachner (1929)

Growth on morphology agar: After 3 days at 25°C, the cells are ellipsoidal; triangular cells are usually also present, (3.5–6.0)×(2.0–6.0) μm, and they are single or in pairs (Fig. 289).

Growth on the surface of malt extract: After 1 month at 20°C, a ring and sometimes a pellicle, are present.

Slide culture on morphology agar: After 14 days at room temperature (20–22°C), there are neither hyphae nor pseudohyphae.

Fermentation: absent.

Assimilation:

Glucose	+	<i>N</i> -Acetyl-D-glucosamine	n

Co-Q: Not determined.

Mol% G+C: 46.1, IFO 0755 (CBS 1040) (*T_m*: Nakase and Komagata 1971g).

Origin of strains studied: CBS 1040, beer in Germany; CBS 1041, variant of CBS 1040 which produces few triangular cells; CBS 4095, grapes in Italy.

Type strain: CBS 1040, “Rasse I” isolated from beer in Germany by Schachner (1929).

Fig. 289. *T. variabilis*, CBS 1041. After 3 days at 25°C in malt extract (Slooff 1970d).

Comments: The proportion of triangular cells to ellipsoidal cells formed by strains of this species is influenced by nitrogen source (Sentheshanmuganathan and Nickerson 1962, Picci and Verona 1962, Šašek and Becker 1969), carbon source (Matthewson and Barnett 1974), incubation temperature (Rambelli 1959, Picci and Verona 1962, Packer and Bersten 1977), presence of the detergents Tween 80 and Span 80, and of short-chain alcohols (Packer and Bersten 1977). It is also dependent on the strain, as is demonstrated by the variant CBS 1041.

Chapter 74

Discussion of teleomorphic and anamorphic genera of heterobasidiomycetous yeasts

T. Boekhout, R.J. Bandoni, J.W. Fell and K.J. Kwon-Chung

Contents

1. Introduction	609
2. Taxonomy of heterobasidiomycetous yeasts	609
3. Molecular phylogeny	612
4. Characterization of orders and families	613

1. Introduction

Many heterobasidiomycetes have a unicellular budding haploid state alternating with a dikaryotic hyphal state, i.e., they are dimorphic and possess a yeast state. In some species, diploid, aneuploid or dikaryotic yeast states occur, and many anamorphic taxa are known only as yeasts. For teleomorphic yeasts, the hyphal state may be limited in culture, e.g., in some species of *Cystofilobasidium* Oberwinkler & Bandoni, but it can be indefinite and perhaps unlimited in many others, e.g., most species of *Rhodosporeidium* Banno, *Tremella* Persoon and *Sirobasidium* de Lagerheim & Patouillard. With few exceptions, our knowledge of development in nature, ecology, and general biology of these fungi is fragmentary or nonexistent. Species parasitizing economically important annual plants (e.g., Ustilaginales) have hyphal phases of known duration and extent, but even in these species, little is known of the frequency of occurrence or distribution of the free-living yeast states. For some taxa, e.g., the sporobolomycetaceous taxa, the abundant and widespread occurrence of the yeast states is known, but occurrence of dikaryotic mycelia in nature is essentially unknown.

The terms "yeast" or "yeast state" are applied to the budding unicellular phase or phases in heterobasidiomycetous life histories. These yeast states are readily obtained from basidiospores in species with macroscopically visible basidiomata, e.g., many species of *Tremella*, *Sirobasidium*, *Holtermannia* Saccardo & Traverso, *Cystobasidium* (de Lagerheim) Neuhoff, *Mycogloea* Olive, and from those causing visible disease symptoms in plants, e.g., species of *Ustilago* (Persoon) Roussel, *Itersonilia* Derx, and others. The yeast states provide one approach to studies of relationships of budding fungi, including determining relationships of anamorphic yeasts of uncertain affinity. Yeasts or yeast states are presently known from Agaricostilbales, Atractiellales, Cryptobasidiales, Exobasidiales, Filobasidiales, Graphiolales, Platyglaoles,

Septobasidiales, Sporidiales, Tremellales, and Ustilaginales (Oberwinkler 1987, and see below). However, yeast states of many of these groups of organisms are rarely isolated in nature, i.e., other than from the basidiocarps.

Fungi that form short hyphal fragments or cellular aggregates are frequently referred to as yeastlike, e.g., species of *Trichosporon* Behrend. It should be stressed, however, that the distinctions among the various morphs (unicellular, yeastlike and pseudohyphal) are not always clear. Yeast/hyphal dimorphism which occurs in many groups of Heterobasidiomycetes, seems to be an important taxonomic feature. This monograph includes only a small number of those taxa in which obligatory and stable yeast states occur in the normal course of the life history.

2. Taxonomy of heterobasidiomycetous yeasts

Brefeld (1881, 1888, 1895a,b) was the first mycologist to make detailed observations of basidiospore germination in heterobasidiomycetous fungi. He described and illustrated budding growth in cultures of many smuts and jelly fungi, and he utilized dimorphism as an important character in his classification. Brefeld's student, A. Möller, followed his example in studies of Brazilian jelly fungi (Möller 1895). Although Brefeld's ideas on dimorphism received little support over the next century, some aspects of his classification system did survive.

The taxon "Heterobasidiomycetes" originated with Patouillard (1900), and the term has been applied at some level (i.e., class, subclass) since that time. The Heterobasidiomycetes have encompassed taxa with septate or deeply divided basidia, complex life histories, basidia often arising from distinct probasidia (teliospores or equivalents in rusts, smuts and others), and germination of basidiospores by ballistoconidia or conidia of other types as opposed to Homobasidiomycetes. Modified versions of this classification system have been in use until the present, by a variety of authors, e.g., Martin (1945, 1952), Lowy (1971), Jülich (1981), and Locquin (1984). Bessey (1950) recognized three subclasses of Basidiomycetes: 1. Teliosporae (fungi with teliospores and transversely septate basidia, and including rusts, smuts, and related fungi), 2. Heterobasidiae (often with gelatinous basidiomata and septate basidia, teliospores or equivalents lacking in most taxa, and including Tremellales, Auriculariales, Dacrymycetales, and Tulasnellales),

Fig. 290. A–C. Basidiospore germination in three species of *Tremella*. (H) *Trimorphomyces papilionaceus*, dikaryotic cells of the form produced both as conidia from filamentous conidiogenous cells and by budding of these, or of the indistinguishable H-shaped yeast cells, RJB 6646 Type, Canada. Bar = 5 μ m.

and 3. Eubasidia for the Homobasidiomycetes (basidia aseptate and not deeply divided).

Talbot (1968) also used three classes, Teliomycetes, Phragmobasidiomycetes, and Holobasidiomycetes, discarding the name Heterobasidiomycetes. Talbot considered the Dacrymycetales and Tulasnellales to be Holobasidiomycetes, and he did not emphasize dimorphism in his classification scheme.

Patouillard's classification permitted ready identification of families, since these were largely based upon basidial morphology. Although the Heterobasidiomycetes and Homobasidiomycetes differed in the types of basidiospore germination, yeast states were not emphasized in Patouillard's classification system. Budding of basidiospores was often mentioned in descriptions, but dimorphism was essentially unknown and unstudied in most basidiomycetous groups until the middle of the 20th century. The smuts are an exceptional group among the Heterobasidiomycetes in that their yeast states were used experimentally to examine mating genetics. Since mating initiates the parasitic phase and determines virulence, there were numerous reports on teliospore germination and mating of "sporidia" in the group (see Fischer and Holton 1957, for extensive references). The first attempt to demonstrate mating pheromones in true fungi was carried out with sporidia of *Ustilago* spp. (Bauch 1925).

It is clear that dimorphic fungi formerly placed in the Heterobasidiomycetes do not form a natural group, but the name is convenient to use as an informal category in studies of dimorphic basidiomycetes. Heterobasidiomycetous yeasts, like ascomycetous yeasts, bud to form soft, often slimy or mucoid colonies. The yeast state usually commences with basidiospore germination (e.g., as in Fig. 290) or cells are budded directly from basidia, as in species of *Agaricostilbum* and *Rhodosporeidium* (Fig. 291). This unicellular haploid state ends at the initiation of the dikaryotic state in those yeasts with known teleomorphs. The majority of Heterobasidiomycetes with haploid yeast states have dikaryotic mycelia that are parasitic on green plants or fungi.

As noted above, budding basidiospores of *Tremella* and *Sirobasidium* were observed and illustrated in the nineteenth century (Brefeld 1881, 1888, Möller 1895). The presence of ballistoconidia in *Sporobolomyces* Kluver & van Niel led Kluver and van Niel (1924, 1927) to suggest that this yeast is basidiomycetous, based on the morphological resemblance of ballistoconidia with actively discharged apiculate basidiospores. The discovery of mating and a sexual state in strains of *Rhodotorula glutinis* (Fresenius) Harrison by Banno (1963, 1967), and the subsequent discovery of sexual states in species of *Rhodosporeidium* (Fig. 291) and *Leucosporidium* (Fell 1970b, 1974, Fell et al. 1969, 1973), *Sporidiobolus* Nyland (Nyland 1949, Bandoni et al. 1971, 1975, Fell and Statzell-Tallman 1980b, 1981, 1982), *Filobasidium* Olive (Olive 1968, Rodrigues de Miranda 1972, Kwon-Chung 1977b, Bandoni et al. 1991), *Filobasidiella* Kwon-

Fig. 291. *Rhodosporeidium toruloides* Banno (Sporidiales). (A) Mature teliospore. (B) Germinating teliospore with basidia. Bar = 10 μ m. (Teliospores obtained by crossing IFO strains 10034 and 05392. Strains provided courtesy of Dr. I. Banno.)

Chung (Kwon-Chung 1975), *Cystofilobasidium* (Oberwinkler et al. 1983), and *Bulleromyces* Boekhout et al. (Boekhout et al. 1991a, demonstrated the basidiomycetous nature of these organisms.

Donk (1973a–c) proposed placement of the basidiomycetous yeasts in Brefeld's hemibasidiomycetes without assigning them to orders. Donk's concept of hemibasidiomycetes included Ustilaginales, Tilletiales, and Graphi-olales.

In the previous edition of this book the basidiomycetous yeasts were divided into five groups: 1. Sporobolomycetaceae Derx (both anamorphic and teleomorphic ballistospore-forming yeasts), 2. Cryptococcaceae Kützing (the remaining anamorphic basidiomycetous yeasts), 3. Filobasidiaceae L. Olive (teleomorphic yeasts with holobasidia), 4. teliospore-forming yeasts (teleomorphic taxa with teliospores) and 5. Tremellales (yeast stages of genera belonging to the Tremellales). Van der Walt (1987) made a clear distinction between teleomorphic and anamorphic basidiomycetous yeasts, which is reflected in his taxonomic concepts (see below). He placed anamorphic yeasts in either the Cryptococcaceae Kützing emend. van der Walt (1987) or the Sporobolomycetaceae Derx emend. van der Walt (1987).

Basidial morphology is considered an important character for the affiliation of basidiomycetous yeast genera to higher taxa. Transversely septate basidia commonly occur in yeasts belonging to the Sporidiales, e.g., *Leucosporidium*, *Rhodosporeidium* and *Sporidiobolus* (Fell

1984a). However, some of these yeasts have one-celled basidia as well, e.g., *Sporidiobolus johnsonii* (Nyland 1949, Bandoni et al. 1971, Fell and Statzell-Tallman 1981). Crucially septate basidia are characteristic for most Tremellales (Bandoni 1987, Oberwinkler 1987), and occur in *Bulleromyces*, the teleomorph of *Bullera alba* (Boekhout et al. 1991a). Holobasidia occur in species belonging to the Filobasidiales, e.g., *Filobasidiella* (Kwon-Chung 1975, 1987), *Filobasidium* (Olive 1968), *Cystofilobasidium* (Oberwinkler et al. 1983, Hamamoto et al. 1988b), and *Xanthophyllumyces* Golubev (Golubev 1995). Teliospores (thick-walled probasidia) commonly occur in the Sporidiales, but have also been found in filobasidiaceous yeasts, such as *Cystofilobasidium* and *Mrakia* (Oberwinkler et al. 1983, Kwon-Chung 1987, Yamada and Komagata 1987). Haustorial branches seem to indicate a Tremellales–Filobasidiales relationship, but the haustorial structures of some simple-pored mycoparasites may be functionally similar (Oberwinkler et al. 1990a).

Anamorphic yeasts can be assigned to the Basidiomycetes by a number of morphological, biochemical, ultrastructural, and physiological criteria. Basidiomycetous yeasts have a positive Diazonium blue B reaction (Simmons and Ahearn 1987, van der Walt and Hopsu-Havu 1976, Hagler and Ahearn 1981), contain pyrophosphatidic acid (Goto et al. 1988), and in contrast with most ascomycetous yeasts, show urease activity (Abadie 1961, 1967, Roberts et al. 1978, Booth and Vishniac 1987). The presence of ballistoconidia and/or red carotenoid pigments also indicate a basidiomycetous affinity. Other basidiomycetous characteristics are found in the ultrastructure of the cell wall (Kreger-van Rij and Veenhuis 1971a, Simmons and Ahearn 1987, Boekhout et al. 1992b) and septa (e.g., Johnson-Reid and Moore 1972, Khan and Kimbrough 1980, Kreger-van Rij and Veenhuis 1971a,b, Moore and Kreger-van Rij 1972, Kwon-Chung and Popkin 1976, Moore 1978, 1979, 1987b, Boekhout et al. 1992b), and in the biochemical composition of the cell wall and capsules (Sugiyama et al. 1985, Weijman and Golubev 1987, Weijman and Rodrigues de Miranda 1983, 1988, Suzuki and Nakase 1988a, Prillinger et al. 1993).

In contrast to most ascomycetous yeasts, the mol% G + C of the majority of basidiomycetous yeasts is above 50 (von Arx 1979b). The coenzyme Q systems are mainly Co-Q 9 and Co-Q 10 (Kuraishi et al. 1985), but lower numbers of isoprenologs occur. More recently, killer toxin (mycocin) spectra have been used to characterize basidiomycetous yeasts. Mycocins of basidiomycetous origin usually act only against other basidiomycetous yeasts (e.g., Golubev 1989a, 1991b, Golubev and Kuznetsova 1989, Golubev and Tsiomenko 1985, Golubev et al. 1988). In summary, basidiomycetous yeasts are unicellular fungi belonging to the Heterobasidiomycetes, characterized by the presence of multilamellate electron-dense cell walls, the presence of xylose and/or fucose in whole-cell hydrolyzates, and the presence of dolipores, or diaphragm-like pores

without Woronin bodies ("simple" pores), or micropore-like structures.

3. Molecular phylogeny

Early molecular studies of 5S ribosomal RNA suggested the presence of two main lines of phylogenetic divergence among basidiomycetous yeasts, which correlates with septal ultrastructure (Walker and Doolittle 1982, Templeton 1983). In more extensive work, including a larger number of heterobasidiomycetous species, the yeast and yeastlike species were shown to belong to four out of eight clusters that correlate well with septal morphology (Walker 1984). This has largely been supported by Blanz and Gottschalk (1984). Two main clusters, one containing Sporidiales and their anamorphs and the other tremellaceous and filobasidiaceous species, can be distinguished from the analysis of partial 26S rRNA and from entire 18S rRNA/rDNA sequences (Fell et al. 1992, 1995, Van de Peer et al. 1992, Suh and Sugiyama 1993b, Sugiyama and Suh 1993, Swann and Taylor 1993, 1995a). This clustering correlates with septal ultrastructure (dolipore versus "simple" pore) and cell wall biochemistry (presence or absence of xylose).

A comparison of 26S rDNA partial sequences from 145 basidiomycetous yeast species (Fell et al. 1995) demonstrated four main clusters: Sporidiales (nom. nud.), Tremellales, *Cystofilobasidium* and related taxa, and the Ustilaginales. Within the Sporidiales there was a major cluster that included *Sporidiobolus* spp., *Rhodospodium toruloides* and related anamorphic and teleomorphic species. Other subclusters demonstrated molecular divergence among the anamorphic and teleomorphic genera *Bensingtonia*, *Rhodotorula*, *Sporobolomyces*, *Kurtzmanomyces*, *Sterigmatomyces*, *Erythrobasidium*, *Leucosporidium* and *Rhodospodium*. The *Cystofilobasidium* cluster included a diversity of genera: *Cystofilobasidium* spp., *Mrakia*, *Trichosporon pullulans*, *Itersonilia perplexans*, *Phaffia* and *Cryptococcus aquaticus*. The Tremellales demonstrated a similar diversity. The genus *Trichosporon*, with the exception of *T. pullulans*, remained a monophyletic clade as did the separate clades *Filobasidiella*, *Filobasidium* and *Fellomyces*. The genus *Cryptococcus* was found to be polyphyletic, and occurred in several subclusters. Other genera occurring in the Tremellales cluster were *Sirobasidium*, *Apiotrichum*, *Holtermannia*, *Tremella* and *Bulleromyces*. The limited study of the Ustilaginales cluster indicated a similar polyphyletic nature, and included the genera *Entyloma*, *Pseudozyma*, *Tilletia*, *Tilletiaria*, *Tilletiopsis* and *Ustilago*.

In a comparison of partial 18S rDNA sequences of basidiomycetous yeasts with entire 18S rDNA sequences of several representatives of Basidiomycetes, the yeasts were found to belong to the Tremellomycetidae and the Urediniomycetes, respectively (Swann and Taylor 1995a). Within this latter group, the yeasts belonged to three clades, namely 1. *Agaricostilbum* clade (*Bensingtonia yuccicola*), 2. Sporidiales clade (*Sporobolomyces*

roseus, *Leucosporidium scottii*, *Rhodospidium toruloides*, *Rhodotorula glutinis*, and 3. *Erythrobasidium* clade (*Erythrobasidium hasegawianum*). The detailed phylogenetic relationships among Heterobasidiomycetes with or without yeast states require further biochemical, ultrastructural and molecular investigations.

4. Characterization of orders and families

4.1. Anamorphic basidiomycetous yeasts

The anamorphic basidiomycetous yeasts are currently assigned to two families:

4.1.1. Cryptococcaceae Kützing (1833) emend. van der Walt (1987): The family is restricted to anamorphic heterobasidiomycetous yeasts and yeastlike fungi; budding is enteroblastic; cell walls are lamellate and hyphal septa have dolipores if perforate; parenthesomes may be present; cell hydrolyzates contain xylose. The type genus is *Cryptococcus*. Other genera are *Bullera*, *Fellomyces*, *Kockovaella*, *Phaffia*, *Trichosporon*, *Tschuchiyaea*, *Udeniomyces* and perhaps *Hyalodendron* and *Moniliella*. These genera usually assimilate myo-inositol and D-glucuronate and produce extracellular starch-like compounds. It can be foreseen that generic concepts will change in the near future as a consequence of the widely divergent ribosomal nucleotide sequences observed in several genera, e.g., *Cryptococcus* and *Bullera* (Guého et al. 1993, Fell et al. 1992, 1995, Nakase et al. 1993). In contrast, other genera, e.g., *Trichosporon*, with the exclusion of *T. pullulans*, were found to be relatively homogeneous (Guého et al. 1992b).

4.1.2. Sporobolomycetaceae Derx (1948) emend. van der Walt (1987): The family is restricted to anamorphic yeasts and yeastlike fungi; budding is enteroblastic; cell walls are lamellate and hyphal septa are diaphragm-like ("simple") if perforate; cell walls are without xylose, but fucose, rhamnose and galactose may be present. The type genus is *Sporobolomyces*. Other genera are *Bensingtonia*, *Kurtzmanomyces*, *Sterigmatomyces* and *Rhodotorula*. These genera usually do not assimilate myo-inositol and D-glucuronate, and do not form extracellular starch-like compounds. Sequence divergence of ribosomal RNA (rRNA) or rDNA suggests taxonomic heterogeneity for a number of genera, such as *Bensingtonia* and *Sporobolomyces* (Nakase et al. 1993, Fell et al. 1992, 1995).

These anamorphic families are artificial taxa, which are maintained here for convenience. It can be expected that they will become superfluous when the taxonomy of the anamorphic basidiomycetous yeasts becomes integrated with the teleomorphic Heterobasidiomycetes. The two anamorph families are partly in accord with the *Rhodotorulaceae* Lodder (1934). However, Lodder's family concept was based on the presence of carotenoid pigments. Recent molecular, biochemical and ultrastructural studies indicate the *Rhodotorulaceae* is a paraphyletic group.

4.2. Teleomorphic Heterobasidiomycetes with yeast states

The Heterobasidiomycetes with yeasts and yeastlike-states are distinguished by basidial morphology, septal pore anatomy, and cell wall composition. The classification of families and orders rests largely on basidial morphology. However, similar basidial types may be present in categories with different septal pores, e.g., the cruciately septate basidium occurs in the Tremellales and Auriculariales. Also, the cylindrical, transversely septate basidium occurs in such families and orders as the Auriculariaceae, Platyglloeales, Uredinales, Septobasidiales, Ustilaginales, Sporidiales and Tremellales. Presently, the pore structure, which correlates well with molecular data (Swann and Taylor 1993), appears to be a more definitive character.

4.2.1. Sporidiales R.T. Moore (nomen nudum, no Latin diagnosis): This order contains the so-called "saprobic smuts". Nyland (1949) placed *Sporidiobolus* among the Heterobasidiomycetes. Other teliospore-forming fungi, specifically the rusts and smuts were placed in a separate class, Teliomycetes (Ainsworth 1973) or subclass Teliomycetidae (Alexopoulos and Mims 1979). The life-cycles of the teliospore-forming yeasts are similar to those of the smuts (see, e.g., Banno 1967, Fell 1984a, Fell et al. 1969). Johnson-Reid and Moore (1972) interpreted the teliospores as encysted proasci and named them ustospores. Moore (1972) placed the ustospore-forming fungi in a separate division Ustomycota (Moore 1972, 1980), characterized by the presence of ustospores and attenuated diaphragm-like ("simple") septa lacking a parenthesome. The Ustomycota were subdivided in the Ustomycetes (smuts) and Sporidiomycetes (yeasts). The latter contained the order Sporidiales, in which two families have been distinguished to accommodate the yeasts and yeastlike fungi, viz., Sporidiaceae R.T. Moore and Sporidiobolaceae R.T. Moore for non-ballistosporous and ballistosporous teliospore-forming yeasts, respectively (Moore 1980). Recent molecular studies indicate that the Ustomycota are polyphyletic (Swann and Taylor 1993, 1995a).

At present, it is appropriate to maintain the teliospore-forming, and phylogenetically related yeasts, in a separate order. We consider the Sporidiaceae and Sporidiobolaceae to be synonymous because they cannot be discriminated by rRNA/rDNA sequence analysis, septal ultrastructure and cell wall biochemistry. We choose Sporidiobolaceae R.T. Moore, with *Sporidiobolus* Nyland as type, which was the first genus to be described in this family (Nyland 1949).

4.2.1.1. Sporidiobolaceae R.T. Moore (1980) emend. (synonym Sporidiaceae R.T. Moore): This family is restricted to teleomorphic yeasts and yeastlike fungi; budding is enteroblastic; dikaryotic mycelium with or without clamp connections, haustorial branches are absent; somewhat thick-walled teliospores are present, basidia are usually transversely septate, but occasionally one-celled; cell walls are lamellate and hyphal septa have

attenuated diaphragm-like (“simple”) septa if perforate and without Woronin bodies; no dolipore is present; xylose is absent in whole-cell hydrolyzates, but fucose, galactose and/or rhamnose may be present. The type genus is *Sporidiobolus*, and other assigned genera are *Leucosporidium* and *Rhodospordium*.

Sporidiobolus, a ballistoconidia-forming, teliospore-forming, and carotenoid pigments producing genus (Nyland 1949), was proven to be the teleomorph of the red-pigmented yeast species of *Sporobolomyces* (Bandoni et al. 1971, 1975, Fell and Statzell-Tallman 1981, Boekhout 1991a). Banno (1963, 1967) described the genus *Rhodospordium*, and Fell et al. (1969) published *Leucosporidium*, the teleomorph genus for the non-carotenoid species *Candida scottii*.

The life cycles include homothallic and heterothallic systems, that may occur within a single species. In the heterothallic system, compatible mating types conjugate and develop a dikaryotic mycelium with clamp connections. Karyogamy takes place in the teliospore, which germinates to a one- to four-celled basidium where meiosis occurs. The heterothallic incompatibility systems are biallelic unifactorial (bipolar), multiple allelic unifactorial or bifactorial (tetrapolar). The homothallic lifecycle is distinguished by dikaryotic hyphal cells that develop from a diploid cell in the absence of mating. Clamp connections may be present, and karyogamy apparently takes place in the teliospore. In *Sporidiobolus johnsonii* and *S. ruineniae*, meiosis does not seem to occur in the basidium, which results in diploid basidiospores. In some cases, e.g., in homothallic strains of *Rhodospordium toruloides*, the diploid cells appear to originate from a failure during meiosis. The progeny from homothallic *Rhodospordium toruloides* are either homothallic or heterothallic. Quantitation of the amount of nuclear DNA by fluorescence cytometry indicates that self-sporulating strains of *Leucosporidium scottii* are diploid (Suh et al. 1993b). Strains of several yeasts, e.g., *Leucosporidium scottii* and *Sporidiobolus pararoseus*, produce teliospores in the absence of mating. Rather than the previously discussed life cycles, the hyphal cells remain uninucleate and clamp connections are lacking. Here, teliospore formation seems the result of monokaryotic fruiting (Fell 1984a). In addition to monokaryotic fruiting, these strains may restore the heterothallic cycle by mating with a compatible strain.

The genera *Leucosporidium*, *Rhodospordium* and *Sporidiobolus* were found to be phylogenetically related to smuts that occur on dicotyledonous hosts (Blanz and Gottschalk 1984). 18S rRNA gene sequences placed *Sporidiobolus johnsonii* and *Leucosporidium scottii* in the “simple-septate” lineage, together with *Cronartium ribicola* (Swann and Taylor 1993). Analysis of 18S and 26S rRNA sequences of teliospore-forming yeasts support the transfer of some species formerly classified in *Rhodospordium* and *Leucosporidium* to *Cystofilobasidium*, e.g., *C. infirmominatum*, *C. bisporidii*, *C. lari-*

marini, *C. capitatum*, and *Mrakia*, e.g., *M. gelidum*, *M. nivalis*, *M. frigidum* and *M. stokesii* (Hamamoto et al. 1988b, Fell and Statzell-Tallman 1992, Yamada and Kawasaki 1989a, Suh and Sugiyama 1993b). Some other taxonomic changes based on nucleotide analysis have been proposed, namely *Kondoa* and *Sakaguchia*, accommodating *Rhodospordium malvinellum* and *Rhodospordium dacryoidum*, respectively (Yamada et al. 1989a, 1994a). *Kondoa* was found to belong to the *Agaricostilbum* clade, and *Sakaguchia* (Yamada et al. 1994a) belongs to the *Erythrobasidium* clade (Swann and Taylor 1995a). Based on partial 26S rRNA sequences, species of *Sporidiobolus*, *Leucosporidium* and *Rhodospordium* form distinct subclusters among the Sporidiobolaceae, together with anamorphic species belonging to *Bensingtonia*, *Rhodotorula* and *Sporobolomyces* (Fell et al. 1992, 1995). The close phylogenetic relationship among ballistoconidia and non-ballistoconidia-forming species, e.g., *Sporidiobolus microsporus* and *Rhodospordium fluviale*, questions the use of ballistoconidia as a useful phylogenetic characteristic among basidiomycetous yeasts.

Erythrobasidium hasegawae, which lacks teliospores, has some phenetic characters in common with the teliospore-forming yeasts (Hamamoto et al. 1988c, Suh and Sugiyama 1993b, Sugiyama and Suh 1993), but was found to belong to a separate clade (Swann and Taylor 1995a). Molecular analysis suggests that *Heterogastridium pycnidioideum* Oberwinkler & Bauer, a teleomorphic heterobasidiomycete with pycnidoid basidiocarps, “simple” septa, and with fucose, but without xylose in the cell wall (H.J. Roelijmans, unpublished observations), and thus far classified in the Heterogastridiales (Oberwinkler et al. 1990b), belongs to the Sporidiales clade (Swann and Taylor 1995a).

4.2.2. Ustilaginales and Tilletiales: Although the economically important smut and bunt fungi have been studied more intensively than many other Heterobasidiomycetes, their classification and relationships remain unclear. Two orders, Ustilaginales and Tilletiales, are often recognized, but they are not generally accepted. Alternatively, when a single order Ustilaginales is used, it is difficult to assign many smut taxa to the families Ustilaginaceae and Tilletiaceae (L.R. Tulasne and C. Tulasne 1847). The Ustilaginales and Tilletiales differ in several important aspects, among which are the basidia, septal pore anatomy, haploid states and conidial types, which support classification in two orders. However, molecular phylogenetic studies suggest a relatively close relationship (Swann and Taylor 1993). Some common genera in temperate areas include *Ustilago*, *Microbotryum*, *Cintractia*, *Schroeteria* and *Sphacelotheca*.

Ustilago is the largest genus in the order with approximately 300 species, and most species parasitize monocotyledonous hosts. Teliospores of *Ustilago* spp. typically germinate with a cylindrical, four-celled basidium. Each basidial cell repeatedly buds off basidiospores (sporidia),

which produce the haploid yeast state. Teliospore germination readily occurs in many species, or it can be induced by treatments such as soaking in water or plant extracts (Fischer and Holton 1957). Conjugation can often be seen when compatible cell types are mixed, but the dikaryophase may be unstable in culture and few species have been grown through the complete life history. Basidium maturation in several species occurs without sporidial development, the four basidial cells conjugating directly in two pairs. Yeast states develop in these species only infrequently when one or more basidial cells remain unconjugated.

Species of *Leucosporidium*, *Rhodospodium* and *Sporidiobolus* have a life cycle similar to *Ustilago* species, but are currently classified in the Sporidiales (see above). Yeastlike anamorphs of Ustilaginales classified in various genera, viz., *Candida fusiformata*, *C. tsukubaënsis*, *Pseudozyma prolifica*, *Sporobolomyces antarcticus*, "*Stephanosascus*" *flocculosus*, "*S.*" *rugulosus*, *Sterigmatomyces aphidis* and *Trichosporon oryzae* have been reclassified in *Pseudozyma* Bandoni emend. Boekhout (Boekhout 1995). Molecular analysis indicates that these taxa form a monophyletic group with *Ustilago maydis* (Boekhout et al. 1995a, Fell et al. 1995).

Tilletia, with about 70 species that mainly parasitize grasses, has a cylindrical basidium that is aseptate or sometimes adventitiously septate and bears elongate basidiospores apically. Only one spore per locus is formed. The basidiospores often conjugate before release, in which case the H-shaped conjugants give rise directly to dikaryotic mycelial colonies or, alternatively, conjugation occurs between closely situated compatible pairs after their release. Ballistoconidia often develop on the mycelia. They are produced and abstricted in the manner of basidiospores of most basidiomycetes. The septal pores are often more complex than those of the Ustilaginales, but they do not reach the complexity of dolipores.

The anamorphic ballistoconidia-forming genus *Tilletiopsis* was placed in the Filobasidiaceae by von Arx et al. (1977). This concept is not supported by septal ultrastructure and cell wall biochemistry (Boekhout 1987, Boekhout et al. 1992b). Morphological, biochemical and molecular similarities suggest *Tilletiopsis* to be related to *Tilletiaria*, a teliospore- and ballistoconidia-forming genus (Bandoni and Johri 1972, Boekhout et al. 1995a). The hyphal system and the presence of falcate ballistoconidia in these genera strongly resembles that of the Tilletiales (Boekhout et al. 1992b). Placement of *Tilletiaria* in the Tilletiaceae Moore (1980) seems appropriate. Budding is unknown or is limited in the Tilletiales, and occurs, e.g., in *Tilletiaria anomala* (Tilletiaceae, Tilletiales) and *Tilletiopsis washingtonensis* (Boekhout 1991a).

4.2.3. Graphiiales: This order contains a small number of poorly-known species of which only the widely spread *Graphiola phoenicis* has been studied in detail. The fungus produces minute blister-like sori on palm leaves.

Catenate globose cells within the sorus are simple basidia. Meiosis occurs in these cells, and haploid basidiospores bud directly from the basidia to yield yeast colonies. The morphology is unlike that of any other basidiomycete, but it is conceivable that the chains of basidia are homologues of chains of teliospores in the Ustilaginales and of basidial chains in the Sirobasidiaceae.

4.2.4. Cryptobasidiales: Although they are holobasidiolate, these fungi resemble smuts in their life histories. Basidia are found in minute clusters on the infected leaves of Laurales and Rhamnaceae in the case of *Coniodyctum* species, or of Fagaceae and Juglandaceae for species of *Microstroma*. The basidiospores, borne on clavate basidia, are not forcibly abstricted, and they give rise to yeast colonies in *Coniodyctum chevalieri* and in *Microstroma juglandis*. Other species in these genera have not been studied in detail.

4.2.5. Exobasidiales: This order includes relatively few described species (<100 spp.) and, with the exception of some *Exobasidium* spp., few are well known. The Exobasidiales, including ca. seven genera in two families, are all plant parasites and found on a variety of plant species. The dikaryotic mycelium grows internally in the host (mostly on leaves of Vacciniaceae in *Exobasidium*), transforming leaves into hypertrophied, inflated, bladderly structures suggestive of fruits. The fine hyphae have "simple" septal pores and they produce basidia at the surfaces of infected parts. The clavate, non-septate basidia, have stout sterigmata whose curvatures are opposite to those in other basidiomycetes. The basidiospores become septate and germinate by producing conidia successively on narrow outgrowths. Haploid states are unicellular yeasts in some species, but the colonies of others consist of short hyphal segments and are more appropriately described as yeastlike.

Exobasidiellum gramineum infects grass leaves; the affected areas are without the hypertrophy associated with *Exobasidium* infections. The basidia and basidiospores are similar to those of *Exobasidium* spp.

Exobasidium spp. and *Laurobasidium lauri* (Geyler) Jülich apparently have similar cell wall carbohydrate compositions (Prillinger et al. 1990b, Prillinger et al. 1993). *L. lauri* is an unusual species inducing clavarioid galls on *Laurus azorica* in Europe. In addition to the unusual galls, *L. lauri* has clamp connections, which are absent in *Exobasidium*.

Dicellomyces gloeosporus produces gelatinous tuberculate to discoid basidiomata on the leaf surfaces of canes of *Arundinaria* spp. in the southern USA. *Brachybasidium pinangae* also produces pustulate basidiomata, but on *Pinanga* spp. (Palmae) from Java. The bisterigmate basidia have slightly thickened probasidial walls. These two genera are sometimes put in a separate order, Brachybasidiales (e.g., McNabb and Talbot 1973), but their features are rather close to those of other Exobasidiales (Oberwinkler 1987).

Fig. 292. (A) *Agaricostilbum hyphaenes* (Hariot & Patouillard) Oberwinkler & Bandoni (Agaricostilbales), basidiomata, RJB 7760, Thailand. Bar = 0.5 mm. 4.2.6. Atractiellales sensu lato and Agaricostilbales:

The order Atractiellales includes a heterogeneous assortment of fungi. Most species produce minute synnemata-like basidiomes (Fig. 292). An exception is *Atractogloea stillata* Oberwinkler & Bandoni, which has small pustulate basidiomes. *Atractiella* species described to date are characterized by strictly hyphal growth. The species of *Agaricostilbum*, placed in the Fungi Imperfecti prior to 1980 (Wright et al. 1981), are xerophytic species growing especially on attached or fallen dead palm parts, or, infrequently, on other monocotyledones. Basidia (Fig. 293) predominantly are produced at or near the apices of synnemata-like structures. The basidia do not arise from teliospores, are mostly four-celled, and the cells bud off multiple spores as in many smuts. Unlike smut basidia, however, the walls thicken with age and the budded basidiospores (also with walls that tend to thicken) mostly remain weakly attached in clusters on their basidial cells. The spores germinate to form rather slimy yeast colonies, but development beyond that is unknown.

Agaricostilbum species are not closely related to other Atractiellales, and they have been segregated into a new order, Agaricostilbales (Oberwinkler and Bauer 1989). This classification is supported by the study of nuclear division (Bauer et al. 1992).

Chionosphaera apobasidialis, *Stilbum vulgare* and *Fibulostilbum phylacicola* (Chionosphaeraceae) are all presumed to be mycoparasites. *C. apobasidialis* is found with various dematiaceous fungi on bark of standing trees (Cox 1976). The species is sometimes present on branches falling from the jungle canopy in Costa Rica (R.J. Bandoni, unpublished observation). This species sporulates readily in culture in the absence of associated fungi (Oberwinkler and Bandoni 1982b), producing clavate nonseptate basidia (Fig. 294), each of which bears a terminal cluster of basidiospores. Germination is by budding. *Stilbum vulgare*, reported from a variety of substrates, is a rather variable species with 2-celled auricularioid basidia (Fig. 295). The basidiospores give rise to yeast colonies (Seifert et al. 1992). Mass spore

Fig. 293. *Agaricostilbum hyphaenes* (Hariot & Patouillard) Oberwinkler & Bandoni (Agaricostilbales). (A) Hyphidium. (B) Three mature basidia, two with attached basidiospores. (C) Basidiospores. (D) Diagrammatic portion of basidium showing thick rough walls, budding locus, and attached basidiospore, note very narrow attachment characteristic of many spores in this species. RJB 7760, Thailand. Bar=10 µm.

isolates frequently produce basidiomata in culture, but the details have not been studied. Unusual here is the near absence of a spreading dikaryotic mycelium, and the basidiomata arise at the margins of yeast colonies (R.J. Bandoni, unpublished observation). A strain of this species, isolated from basidiomes of *Yucca brevifolia*, produced narrow hyphae with haustoria at the surfaces of hyphae from a nearby *Cladosporium* sp. *Fibulostilbum phylacicola* produces basidiomata on and around ascomata of *Phylacia* spp. Attempts to culture the fungus have not been successful.

Aractogloea stillata apparently has been collected only once (Oberwinkler and Bandoni 1982c). Although budding was not noted in the original description, a yeast state was reported by Oberwinkler and Bauer (1989). It has a diglobular spindle pole body, and thus differs from other Atractiellales sensu lato. According to Prillinger et al. (1993), the cell wall carbohydrate pattern agrees with the pattern in *Cystofilobasidium* species and *Tremella mesenterica*.

4.2.7. Septobasidiales: Basidiospores of *Septobasidium* species were first reported to bud by Couch (1938). All species are associated with scale insects on a variety of woody plants. An effused thallus develops on the bark or epidermal surface of the living plants; many scale insects dwell within the thallus or beneath it. Some individual scale insects are parasitized by *Septobasidium*,

Fig. 296. *Septobasidium* sp. (A) Two probasidia. (B) Developing 2-celled basidia. (C) Mature basidium, one cell spent and collapsed, and portion of a sterigma with developing spore. (D) Four basidiospores, one of which has become septate during germination to produce yeast phase. (E) Hyphae from context bearing conidial clusters. A-A and RJB 11074, Thailand. Bars = 10 μ m.

the fungus producing coiled haustoria within the insect gut. However, most of the insects are unparasitized, moving about freely and reproducing in or under the thallus. Similar haustoria are characteristic of several other auricularioid fungi. Details of the morphology, life histories and biology were included in the monograph by Couch (1938). Many species have typical transversely septate, four-celled basidia similar to those of the rusts, but one- or two-celled basidia (Fig. 296) are characteristic of some species. The basidiospores are born on sterigmata and are abstricted from basidia scattered at the basidiome surface, i.e., not forming a compact hymenium. At germination, yeast colonies develop in species of *Septobasidium* (Couch 1938) and in *Auriculoscypha anacardiicola* Reid & Manimohan (Lalitha and Leelavathy 1990). The cupulate basidiomata of *A. anacardiicola* arise from small tubercles, each of which contains a female coccid.

4.2.8. Platygloales: The Platygloales include a variety of fungi with mostly four-celled "auricularioid" basidia, mostly abstricted basidiospores, and effused, pustulate, or clavarioid basidiomes. The ordinal name was badly selected as there is considerable disagreement over the choice of *Platygloea* vs. *Achroomyces* for the species which provides the basionym (*Platygloea tiliae*).

The species are saprobes on wood or they parasitize fungi, ferns, mosses, or vascular plants. Most species have haploid hyphal phases, so far as is known, but *Cytobasidium lasioboli* that parasitizes *Lasiobolus* sp. on dung, was reported to have a yeast state (de Lagerheim 1898), as does *Platygloea fimetaria*¹ (Fig. 297) (Bandoni

1984). *Colacogloea (Platygloea) peniophorae* (Fig. 298), which parasitizes corticiaceous hosts, produces abundant dikaryotic conidia and auricularioid basidia on the host hymenium.

The yeast state in *Platygloea fimicola* is pink (R.J. Bandoni, unpublished observations), whereas that of *C. peniophorae* is white. Yeast states also occur in *Tjibodasia pezizoidea* Holtermann (Holtermann 1898) and in *Mycogloea* spp. (Olive 1950, Bandoni 1984).

Mycogloea includes four described species with gelatinous pustulate basidiomata bearing abundant basidia (Fig. 299). The basidia, cylindric and 2–4-celled, are deciduous at maturity and are thus important disseminules. Unusual is the ability of the basidia to produce either sessile, passively released basidiospores or ballistospores on sterigmata (Olive 1950).

4.2.9. Tremellales: The Tremellales include three families, the largest of which, the Tremellaceae, comprises 5 genera and ca. 500 binomials, of which perhaps 150 are distinct species. Primarily on the basis of field observations, the species are thought to be mycoparasites that occur on ascomycetes or basidiomycetes, especially those colonizing recently killed woody twigs, and on lichens. Species of *Tremella* occur in dacrymycetaceous basidiocarps (Figs. 300, 301), on hymenia of polypores,

Fig. 297. *Platygloea fimetaria* (Schumacher:Persoon) Höhnel (Platygloales). (A) Thin-walled probasidia with basidial initials. (B) Developing basidia. (C) Portion of mature basidium with attached basidiospore. (D) Basidiospores, one germinating by repetition. RJB 693, Canada. Bar = 10 μ m.

¹ *Platygloea fimetaria* may be a synonym of *Cytobasidium lasioboli*, but this is not yet certain.

on hymenia of corticioid fungi (Fig. 302), growing from perithecial ostioles or on pyrenomycete stromata, in apothecia of bitunicate ascomycetes, and on lichen thalli. Some species (e.g., *Tremella mesenterica*, Fig. 302), grow on wood often with no conspicuous physical contact with other fungi. In *T. mesenterica*, however, haustorial branches can often be found attached to structures of nearby fungi. *Tremella* is not a natural genus as is apparent from both morphological studies and biochemical analyses. However, few species have been examined intensively by any method.

Bulleromyces Boekhout & A. Fonseca (Boekhout et al. 1991a), a recently added taxon in the Tremellaceae, is based upon a teleomorph obtained by mating strains of *Bullera alba*. The single species, *Bulleromyces albus*, produces dikaryotic hyphae when compatible strains are mated in culture. Basidiocarps are not produced, but typical tremellaceous basidia develop on the hyphae, which may produce buds or ballistospores. Other characteristics are the presence of *Tremella*-like haustorial branches, dolipores with a cupulate parentheses, assimilation of *myo*-inositol and D-glucuronate, and the production of extracellular starch-like compounds. Partial 26S rRNA se-

Bar = 10 μ m.

quences of the anamorph *Bullera alba*, suggest *B. albus* to have a close phylogenetic relationship with *Cryptococcus laurentii* (Fell et al. 1992). Van de Peer et al. (1992) found *Bullera alba* to be a sister species of *Filobasidiella neoformans* based on the entire 18S ribosomal RNA sequences.

Trimorphomyces, a monotypic genus, differs from *Tremella* by having a distinctive dikaryotic yeast state in addition to the haploid one (Figs. 303, 304). The minute basidiomes typically have mixed conidia and basidia, with the latter generally present in low numbers. Conidiogenesis is identical to bud development in the dikaryotic yeast cells. The conidia can give rise directly to a dikaryotic yeast state upon germination.

Phyllogloea tremelloidea Lowy, a species with "auricularioid" basidia, but with *Tremella*-type dolipore septa, belongs in the Tremellaceae (F. Oberwinkler, personal communication), as do the species of *Xenolachne* Rogers. The latter have haustorial branches of the *Tremella* type and are parasites of discomycetes. Yeast phases are unknown in these species, although budding has been observed in both groups.

Fig. 302. Tremellales. (A) *Sirobasidium magnum* Boedijn basidiocarp, A-A and RJB 9082, Taiwan. Bar = 1 mm. (B) Two dikaryotic yeast cells (arrows) germinating in the presence of host hyphae (not visible); the lower cell is much distorted, its form characteristic of older cells that have produced many buds (a mature bud is attached to it on the left). Each germinating cell has produced a short hypha and haustorial branch; ungerminated dikaryotic yeast cells are present on the right, culture of RJB 6646, Type, Canada. Bar = 5 μ m. (C) *Holtermannia* sp., basidiocarps, A-A and RJB 9832, Thailand. Bar=0.5 mm. Photo courtesy of Dr. T. Flegel.

Holtermannia species have basidiomes composed of aggregates of erect, simple or branched teeth. Although mycoparasitism was not mentioned by Kobayasi (1937) in his monograph, a common Thai species occurs only on shelving polypore basidiocarps or on wood heavily

decayed by a white pocket rot fungus (R.J. Bandoni, unpublished observations).

Species of *Sirotrema* Bandoni (1986) grow in the hymenia of phacidiaceous apothecia (Figs. 302, 305), producing minute gelatinous basidiomata. The basidia often occur in short chains and the epibasidia are retained on the basidia. *Sirotrema* has some intermediate characteristics between the Tremellaceae and Sirobasidiaceae which, taken with other intermediate taxa currently placed in *Tremella*, suggests that the family Sirobasidiaceae is superfluous. However, recent molecular studies (E.C. Swann, personal communication) indicate a more distant relationship and additional analyses are needed.

The second family of Tremellales with a yeast state, the Sirobasidiaceae, currently contains only two genera, *Sirobasidium* and *Fibulobasidium*. In *Sirobasidium*, basidia are catenate (Figs. 306, 307), maturing basipetally from successive lower cells of fertile hyphae. The basidiospores, clavate to fusiform and passively released, are probably homologs of *Tremella* epibasidia (Bandoni 1957). *Fibulobasidium* basidia develop by direct expansion of successively formed clamp connections with the basidia laterally fused (Fig. 308). Basidiomata of *Sirobasidium* spp. are exposed and conspicuous, whereas those of *Fibulobasidium* species are subcortical on recently killed branches. As in *Sirobasidium*, the fusiform, passively released basidiospores of *F. inconspicuum* can germinate either by budding or by producing a sterigma and ballistospore.

Itersonilia Derx, an anamorphic genus placed by von Arx et al. (1977) in the Filobasidiaceae, appears to be related to the Tremellales/Filobasidiales because of its dolipore septum and the presence of xylose in whole-cell hydrolyzates. However, a parentheses is absent, and molecular data suggest a more distant relationship (Fell et al. 1995). *Sterigmatosporidium polymorphum* Kraepelin and Schulze (1982) also seems related to the Tremellales or Filobasidiales.

4.2.10. Filobasidiales: The Filobasidiales, which appear to be closely related to the Tremellales, lack conspicuous basidiocarps and have holobasidia and passively released basidiospores. They have the *Tremella*-type haustorial branches. Most species with yeast states are placed in the family Filobasidiaceae L.S. Olive (1968) but some are also classified in the Syzygosporaceae Jülich. The order is restricted to teleomorphic, heterobasidiomycetous yeasts and yeastlike fungi. Budding is enteroblastic and hyphae usually form clamp connections and haustorial branches; teliospores are usually absent; holobasidia are clavate with sessile basidiospores; cell walls are lamellate and hyphal septa, if perforate, have dolipores; parentheses, if present, are cupulate; xylose is present in whole-cell hydrolyzates. The type genus is *Filobasidium*; other genera belonging here are *Filobasidiella* and probably *Cystofilobasidium*, *Mrakia* and *Xanthophyllomyces* Golubev (Golubev 1995).

Based on basidial morphology and the manner in which dikaryotization occurs in *Filobasidium floriforme*, Olive (1968) placed the Filobasidiaceae in the Ustilaginales, which in his concept included both Ustilaginaceae and Tilletiaceae. The family was established to accommodate *Filobasidium floriforme*, found in a culture dish in which dead florets of *Erianthus giganteus* had been placed (Olive 1968). Three species of *Filobasidium* on *Yucca brevifolia* (Fig. 309) produce aggregates of basidia that can readily be seen with low magnification (Bandoni et al. 1991). *Filobasidiella*, containing the only animal parasitic species known in the group, has basidia like those in *Filobasidium* spp., but basidiospores develop in basipetal chains. Haustorial branches are found in *Filobasidiella neoformans*, suggesting that the species primarily is a fungal parasite and secondarily acts as an opportunistic animal pathogen.

Thick-walled teliospores are present in *Cystofilobasidium*, but are absent in the remaining genera of the Filobasidiales. *Cystofilobasidium* has Co-Q 8, *Filobasidiella* and *Xanthophyllomyces* Co-Q 10 (Sugiyama et al. 1985), and *Filobasidium* either Co-Q 9 or 10 (Yamada and Kondo 1972a, 1973).

Filobasidium capsuligenum and *Xanthophyllomyces dendrorhous* (anamorph *Phaffia rhodozyma*) are able to ferment glucose, whereas the remaining taxa are unable to ferment carbohydrates. All taxa assimilate *myo*-inositol

Fig. 309. *Filobasidium globosporum* Bandoni & Oberwinkler (Filobasidiales). (A) Two spent basidia. (B) Young basidium. (C) Upper portion of basidium with spores still attached. (D) Adherent basidiospores as released from basidia. A-A and RJB 8197B, California. Bar = 10 μ m.

and D-glucuronate, and produce extracellular starch-like compounds.

The species are either homothallic or heterothallic, the latter apparently controlled by biallelic unifactorial mating systems. Upon conjugation, clamped dikaryotic hyphae develop, which may form haustorial branches. Basidia are clavate, and basidiospores are formed terminally. Species of the Filobasidiaceae differ from the Sporidiobolaceae by the presence of dolipores and the presence of xylose in their cell walls (Sugiyama et al. 1985, Boekhout et al. 1992b, 1993, Prillinger et al. 1993).

Cox (1976) proposed transferring the Filobasidiaceae to the Aphyllphorales (Holobasidiomycetes/Homobasidiomycetes), because of the presence of holobasidia. Jülich (1981) established the order Filobasidiales to accommodate the Filobasidiaceae, without indicating the demarcation between Filobasidiales and Tremellales. The Filobasidiaceae were considered by Oberwinkler (1987) to be sufficiently close to the Tremellales to constitute a family in that order. This interpretation has since been supported by comparison of 18S rRNA gene sequencing studies (Swann and Taylor 1993). Subdivision of the basidiomycetes based on basidial morphology is no longer accepted because basidial form and septation appear to be less reliable criteria than septal pore ultrastructure and ribosomal DNA sequences for determining relationships among these fungi (Bandoni 1984, Walker 1984, Gottschalk and Blanz 1985, Fell et al. 1992). The distinction of Filobasidiales and Tremellales is not

Table 66, notes

^a Although economically important smuts have been studied in detail, type of teliospore germination is unknown in many species. Direct conjugation of basidial cells occurs in some taxa with *Ustilago*-like basidia and this can result in the complete absence or infrequent occurrence of a yeast state.

^b *Kriegeria (Xenogloea) eriophori* (monotypic) parasitizes monocots; its relationship to the mycoparasitic taxa placed in the Cystobasidiaceae and to most other Platygliales, may be distant.

^c Yeast states probably occur in these two genera.

^d Basidia can be cylindrical, transversely septate (e.g., in *Stilbum*), or clavate, holobasidia (e.g., as in *Chionosphaera*).

^e *Itersonilia perplexans* appears to belong in this group (but see also under f), but basidia have not been found. Because of the known features, and the rather isolated position among anamorphic yeast groups, it is classified with the Tremellales here.

^f *Cystofilobasidium* has thick-walled teliospores which germinate with holobasidia. Because of biochemical traits such as cell wall composition, dolipores without parenthesomes, and apparently unique molecular characteristics, we tentatively place the genus here. Recent partial 26S rDNA sequences (Fell et al. 1992, 1995) suggest a more distant relationship between *Cystofilobasidium*, *Mrakia*, *Xanthophyllomyces* and *Itersonilia* on one side with the Tremellales and the genera *Filobasidium* and *Filobasidiella* on the other.

supported by partial 26S rRNA sequences (Fell et al. 1992, 1995, Guého et al. 1993), nor by 18S rDNA sequences (Swann and Taylor 1993). For definitive conclusions, more taxa need to be studied with molecular methods. Therefore, and for reasons of convenience, we maintain the Filobasidiaceae in the Filobasidiales, as they are represented by a number of morphologically uniform genera, which share holobasidia, lack ballistospores, mostly lack basidiocarps and frequently have a different ecology. Recent molecular analyses suggest that the teliospore-forming taxa, such as *Cystofilobasidium* and *Mrakia*, do not form a monophyletic group with *Filobasidiella* and *Filobasidium* (Fell et al. 1995, Swann and Taylor 1993, 1995a).

Filobasidium and *Filobasidiella* are characterized by haustorial branches (Olive 1968, Kwon-Chung 1975) similar to those seen in *Tremella*, and the septal pore apparatus is also similar in the two groups (Moore and Kreger-van Rij 1972, Bandoni 1987, Moore 1978, 1987b, Khan 1976, Patrignani et al. 1984). Moreover, species of *Filobasidium* and *Filobasidiella* produce an extracellular polysaccharide with a chemical structure similar to that occurring in *Tremella* species (Battacharjee et al. 1978), and extracellular enzymes, such as deoxyribonuclease produced by *Filobasidium* and *Filobasidiella* are also found in *Tremella* species. The main differentiating character between the Filobasidiales and Tremellales is the presence of holobasidia in the first group, whereas the second group usually has cruciately septate basidia (Oberwinkler 1987, Bandoni 1987).

Syzygospora and *Christiansenia* species parasitize basidiomycetes or ascomycetes, inducing tumor-like swellings in some hosts, e.g., *Christiansenia* spp. on *Collybia dryophila* (Ginns and Sunhede 1978). Basidiocarps and yeast states of *Syzygospora alba* Martin are similar to those of some *Tremella* spp. Haploid states of *Christiansenia* species examined by Ginns (1986) were “yeastlike” and similar to those in some species of *Exobasidium*, but a yeast state is known in *C. pallida* (Oberwinkler et al. 1984). The haustorial apparatus in this species is similar to that in tremellaceous fungi (Bauer and Oberwinkler 1990b).

In the previous edition of this book, the genus *Chionosphaera* was included in the family Filobasidiaceae based on Cox's description of the genus. *Chionosphaera*, however, has been transferred to the Chionosphaeriaceae (Atractiellales, see above) by Oberwinkler and Bandoni (1982c). *Chionosphaera apobasidialis*, the type species, does not fit into the Filobasidiaceae, because of the presence of capitate basidiocarps, the absence of dolipores, and the inability to assimilate *myo*-inositol.

The monotypic genus *Rogersomyces* was placed in the family Filobasidiaceae by Crane and Schoknecht (1978). This genus does not fit into the Filobasidiaceae, since *R. okefenokeensis* produces holobasidia with basidiospores formed on sterigmata.

The system of classification accepted for heterobasidiomycetous taxa in the present edition of *The Yeasts*, is outlined in Table 66.

1. Diagnostic descriptions

1.1. Teleomorphic genera

1.1.1. *Agaricostilbum*:

Vegetative reproduction: Yeast colonies are yellowish-cream and butyrous. Yeast cells are ellipsoidal-fusoidal, sometimes adhering in chains and with polar budding.

Sexual reproduction: Basidiocarps are synnemata-like. Hyphae lack clamp connections. Basidia are cylindrical, 4-celled and transversely septate, with the basidiospores laterally budding off (Figs. 292A, 293). Septal pores are “simple”.

Physiology: Fermentation is absent. D-Glucuronate is assimilated, *myo*-inositol and nitrate are not assimilated. Starch-like compounds are not produced. Diazonium blue B and urease reactions are positive. Coenzyme Q is not determined. Xylose is absent in whole-cell hydrolyzates.

1.1.2. *Bulleromyces*:

Vegetative reproduction: Yeast colonies are cream-colored and butyrous to mucoid. Yeast cells are ellipsoidal, subglobose to cylindrical with polar budding; pseudohyphae may be present. Ballistoconidia are rotationally symmetrical.

Sexual reproduction: Basidiocarps are absent. Hyphae have clamp connections. Basidia are tremelloid with 2–4 cells. Septal pores are dolipores with cupulate parenthesomes.

Physiology: Fermentation is absent. D-Glucuronate and *myo*-inositol are assimilated; nitrate is not assimilated. Starch-like compounds are produced. Diazonium blue B and urease reactions are positive. Coenzyme Q-10 is formed. Xylose is present in whole-cell hydrolyzates.

1.1.3. *Chionosphaera*:

Vegetative reproduction: Yeast colonies are cream-colored and butyrous to mucoid. Yeast cells are ellipsoidal to allantoidal and have polar budding.

Sexual reproduction: Basidiocarps are stilbelloid, waxy-arid or subgelatinous. Hyphae lack clamp connections.

Basidia are 1-celled and clavate, with sessile basidiospores (Figs. 292B, 294). Septal pores are “simple”.

Physiology: Fermentation is absent. D-Glucuronate, *myo*-inositol and nitrate are not assimilated. Starch-like compounds are produced. Diazonium blue B and urease reactions are positive. Coenzyme Q-10 is formed. Cell-wall composition is not determined.

1.1.4. *Cystofilobasidium*:

Vegetative reproduction: Yeast colonies are orange, salmon, cinnamon or pale. Yeast cells are ovoidal to elongate, and pseudohyphae may be present.

Sexual reproduction: Basidiocarps are absent. Hyphae may or may not have clamp connections. Endospores are sometimes present. Teliospores are present. Basidia are 1-celled, and clavate or capitate. Septal pores are dolipores without parenthesomes.

Physiology: Fermentation is usually absent. D-Glucuronate, *myo*-inositol and nitrate are assimilated. Starch-like compounds are produced. Diazonium blue B and urease reactions are positive. Coenzyme Q-8 is formed. Xylose is present in whole-cell hydrolyzates.

1.1.5. *Erythrobasidium*:

Vegetative reproduction: Yeast colonies are orange-red. Yeast cells are ovoidal to elongate, and have multilateral budding.

Sexual reproduction: Basidiocarps are absent. Hyphae have pseudoclampe connections. Basidia are 1-celled. Septal pores are “simple”.

Physiology: Fermentation is absent. D-Glucuronate and nitrate are assimilated, but *myo*-inositol is not assimilated. Starch-like compounds are not produced. Diazonium blue B and urease reactions are positive. Coenzyme Q-10(H₂) is formed. Xylose is absent in whole-cell hydrolyzates.

1.1.6. *Fibulobasidium*:

Vegetative reproduction: Yeast colonies are grayish to brownish-yellow, and butyrous. Yeast cells are subglobose to globose. Ballistoconidia are rotationally symmetrical.

Sexual reproduction: Basidiocarps are pulvinate and gelatinous. Hyphae have clamp connections. Basidia are tremelloid, occur in chains and develop from successively formed basal clamp connections of earlier basidia (Fig. 308). Septal pore structure is not known.

Physiology: Fermentation is absent. D-Glucuronate and *myo*-inositol are assimilated; nitrate assimilation is absent or weak. Starch-like compounds are produced. Diazonium blue B and urease reactions are positive. Coenzyme Q-9 is formed. Cell-wall composition is not determined.

1.1.7. *Filobasidiella*:

Vegetative reproduction: Yeast colonies are whitish to yellowish-cream and usually mucoid. Yeast cells are globose, ovoidal, apiculate, and have polar or multilateral budding.

Sexual reproduction: Basidiocarps are absent. Hyphal colonies, if present, are whitish and velutinous. Hyphae usually have clamp connections. Basidia are 1-celled and stipitate-capitate with basipetally formed chains of basidiospores. Septal pores are dolipores with or without cupulate parenthesesomes.

Physiology: Fermentation is absent. D-Glucuronate and *myo*-inositol are assimilated; nitrate is not assimilated. Starch-like compounds are produced. Diazonium blue B and urease reactions are positive. Coenzyme Q-10 is formed. Xylose is present in whole-cell hydrolyzates.

1.1.8. *Filobasidium*:

Vegetative reproduction: Yeast colonies are white, cream or pinkish and mucoid. Yeast cells are globose, ovoidal, ellipsoidal or elongate. Pseudohyphae may be present.

Sexual reproduction: Basidiocarps are absent. Hyphae have clamp connections. Basidia are 1-celled and clavate, with sessile basidiospores (Fig. 309). Septal pores are dolipores with or without cupulate parenthesesomes.

Physiology: Fermentation may be present. D-Glucuronate, *myo*-inositol and nitrate are sometimes assimilated. Starch-like compounds are produced. Diazonium blue B and urease reactions are positive. Coenzyme Q-9 or 10 are formed. Xylose is present in whole-cell hydrolyzates.

1.1.9. *Holtermannia*:

Vegetative reproduction: Yeast colonies are yellowish-white and mucoid. Yeast cells are ellipsoidal and have polar budding.

Sexual reproduction: Basidiocarps are erect, coralloid, gelatinous, and occur in dense aggregates (Fig. 303C). Hyphae have clamp connections. Basidia are tremelloid. Septal pore structure is not known.

Physiology: Fermentation is absent. D-Glucuronate and *myo*-inositol are assimilated; nitrate is not assimilated. Starch-like compounds are produced. Diazonium blue B and urease reactions are positive. Coenzyme Q is not determined. Xylose is present in whole-cell hydrolyzates.

1.1.10. *Leucosporidium*:

Vegetative reproduction: Yeast colonies are cream-colored and mucoid. Yeast cells are ovoidal to elongate and pseudohyphae may be present.

Sexual reproduction: Basidiocarps are absent. Hyphae usually have clamp connections. Teliospores are present. Basidia are transversely septate. Septal pores are "simple".

Physiology: Fermentation is absent. D-Glucuronate is sometimes assimilated; *myo*-inositol is not assimilated; nitrate is assimilated. Starch-like compounds are not produced. Diazonium blue B and urease reactions are positive. Coenzyme Q-9 or 10 are formed. Xylose is absent in whole-cell hydrolyzates.

1.1.11. *Mrakia*:

Vegetative reproduction: Yeast colonies are whitish or cream-colored and mucoid. Yeast cells are ovoidal to elongate, and pseudohyphae may be present.

Sexual reproduction: Basidiocarps are absent. Hyphae lack clamp connections. Teliospores are present. Basidia are 1-celled or transversely septate. Septal pores are dolipores without parenthesesomes.

Physiology: Glucose and sometimes galactose may be fermented. D-Glucuronate and nitrate are assimilated, and *myo*-inositol is sometimes assimilated. Starch-like compounds are produced. Diazonium blue B and urease reactions are positive. Coenzyme Q-8 is formed. Xylose is present in whole-cell hydrolyzates. Maximum temperature of growth is below 20°C.

1.1.12. *Rhodosporidium* (this treatment includes *Kondoa* and *Sakaguchia*):

Vegetative reproduction: Yeast colonies are orange, red or yellowish, and butyrous to mucoid. Yeast cells are ovoidal to elongate, and pseudohyphae may be present.

Sexual reproduction: Basidiocarps are absent. Hyphae may or may not have clamp connections. Teliospores are present. Basidia are transversely septate (Fig. 291). Septal pores are "simple".

Physiology: Fermentation is absent. D-Glucuronate and nitrate are sometimes assimilated, but *myo*-inositol is not assimilated. Starch-like compounds are not produced. Diazonium blue B and urease reactions are positive. Coenzyme Q-9 or 10 are formed. Xylose is absent in whole-cell hydrolyzates.

1.1.13. *Sirobasidium*:

Vegetative reproduction: Yeast colonies are yellowish to yellowish-cream and mucoid. Yeast cells are ellipsoidal to subglobose and have polar budding. Ballistoconidia are bilaterally symmetrical. Pseudohyphae may be present.

Sexual reproduction: Basidiocarps are pulvinate to irregularly lobed or foliaceous. Hyphae have clamp connections. Basidia are tremelloid, occur in chains, and mature basipetally from contiguous cells of fertile hyphae (Figs. 302A, 306, 307). Septal pores are dolipores with cupulate parenthesesomes.

Physiology: Fermentation is absent. D-Glucuronate and *myo*-inositol are assimilated; nitrate is not assimilated. Starch-like compounds are produced. Diazonium blue B

and urease reactions are positive. Coenzyme Q and cell-wall composition are not determined.

1.1.14. *Sporidiobolus*:

Vegetative reproduction: Yeast colonies are reddish to pink. Yeast cells are ellipsoidal to elongate and have polar budding. Ballistoconidia are bilaterally symmetrical. Pseudohyphae may be present.

Sexual reproductions: Basidiocarps are absent. Hyphae usually have clamp connections. Teliospores are present. Basidia are usually transversely septate, but sometimes 1-celled. Septal pores are "simple".

Physiology: Fermentation is absent. D-Glucuronate and *myo*-inositol are not assimilated; nitrate is sometimes assimilated. Starch-like compounds are not produced. Diazonium blue B and urease reactions are positive. Coenzyme Q-10 is formed. Xylose is lacking in whole-cell hydrolyzates.

1.1.15. *Sterigmatosporidium*:

Vegetative reproduction: Yeast colonies are cream-colored and butyrous. Yeast cells are ellipsoidal to elongate, and have polar budding, usually on stalks with the septa at the distal end. Pseudohyphae are present.

Sexual reproduction: Basidiocarps are absent. Hyphae have clamp connections. Dikaryotic chlamydospore-like structures are present. Basidia-like structures are 1-celled. Septal pore structure is not known.

Physiology: Fermentation is absent. D-Glucuronate and *myo*-inositol are assimilated; nitrate is not assimilated. Starch-like compounds are produced. Diazonium blue B and urease reactions are positive. Coenzyme Q-10 is formed. Xylose is present in whole-cell hydrolyzates.

1.1.16. *Tilletiaria*:

Vegetative reproduction: Colonies are grayish-brown and tough. Yeast cells are absent. Hyphae lack clamp connections. Chlamydospores are present. Ballistoconidia are bilaterally symmetrical.

Sexual reproduction: Basidiocarps are absent. Teliospores are echinulate and brown. Basidia are transversely septate. Septal pores are "primitive" dolipores without parentheses.

Physiology: Fermentation is absent. D-Glucuronate is assimilated, but *myo*-inositol and nitrate are not assimilated. Starch-like compounds are not produced. Diazonium blue B reaction is not determined, but the urease reaction is positive. Coenzyme Q-10 is formed. Xylose is absent from whole-cell hydrolyzates.

1.1.17. *Tremella*:

Vegetative reproduction: Yeast colonies are cream-colored to pale brown and mucoid. Yeast cells are ellipsoidal, subglobose to globose, and have polar or multipolar budding. Pseudohyphae may be present.

Sexual reproduction: Basidiocarps are usually foliaceous, effuse, pulvinate or cerebriform, but may be absent in some taxa. Hyphae usually have clamp connections. Basidia are tremelloid (Figs. 290A–G, 300, 301,

302C,D). Septal pores are dolipores with cupulate parentheses.

Physiology: Fermentation is absent. D-Glucuronate and *myo*-inositol may or may not be assimilated, but nitrate is not assimilated. Starch-like compounds may or may not be produced. Diazonium blue B and urease reactions are positive. Coenzyme Q-10 is formed. Xylose is present in whole-cell hydrolyzates.

1.1.18. *Trimorphomyces*:

Vegetative reproduction: Haploid yeast colonies are pale pinkish-yellow to pinkish-brown and butyrous. The cells are subglobose, ellipsoidal, somewhat triangular, or elongate, and have polar or multipolar budding. Dikaryotic yeast colonies are of similar appearance, but the yeast cells here are H-shaped in most strains. The H-shaped cells develop synchronously as closely situated, mostly polar "twins"; they conjugate before maturity and are released as new H-shaped cells (Fig. 304).

Sexual reproduction: Basidiocarps are small, pulvinate, and occur associated with *Arthrimum* on bamboo and other grasses. Hyphae have clamp connections. Basidia are tremelloid (Figs. 303A,B, 304). Septal pores are dolipores with cupulate parentheses.

Physiology: Fermentation is absent. D-Glucuronate is assimilated, *myo*-inositol is sometimes assimilated, but nitrate is not assimilated. Starch-like compounds are sometimes produced. Diazonium blue B and urease reactions are positive. Coenzyme Q is not determined. Xylose is present in whole-cell hydrolyzates.

1.1.19. *Xanthophyllomyces*:

Vegetative reproduction: Yeast colonies are orange to salmon-red and butyrous. Yeast cells are ellipsoidal. Pseudohyphae and chlamydospores may be present.

Sexual reproduction: Basidiocarps are absent. Hyphae are absent. Basidia originate from conjugation between a cell and its bud, and are 1-celled.

Physiology: Fermentation is present. D-Glucuronate is assimilated, but *myo*-inositol and nitrate are not assimilated. Starch-like compounds are produced. Diazonium blue B and urease reactions are positive. Coenzyme Q-10 is formed. Xylose is present in whole-cell hydrolyzates.

1.2. Anamorphic genera

1.2.1. *Bensingtonia*:

Vegetative reproduction: Colonies are whitish, pinkish, ochraceous, brown to grayish-red, and butyrous. Yeast cells are ellipsoidal, ovoidal to elongate, and usually have polar budding. Ballistoconidia are bilaterally symmetrical. Chlamydospores, hyphae and pseudohyphae may be present. Septal pores, if present, are "simple" (teliospore formation has been observed in matings of *B. intermedia*, personal communication, W.I. Golubev).

Physiology: Fermentation is absent. D-Glucuronate and

nitrate are sometimes assimilated, but *myo*-inositol is not assimilated. Starch-like compounds are not produced. Diazonium blue B and urease reactions are positive. Coenzyme Q-9 is formed. Xylose is absent in whole-cell hydrolyzates.

1.2.2. *Bullera* (including *Udeniomyces*; teleomorph is *Bulleromyces*):

Vegetative reproduction: Colonies are whitish, orange to reddish-brown, and butyrous to mucoid. Yeast cells are subglobose, ellipsoidal to elongate, and usually have polar budding. Hyphae and pseudohyphae may be present. Ballistoconidia are rotationally symmetrical (in *Bullera* sensu stricto) or bilaterally symmetrical (in *Udeniomyces*). Septal pores, if present, are dolipores with cupulate parentheses (clamp connections are present in the dikaryophase of *B. variabilis*).

Physiology: Fermentation is absent. D-Glucuronate is assimilated, and *myo*-inositol and nitrate are sometimes assimilated. Starch-like compounds are sometimes produced. Diazonium blue B and urease reactions are positive. Coenzyme Q-10 is formed. Xylose is present in whole-cell hydrolyzates. (Note: considerable evidence suggests that *Udeniomyces* represents a separate genus, distinct by bilaterally symmetrical ballistoconidia, presence of collarettes and assimilation of nitrate).

1.2.3. *Cryptococcus* (yeast stages of Tremellales are similar to *Cryptococcus*):

Vegetative reproduction: Colonies are whitish, cream-colored, reddish, yellowish to brown, and usually mucoid. Yeast cells are globose to subglobose, ovoidal to elongate, and with polar or multilateral budding. Hyphae and pseudohyphae may be present. Chlamydospore-like cells and clamp connections may be formed following conjugation. Septal pores, if present, are dolipores without parentheses.

Physiology: Fermentation is absent. D-Glucuronate is assimilated, *myo*-inositol is usually assimilated, and nitrate is sometimes assimilated. Starch-like compounds are usually produced. Diazonium blue B and urease reactions are positive. Coenzyme Q-8, 9 or 10 are formed. Xylose is present in whole-cell hydrolyzates.

1.2.4. *Fellomyces*:

Vegetative production: Colonies are cream-colored and butyrous. Yeast cells are globose to subglobose to ellipsoidal, with budding occurring on stalks with the septa at the distal ends. Hyphae and pseudohyphae may be present. Septal pore structure is not determined.

Physiology: Fermentation is absent. D-Glucuronate and *myo*-inositol are assimilated; nitrate is not assimilated. Starch-like compounds are produced. Diazonium blue B and urease reactions are positive. Coenzyme Q-10 is formed. Xylose is present in whole-cell hydrolyzates.

1.2.5. *Hyalodendron* (possibly synonymous with *Trichosporon*, G.S. de Hoog, personal communication):

Vegetative reproduction: Colonies are whitish to cream-colored and farinose to velvety. Hyphae may disarticulate. Truncate blastoconidia occur in acropetal chains. Chlamydospore-like structures and yeastlike cells may be present. Septal pores are dolipores with cupulate parentheses.

Physiology: Fermentation is absent. D-Glucuronate assimilation is not known; *myo*-inositol is assimilated, but nitrate is not assimilated. Production of starch-like compounds is not known. Diazonium blue B and urease reactions are positive. Coenzyme Q-9 is formed. Xylose is present in whole-cell hydrolyzates.

1.2.6. *Itersonia*:

Vegetative reproduction: Hyphal colonies are whitish, hairy, velvety, arachnoid or velutinous. Hyphae have clamp connections and chlamydospore-like ("sporogenous") cells. Ballistoconidia are bilaterally symmetrical. Yeast colonies are yellowish cream-colored and butyrous. Yeast cells are ellipsoidal to elongate, and usually have polar budding. Hyphae and pseudohyphae may be present. Septal pores are dolipores without parentheses.

Physiology: Fermentation is absent. D-Glucuronate is assimilated, *myo*-inositol is sometimes assimilated, and nitrate is usually assimilated. Starch-like compounds are not produced. Diazonium blue B and urease reactions are positive. Coenzyme Q-9 is formed. Xylose is present in whole-cell hydrolyzates. (*I. perplexans* may represent a cryptic teleomorph).

1.2.7. *Kockovaella*:

Vegetative reproduction: Colonies are grayish-orange to yellow, and butyrous to mucoid. Yeast cells are globose to subglobose, ellipsoidal to kidney-shaped, and with budding on stalks with the septa at the distal end. Ballistoconidia are bilaterally symmetrical. Hyphae and pseudohyphae are absent.

Physiology: Fermentation is absent. D-Glucuronate and *myo*-inositol are assimilated, but nitrate is not assimilated. Starch-like compounds are not produced. Diazonium blue B and urease reactions are positive. Coenzyme Q-10 is formed. Xylose is present in whole-cell hydrolyzates.

1.2.8. *Kurtzmanomyces*:

Vegetative reproduction: Colonies are pinkish and butyrous. Yeast cells are globose to subglobose, ovoidal to cylindrical, and with budding on stalks with the septa at the distal end. Hyphae may be present. Septal pore structure is not known.

Physiology: Fermentation is absent. D-Glucuronate and *myo*-inositol are not assimilated; nitrate is assimilated. Starch-like compounds are not produced. Diazonium blue B and urease reactions are positive. Coenzyme

Q-10 is formed. Xylose is absent in whole-cell hydrolyzates.

1.2.9. *Malassezia*:

Vegetative growth: Colonies are pale yellowish-brown and butyrous to rather dry. Yeast cells are globose to subglobose to ellipsoidal, and usually have monopolar budding, but occasionally sympodial proliferation occurs. Septal pores are absent or "micropore"-like. (Note: short hyphae can be present on skin.)

Physiology: Fermentation is absent. D-Glucuronate, *myo*-inositol, nitrate assimilation and production of starch-like compounds are not determined. Coenzyme Q-9 is formed. Xylose is absent in whole-cell hydrolyzates.

1.2.10. *Moniliella*:

Vegetative growth: Colonies initially are cream-colored, but soon become grayish to olivaceous-black, and are smooth to velvety. Hyphae may disarticulate. Acropetal chains of truncate blastoconidia originate from short denticles. Thick-walled, clavate, aseptate setae, chlamydospores and pseudohyphae may be present. Yeast cells are ellipsoidal to subcylindrical. Septal pores are dolipores without parenthesomes.

Physiology: Fermentation is present. D-Glucuronate assimilation is not known; *myo*-inositol is not assimilated, but nitrate is assimilated. Production of starch-like compounds is not known. Coenzyme Q-9 is formed. Xylose is absent from whole-cell hydrolyzates.

1.2.11. *Phaffia* (teleomorph *Xanthophyllumycetes*):

Vegetative growth: Colonies are orange to salmon-red, and butyrous. Yeast cells are ellipsoidal. Pseudohyphae and chlamydospores may be present.

Physiology: Fermentation is present. D-Glucuronate is assimilated, but *myo*-inositol and nitrate are not assimilated. Starch-like compounds are produced. Diazonium blue B and urease reactions are positive. Coenzyme Q-10 is formed. Xylose is present in whole-cell hydrolyzates.

1.2.12. *Pseudozyma* (teleomorphs may belong to the *Ustilaginales*):

Vegetative reproduction: Colonies are whitish, pinkish, orange or brown, and usually dimorphic. Hyphae are present and lack clamp connections. Acropetal chains of fusiform blastoconidia originate from lateral sterigmata-like structures. Chlamydospores may be present. Yeast cells are ellipsoidal, ovoidal to cylindrical, and usually have polar budding. Pseudohyphae may be present. Septal pores, if present, are "micropore"-like structures.

Physiology: Fermentation is absent. D-Glucuronate, *myo*-inositol and nitrate are assimilated. Starch-like compounds are not produced. Diazonium blue B and urease reactions are positive. Coenzyme Q-10 is formed. Xylose is absent in whole-cell hydrolyzates.

1.2.13. *Reniforma*:

Vegetative reproduction: Colonies are white to cream-colored, and waxy or dry. Yeast cells are allantoidal and

frequently occur in stacks. Hyphae and pseudohyphae are absent.

Physiology: Fermentation is absent. D-Glucuronate assimilation is not known, and *myo*-inositol and nitrate are not assimilated. Starch-like compounds are not produced. Diazonium blue B and urease reactions are positive. Coenzyme Q-7 is formed. Xylose is absent in whole-cell hydrolyzates.

1.2.14. *Rhodotorula* (teleomorphs belong to *Rhodospodidium*):

Vegetative reproduction: Colonies are orange, red, yellow or pale, and butyrous to mucoid. Yeast cells are globose to subglobose, ellipsoidal, ovoidal to elongate, and usually have polar budding. Hyphae and pseudohyphae may be present. Septal pore structure is not known.

Physiology: Fermentation is absent. D-Glucuronate and nitrate are sometimes assimilated, but *myo*-inositol is usually not assimilated. Starch-like compounds are not produced. Diazonium blue B and urease reactions are positive. Coenzyme Q-9 or 10 is formed. Xylose is absent in whole-cell hydrolyzates.

1.2.15. *Sporobolomyces* (including *Ballistosporomyces*; teleomorphs belong to *Sporidiobolus*):

Vegetative reproduction: Colonies are pink, orange, red, yellowish or pale, and butyrous to mucoid. Yeast cells are globose to subglobose, ellipsoidal, fusoidal to cylindrical, and usually have polar budding, but multilateral budding may occur as well. Ballistoconidia are bilaterally symmetrical. Hyphae and pseudohyphae may be present. Septal pore structure is not known.

Physiology: Fermentation is absent. D-Glucuronate and nitrate may or may not be assimilated, and *myo*-inositol is usually not assimilated. Starch-like compounds are not produced. Diazonium blue B and urease reactions are positive. Coenzyme Q-10 or 10 (H₂) are formed. Xylose is absent from whole-cell hydrolyzates.

1.2.16. *Sterigmatomyces*:

Vegetative reproduction: Colonies are white or cream-colored and butyrous. Yeast cells are globose to subglobose to ovoidal, and with budding on stalks with the septum in the mid-region. Hyphae and pseudohyphae may be present. Septal pore structure is not known.

Physiology: Fermentation is absent. D-Glucuronate and nitrate are variably assimilated, but *myo*-inositol is not assimilated. Starch-like compounds are not produced. Diazonium blue B and urease reactions are positive. Coenzyme Q-9 is formed. Xylose is absent from whole-cell hydrolyzates.

1.2.17. *Sympodiomyces*:

Vegetative reproduction: Colonies are cream-colored and butyrous to mucoid. Yeast cells are obclavate, obovoid to elongate, with holoblastic-annellidic or holoblastic-sympodial budding. Blastoconidia are formed on short acropetal and sympodially branching chains, or are single. Chlamydospore-like structures may be present.

Hyphae and pseudohyphae are present. Septal pores are "simple".

Physiology: Fermentation is absent. D-Glucuronate assimilation is not known, but *myo*-inositol and nitrate are assimilated. Starch-like compounds are not produced. Diazonium blue B and urease reactions are positive. Coenzyme Q-10 is formed. Trace amounts of xylose are present in whole-cell hydrolyzates.

1.2.18. *Tilletiopsis* (teleomorphs may belong to the *Tilletiales*):

Vegetative reproduction: Colonies are white, cream-colored, pink, yellow to brown, venose or velutinous, and tough to butyrous. Yeast cells, if present, are ellipsoidal to elongate, and have polar budding. Hyphae lack clamp connections. Chlamydo-spores may be present. Ballistoconidia are bilaterally symmetrical. Septal pores are "micropore"-like.

Physiology: Fermentation is absent. D-Glucuronate and *myo*-inositol are sometimes assimilated, but nitrate is not assimilated. Starch-like compounds are not produced. Diazonium blue B and urease reactions are positive. Coenzyme Q-10 is formed. Xylose is absent in whole-cell hydrolyzates.

1.2.19. *Trichosporon*:

Vegetative reproduction: Colonies are cream-colored, and moist to dry. Yeast cells, if present, are ellipsoidal to elongate, with polar budding. Hyphae usually disarticulate into arthroconidia. Endospores and chlamydo-spore-like cells may be present. Septal pores, if present, are dolipores with or without cupulate parentheses, but are "micropore"-like in *T. pullulans*.

Physiology: Fermentation is absent. D-Glucuronate and

myo-inositol are usually assimilated, but nitrate usually is not assimilated. Starch-like compounds are sometimes produced. Diazonium blue B and urease reactions are positive. Coenzyme Q-9 or 10 are formed. Xylose is present in whole-cell hydrolyzates.

1.2.20. *Trichosporonoides* (probably synonymous with *Moniliella*, G.S. de Hoog, personal communication):

Vegetative reproduction: Colonies are cream-colored, but soon become olivaceous-brown, and smooth or cerebriform. Yeast cells, if present, are ellipsoidal with sympodial proliferation. Hyphae may disarticulate. Blastoconidia occur in acropetal chains. Pseudohyphae may be present. Septal pores are dolipores without parentheses.

Physiology: Fermentation is present. D-Glucuronate assimilation is not known; *myo*-inositol is not assimilated, but nitrate is assimilated. Production of starch-like compounds is not known. Diazonium blue B and urease reactions are positive. Coenzyme Q-9 is formed. Xylose is absent in whole-cell hydrolyzates.

1.2.21. *Tsuchiyaea*:

Vegetative reproduction: Colonies are pale and butyrous. Yeast cells are globose to subglobose, ovoidal to cylindrical, with budding on stalks and with the septum in the mid-region.

Physiology: Fermentation is absent; D-Glucuronate and *myo*-inositol are assimilated; nitrate is not assimilated. Starch-like compounds are absent or weakly produced. Diazonium blue B and urease reactions are positive. Coenzyme Q-9 is formed. Xylose is present in whole-cell hydrolyzates.

1. a Basidiocarps present on natural substrates → 2
b Basidiocarps absent on natural substrates → 8
- 2(1). a Basidiocarps synnema-like; basidia non-septate or transversely septate; septa "simple" → 3
b Basidiocarps tuberculate to cerebriform or foliaceous and gelatinous; basidia longitudinally septate (tremelloid); septa with dolipores → 4
- 3(2). a Basidia clavate, non-septate, with sessile terminal spores; basidiocarps waxy-arid or subgelatinous; D-glucuronate not assimilated; starch-like compounds produced *Chionosphaera*: p. 643
b Basidia cylindric, transversely septate, with basidiospores laterally budding off; basidiocarps capitate to clavate or stemonitoid; D-glucuronate assimilated; starch-like compounds not produced *Agaricostilbum*: p. 639
- 4(2). a Basidia catenulate; basidiospores passively released, sessile, fusiform to narrowly clavate → 5
b Basidia virtually all terminal, single (rarely catenulate); basidiospores actively released, sterigmate, usually globose to ovoidal or bullate → 6
- 5(4). a Basidia developing from successive basal clamp connections of a first terminal basidium, maturing acropetally *Fibulobasidium*: p. 710
b Basidia developing from contiguous hyphal cells, maturing basipetally *Sirobasidium*: p. 710
- 6(4). a Basidiocarps erect, coralloid, occurring in dense aggregates, tough, gelatinous, simple or branched *Holtermannia*: p. 711
b Basidiocarps not erect, irregularly pulvinate to cerebriform or foliaceous, (but lacking in some parasitic forms) → 7
- 7(6). a H-shaped conidia and/or yeast cells usually present; basidiocarps associated with *Arthrinium* on bamboo and other grasses *Trimorphomyces*: p. 717
b Conidia subglobose to subcylindric, never H-shaped; basidiocarps mainly on woody angiosperms or on fungi or lichens *Tremella*: p. 712
- 8(1). a Teliospores and/or basidia present → 9
b Teliospores and/or basidia absent (anamorphic taxa) → 19
- 9(8). a Teliospores present → 10
b Teliospores absent → 15
- 10(9). a Teliospores brown and echinulate; only hyphal vegetative cells *Tilletiaria*: p. 703
b Teliospores hyaline and smooth-walled; unicellular vegetative cells usually present → 11

- 37(36). a Conidiogenesis usually in acropetal chains; septal pore, if present, a “micropore”-like structure; xylose absent in whole-cell hydrolyzates *Pseudozyma*: p. 790
 b Conidiogenesis usually with sympodial proliferation; septal pore “simple”; xylose present in trace amounts in whole-cell hydrolyzates *Sympodiomyces*: p. 846
- 38(33). a Fermentation present *Phaffia*: p. 789
 b Fermentation absent → 39
- 39(38). a *myo*-Inositol usually assimilated; starch-like compounds usually produced; xylose present in whole-cell hydrolyzates *Cryptococcus*: p. 742
 b *myo*-Inositol usually not assimilated; starch-like compounds not produced; xylose absent in whole-cell hydrolyzates *Rhodotorula*: p. 800

Chapter 76

Keys to the genera and species of ballistoconidia-forming yeasts and yeastlike fungi

T. Boekhout

1. Key to the genera of ballistoconidia-forming yeasts and yeastlike fungi

1. a Basidiocarps present on natural substrates → 2
b Basidiocarps absent on natural substrates → 3
- 2(1). a Basidia develop from successive basal clamp connections of a first terminal basidium and mature acropetally *Fibulobasidium*: p. 710
b Basidia develop from contiguous hyphal cells and mature basipetally *Sirobasidium*: p. 710
- 3(1). a Clamp connections present; hyphae usually dikaryotic → 4
b Clamp connections absent; hyphae and yeast cells usually monokaryotic → 6
- 4(3). a Teliospores present; colonies red, orange-red or pinkish-red; ballistoconidia bilaterally symmetrical *Sporidiobolus*: p. 693
b Teliospores absent; colonies whitish; ballistoconidia bilaterally or rotationally symmetrical → 5
- 5(4). a Phragmobasidia present; haustorial branches present; ballistoconidia rotationally symmetrical *Bulleromyces*: p. 641
b Phragmobasidia absent; haustorial branches absent; ballistoconidia bilaterally symmetrical *Itersoniella*: p. 775
- 6(3). a Ballistoconidia rotationally symmetrical *Bullera*: p. 731
b Ballistoconidia bilaterally symmetrical → 7
- 7(6). a Colonies mainly consist of narrow hyphae → 8
b Colonies mainly consist of yeast cells; monokaryotic hyphae sometimes present → 9
- 8(5). a Echinulate, brown teliospores present *Tilletiaria*: p. 703
b Echinulate, brown teliospores absent *Tilletiopsis*: p. 848
- 9(7). a Blastoconidia (buds) formed on long stalks *Kockovaella*: p. 777
b Blastoconidia (buds) sessile or on short denticles, only rarely on somewhat elongated stalks → 10
- 10(9). a Colonies red, orange, orange-red or pinkish-red *Sporobolomyces*: p. 828
b Colonies whitish, cream, brownish-yellow, ochraceous, brown or pale pink → 11
- 11(10). a Ballistoconidia large (up to 18 µm long and 10–14 µm wide); conidia (buds) usually leave distinct scars forming annellations or collarettes; D-glucuronate and nitrate usually assimilated; xylose present in whole-cell hydrolyzates *Bullera* (*Udeniomyces*): p. 731
b Ballistoconidia usually smaller; conidia (buds) usually do not leave collarettes or collarettes are not distinct; either D-glucuronate or nitrate may be assimilated; xylose absent in whole-cell hydrolyzates → 12
- 12(11). a Colonies may be bright orange or red; main ubiquinone CoQ-10 or 10(H₂) *Sporobolomyces* (including *Ballistosporomyces*): p. 828
b Colonies not bright orange or red; main ubiquinone Q 9 *Bensingtonia*: p. 723

This Page Intentionally Left Blank

77. *Agaricostilbum* Wright

R.J. Bandoni and T. Boekhout

Diagnosis of the genus

Basidia occur predominantly in synnemata-like basidiomata, (Fig. 292a, p. 616) but reduced basidiocarps may consist of only a few hyphal strands. The fertile hyphae usually terminate with four-celled basidia (Fig. 293, p. 617) and each basidial cell buds off sporidia. Many of the spores remain attached at any one time. Both the basidia and the basidiospores tend to become thick-walled, perhaps because of the exposed habitats occupied by these fungi.

Little is known of the biology of these fungi. They typically occur on well-weathered palm material with numerous other fungi, but whether or not they are mycoparasites is unknown. The life cycle appears to be as follows: haploid yeast states conjugate and give rise to dikaryotic hyphae without clamp connections; these form synnemata on which the basidia occur; germination of the basidiospores result in the haploid yeast state. Conidial states are not known. Basidiomata of *A. pulcherrimum* and *A. hyphaenes* develop readily in culture. The yeast state of a single species is characterized here.

Systematic discussion of the species

77.1. *Agaricostilbum hyphaenes* (Harrison & Patouillard) Oberwinkler & Bandoni (1982b)

Growth on 5% malt extract agar: After 5 days at 25°C, the cells are ellipsoidal to fusoidal, occasionally somewhat cylindrical, (4.0–10.0) × (2.0–4.0) μm, and single. Budding is polar with enteroblastic proliferation and usually on a short denticle. Colonies are pale yellowish-cream, smooth, shiny, butyrous, and with the margin entire.

Growth on the surface of assimilation media (glucose): Growth is absent, but a sediment is formed.

Dalmeu plate culture on morphology agar: After 5 days at 25°C, no hyphae or pseudohyphae are formed, but short filaments may occur. Aerobic growth is pale yellowish-cream, dull, butyrous, flat, smooth or somewhat warty, and with the margin entire. Cells are similar to those on malt extract agar, but frequently form short chains or aggregates.

Fermentation: absent.

Assimilation (25°C):

Glucose	+	<i>N</i> -Acetyl-D-glucosamine	n
Galactose	–	Methanol	–
L-Sorbose	s	Ethanol	+
Sucrose	+	Glycerol	+

Co-Q: Not determined.

Mol% G+C: Not determined.

Origin of the strain studied: CBS 7811, from basidiomes growing on a palm spathe (*Pheonix canariensis*), collected by W. Schofield, Stanford, California, USA.

Representative strain: CBS 7811.

Comments on the genus

The genus *Agaricostilbum* Wright was erected for a fungus first thought to be a synnematus hyphomycete (Wright 1970). The fungus, *A. palmicolum* Wright, was later found to be a gasteroid heterobasidiomycete (Wright et al. 1981), and was placed in the heterogeneous order, Atractiellales, by Oberwinkler and Bandoni (1982b) with *A. hyphaenes* (Harrison & Patouillard) Oberwinkler & Bandoni as the only other species. *A. palmicolum*, now known as *A. pulcherrimum* (Berkeley & Broome) Brady, Sutton & Samson, was assigned to a new order, Agaricostilbales, based on septal pore structure, discoidal spindle pole bodies (SPB), and morphological features of the basidia and basidiomata (Oberwinkler and Bauer 1989, Bauer et al. 1992).

Although the basidia of *Agaricostilbum* are similar to those of *Ustilago* species, the genus *Agaricostilbum* does not appear to be closely related to any other heterobasidiomycetous groups on the basis of 5S ribosomal RNA sequence comparisons (Gottschalk 1985, Gottschalk and Blanz 1985). Bauer et al. (1992) found that the structure of the SPB was intermediate between those of the smuts and rusts.

Species of *Agaricostilbum* are common on dead palm fronds and inflorescences. *A. pulcherrimum* has also been reported from a species of *Xanthorrhoea*. Representatives of the genus are among the commonest fungi occurring

on palm litter in warmer areas of Australia and parts of Asia (R.J. Bandoni, personal observation) and probable other regions where palms grow. The species are of seasonal occurrence, however, and therefore are not always present in spite of having rather tough, persistent basidiomata.

78. *Bulleromyces* Boekhout & A. Fonseca

T. Boekhout

Diagnosis of the genus

Yeast cells are ellipsoidal, subglobose or cylindroid, and monokaryotic. Budding is polar, with buds enteroblastic, sessile or on short denticles and with percurrent or sympodial proliferation. Ballistoconidia are rotationally symmetrical, subglobose. Colonies are cream, smooth, butyrous or mucoid.

The teleomorphic state may be heterothallic or self-sporulating. Basidiocarps are absent. Dikaryotic hyphae are regularly branched, septate, with clamp connections and haustorial branches. Septal pores are dolipores with cupulate parenthesomes. Basidia are subglobose, clavate or ovoidal, and after karyogamy become longitudinally, obliquely or transversely and two to four-celled septate. Germination of basidia gives yeast cells or hyphae on which yeast cells or ballistosporangia originate.

Fermentation is absent. D-glucuronate and *myo*-inositol are assimilated, but nitrate is not assimilated. Starch-like compounds are produced. Diazonium blue B and urease reactions are positive. Coenzyme Q-10 is formed. Xylose is present in whole-cell hydrolyzates.

The anamorph is assigned to *Bullera*.

Type species

Bulleromyces albus Boekhout & A. Fonseca

Species accepted

1. *Bulleromyces albus* Boekhout & A. Fonseca

Systematic discussion of the species

78.1. *Bulleromyces albus* Boekhout & A. Fonseca (Boekhout 1991a)

Anamorph: *Bullera alba* (Hanna) Derx

Synonyms:

Sporobolomyces albus Hanna (Bisby et al. 1929)

Bullera alba (Hanna) Derx (1930)

Growth of yeast cells on 5% malt extract agar: After 7 days at 17°C, cells are ellipsoidal, ovoidal or subglobose, (5.0–11.0) × (3.0–6.0) μm, and single. Budding is polar and buds are sessile or on short denticles. Cells sometimes form hyphal outgrowths of up to ca. 80 μm long and 2.0–5.0 μm wide. Growth is mucoid, flat or slightly raised, smooth, dull or shiny, cream to brownish-cream, and with an entire margin.

Growth on the surface of glucose assimilation medium: A thin film, islets, a ring and a sediment are formed.

Dalmau plate culture on morphology agar: After 7 days at 17°C, hyphae are sometimes formed, ca. 100 μm long and 2.0–4.0 μm wide. Subglobose, somewhat thick-walled cells occur with the outer cell wall layer peeling off. Aerobic growth is cream, pale yellowish, or pale yellowish-brown, shiny, mucoid, smooth or slightly venose, flat, and the margin entire, straight or crenulate.

Formation of ballistoconidia: Ballistoconidia that form on corn meal agar and malt extract agar are ellipsoidal to subglobose, and measure (4.0–9.5) × (3.5–7.0) μm (Fig. 310).

Formation of dikaryophase: Conjugation occurs

after mixing of strains of different mating types on corn meal agar at 17°C or at room temperature. Self-sporulating strains also occur. Dikaryotic hyphae are made up of cells measuring (40–130) × (1.5–3.0) μm, with clamp connections and haustorial branches. Basidia occur laterally and terminally on hyphae or hyphal branchlets, and measure (5.0–10.0) × (4.0–7.0) μm, finally becoming 2–4 celled, because of longitudinal, transverse or oblique septation (Fig. 311). Basidia germinate by forming yeast cells or hyphae on which yeast cells or ballistosporangia are formed.

Fermentation (17°C): absent.

Assimilation (17°C):

Additional assimilation tests and other growth characteristics:

2-Keto-D-gluconate	+	Nitrite	-
50% Glucose	-	Growth at 25°C	+
Starch formation	+	Growth at 30°C	v
Urease	+	Growth at 37°C	-

Co-Q: 10 (Nakase and Suzuki 1986a).

Mol% G+C: 53.3–54.4, four strains, CBS 500, CBS 501, CBS 502, CBS 6302 (T_m : Boekhout 1991a); 54.5 (T_m : Nakase et al. 1990c); 54.4 (T_m : Nakase and Komagata 1971g).

Origin of the strains studied: CBS 500, type of *Sporobolomyces albus* Hanna, straw of *Hordeum jubatum* infected by rust fungi, W.F. Hanna, USA; CBS 501, air in dairy, B.W. Hammer, USA; CBS 502, air in dairy, B.W. Hammer, USA; CBS 6097, frass of *Sinoxylon ruficorne*, J.P. van der Walt, South Africa; CBS 6302, grass, P.F. Dupont, USA; CBS 7440, leaf of poplar (*Populus* sp.), A. Fonseca, Portugal; CBS 7441, leaf of poplar (*Populus* sp.), A. Fonseca, Portugal; CBS 7503, leaf of walnut (*Juglans* sp.), G. Giménez, Portugal.

Complementary mating types: CBS 500 (mt A), CBS 7441 (mt A), CBS 7503 (mt A), CBS 501 (mt B), CBS 6097 (mt B), CBS 6302 (mt B).

Type strain: CBS 500 \times CBS 6302 (herbarium, CBS).

Comments on the genus

Lodder and Kreger-van Rij (1952) designated strain No 16, isolated by Hammer as neotype for *Bullera alba*. However, CBS 500, originally isolated by Hanna, and the type strain of *Sporobolomyces albus*, is the original type strain of *Bullera alba*.

Bullera alba var. *lactis* was found to be conspecific with *Bullera sinensis* (Nakase et al. 1990c, Boekhout 1991a). As a consequence, no mating reactions occurred between this species and the monokaryophase of *Bulleromyces albus*. The monokaryophase of *B. albus* (= *Bullera alba*) can

be differentiated from related species by assimilation of inulin. In addition, the frequent assimilation of L-sorbose, D-glucosamine, and erythritol, and lack of growth with nitrite may be used to differentiate this species.

Bandoni (1987) reported the occurrence of mating and formation of dikaryotic hyphae with clamp connections. Boekhout et al. (1991a) observed phragmobasidia of the *Tremella*-type after mating strains of *Bullera alba*. The septal pore is a dolipore with a cupulate parenthesome (*Tremellales* type), which supports the proposed relationship of *Bullera* with the *Tremellales* (Phaff 1970d, Boekhout et al. 1991a).

Formation of dikaryotic hyphae and probasidium-like cells was also observed among strains of *Bullera variabilis* (Boekhout et al. 1991a, Boekhout 1991a). However, in this case no development of basidia was observed.

Fig. 311. *B. albus*, CBS 6302 \times 7441. Dikaryophase. Hyphae and basidia on corn meal agar. Bar = 10 μ m.

79. *Chionosphaera* Cox

K.J. Kwon-Chung

Diagnosis of the genus

Asexual reproduction is by polar budding of ellipsoidal to sausage-shaped single cells (Fig. 312A). Basidiocarps are white, minute, stipitate-capitate, and abundant (Fig. 312B). The stipes are composed of bundles of parallel, infrequently septate hyphae with no clamp connections (Fig. 312C, 313A1). Septal pores are simple. Basidial caps are often waxy, but sometimes cottony, globose to slightly flattened, without hyphidia or other sterile elements (Fig. 312B). Basidia are clavate, terminal, and produced mostly on unilaterally proliferating hyphal branches (Fig. 312C). Basidiospores are hyaline, oblong to ellipsoidal or reniform, one-celled, smooth (Fig. 312D), six to eight in number, and produced on short sterigmata in tight apical clusters (Fig. 313A3). After the basidiospores are released, the basidial apex is crown-like, due to the plugged short sterigmata (Fig. 313A4).

Fig. 312. *C. apobasidialis*. (A) Yeast cells grown on malt agar. Bar=10 μ m. (B) Mature basidiocarps on dead limbs of *Carpinus*. Bar=0.3 mm (Cox 1976). (C) Young basidia produced terminally on septate hyphae. Bar=10 μ m. (D) Ovoidal to reniform basidiospores. Bar=10 μ m.

Fermentation is absent. D-glucuronate, *myo*-inositol and nitrate are not assimilated. Starch-like compounds are produced. Diazonium blue B and urease reactions are positive. Coenzyme Q-10 is formed. Cell wall composition is not determined.

Type species

Chionosphaera apobasidialis Cox

Species accepted

1. *Chionosphaera apobasidialis* Cox (1976)

Systematic discussion of the species

79.1. *Chionosphaera apobasidialis* Cox (1976)

Growth on yeast extract–2% malt agar: After 3 days at 25°C, the cells are ellipsoidal to sausage-shaped, $(1.5\text{--}3)\times(3\text{--}6)\mu\text{m}$, and are single or in pairs (Fig. 312A). The colony is slightly mucoid and cream-colored. Dikaryotic mycelium is formed if the isolates are self-fertile.

Growth on the surface of assimilation media (yeast nitrogen base plus glucose): No pellicles, but rings are formed.

Morphology on corn meal agar: After 3 days at 25°C, the cells are ovoid, ellipsoidal to sausage-shaped, measuring $(1.2\text{--}4)\times(3\text{--}7)\mu\text{m}$, and are single or in pairs. A limited amount of pseudohyphae is produced in old cultures.

Life cycle: Yeast cells of the two opposite mating types fuse by a conjugation tube, and the contents of one of the fused cells flows into the other cell via the conjugation tube. Dikaryotic hyphae without clamp connections arise from the second cell and eventually produce white, erect, capitate fascicles. The fascicles are composed of compact, predominantly parallel, infrequently branched, and infrequently septate hyphae which form synnemata (Fig. 313B). The synnemata are terminated with a globose sporocarp (0.25–0.75 mm) covered with a hymenium (Fig. 313C). The hymenium is composed of frequently-branched hyphae bearing terminal basidia (Fig. 312C). Basidia, $(20\text{--}49\times 3\text{--}5)\mu\text{m}$, are evenly or undulately clavate, bearing six to eight thick-walled basidiospores apically on short denticles (sterigmata). The sterigmata collapse after the spores are detached. Basidiospores, $(3.5\text{--}5\times 7\text{--}10)\mu\text{m}$, are hyaline, smooth, ellipsoidal to ovoidal, or reniform. Basidiospores germinate to produce uninucleate yeast cells.

Two isolates, CBS 7430 and CBS 7431, were both self-fertile and produced basidiocarps when the yeast cells were initially grown on yeast extract–malt (2%) agar for the formation of dikaryotic mycelium followed by transfer of the mycelial blocks onto water agar. Single basidiospores isolated from CBS 7430 produced two kinds of isolates: self-fertile and self-sterile. Crossing of self-sterile isolates in all possible combinations revealed that they belong to two different mating types. It appears, therefore, that *C. apobasidialis* has bipolar heterothallism, as Cox (1976) has suggested. The isolates lose the ability to form basidiocarps when they are maintained on agar media. The species descriptions of *C. apobasidialis* by Cox (1976), and subsequently by Oberwinkler and Bandoni (1982b), are based on the basidiocarps produced in its natural habitat, the bark of *Quercus* and *Carpinus* trees. The basidiocarps, (0.5–3 mm high), produced on the tree bark resemble minute mushrooms with white, globose to depressed globose caps, often waxy, and with short stipes (Fig. 312B). Such well-developed basidiocarps have been rarely observed in pure culture on agar media. Cox (1976) has reported that, in the presence of dematiaceous hyphomycetes such as *Cladosporium* or *Chloridium*, fasciculate, globose basidiocarps are produced by *C. apobasidialis* on agar medium. Most of the basidiocarps produced in pure culture were loosely fasciculated, bearing a scanty hymenium at their tips.

Fermentation: absent.

Origin of the strains studied: CBS 7430 (NRRL Y-17229) and CBS 7431 (NRRL Y-17230) isolated by Clark T. Rogerson from twigs of *Carpinus caroliniana*. Other strains of *C. apobasidialis* have been isolated from deciduous trees such as *Quercus macrocarpa*, *Q. stellata*, and *Carpinus caroliniana* (Oberwinkler and Bandoni 1982b, Cox 1976).

Type strain: CBS 7430, a self-fertile strain received from Clark Rogerson, was collected in Chester County, Pennsylvania, USA.

Comments on the genus

The genus *Chionosphaera* was described by Cox (1976)

to accommodate a yeast which produces minute, stipitate-capitate basidiocarps resembling those of the homobasidiomycetes. The genus *Chionosphaera* is monotypic. In spite of the presence of basidiocarps, Cox classified *C. apobasidialis* in the family Filobasidiaceae because the basidia are long, nonseptate, and produce apical basidiospores in a flower-like arrangement, characteristics shared by members of the Filobasidiaceae. Cox's isolates were not preserved for further study, and the description of *C. apobasidialis* appearing in the previous edition of this book was based solely on Cox's report. He also proposed to classify Filobasidiaceae in the order Aphyllophorales of the Homobasidiomycetes on the basis that the family produces holobasidia. In 1982, Oberwinkler and Bandoni made a critical study on newly isolated cultures of *C. apobasidialis* (isolated by C. Rogerson) and the herbarium specimen on *Quercus stellata* (collected by Cox). They concluded that *C. apobasidialis* does not fit into the family Filobasidiaceae, and transferred it into the newly described family, Chionosphaeriaceae. Unlike members of the Filobasidiaceae, *C. apobasidialis* produces basidiocarps, and basidiospores are formed on the sterigmata. The hyphal septa in *C. apobasidialis* are simple and resemble those of rust fungi (Oberwinkler and Bandoni 1982b). Hyphal septa of the Filobasidiaceae have primitive to well-developed dolipores without parentheses (Kwon-Chung and Popkin 1976, Moore and Kreger-van Rij 1972, Oberwinkler et al. 1983). Physiologically, *C. apobasidialis* differs from the members of the Filobasidiaceae by not being able to assimilate inositol or to produce a strong urease reaction. Nucleotide sequence analysis of the 5' portion of LSU rDNA (J. Fell, personal communication) demonstrated that *C. apobasidialis* is a Uredinomycete and possibly a member of the Agaricostilbales.

80. *Cystoflobasidium* Oberwinkler & Bandoni

K.J. Kwon-Chung

Diagnosis of the genus

Species of the genus *Cystoflobasidium* except *C. lari-marini*, produce bright orange, pinkish-salmon to cinnamon-colored colonies due to the presence of carotenoid pigments. Asexual reproduction is by polar budding of haploid or diploid, ovoidal to elongated cells. Ballistoconidia are not formed. Rudimentary pseudohyphae may be produced in some species. True mycelium with or without clamp connection is produced during sexual reproduction. Mycelial septa have dolipores without parenthesomes.

In the teleomorphic state, intercalary, globose, thick-walled dark pigmented probasidia (teliospores) are produced on the mycelium. Probasidia germinate to form slender, tubular or short, pyriform holometabasidia with non-deciduous terminal, and sessile basidiospores. Species may be homothallic or heterothallic.

Fermentation may be present. D-Glucuronate, *myo*-inositol and nitrate are sometimes assimilated. Starch-like compounds are produced. Diazonium blue B and urease reactions are positive. Coenzyme Q-9 or 10 is formed. Xylose is present in whole-cell hydrolyzates.

Systematic discussion of the species

80.1. *Cystoflobasidium bisporidii* (Fell, I.L. Hunter & Tallman) Oberwinkler & Bandoni (Oberwinkler et al. 1983)

Synonym:

Rhodosporeidium bisporidii Fell, I.L. Hunter & Tallman (1973)

Growth in 2% malt extract broth: Haploid cells grown for 3 days at 12°C are subglobose to elongate, (3–5) × (5–11) μm, and usually single or in pairs.

Reproduction is by polar budding, and there is a light sediment. A light pellicle and a moderate sediment are present after one month.

Growth on 2% malt agar: After 3 days at 12°C, the colony is orangish-pink, smooth, glistening, and the margin is entire. The yeast cell morphology is subglobose to elongate resembling in size those cells grown in malt broth (Fig. 314A). After one month, the color is the same as at 3 days and the colony is mucoid and slightly runny.

Fig. 314. *C. bisporidii*. (A) Yeast cells grown on 2% malt extract agar. Bar = 10 μm . (B) Basidium with paired primary sporidia. Bar = 5 μm . (Fell et al. 1973). (C) Germ tube formation from the primary sporidia. Bar = 4 μm . (Fell et al. 1973).

At 24°C, the cell morphology is the same as at 12°C, except that brown areas containing globose (5–11 μm in diameter) to subglobose (7–9.5) \times (8–10) μm , thick-walled, granulated cells develop within one month of growth. The granulated cells differ from teliospores by thinner walls.

Dalmau plate cultures on corn meal agar: After incubation for 2 weeks at 12°C or at 24°C, a true mycelium or typical pseudomycelium is absent. Occasional rudimentary pseudohyphae or short chains of cells may be present.

Life cycle (Fig. 315): The yeast cells (48 h stock culture) of the two compatible mating types (*A1B1* \times *A2B2*

or *A2B1* \times *A1B2*) conjugate within 4 days when they are mixed on corn meal agar at 12°C. The results are not always dependable, and the procedure may have to be repeated before the mating reaction can be observed. Dikaryotic hyphae with hook-to-peg clamp connections develop from conjugated cells within 4 days. Conidia are absent on the mycelium. The teliospores are globose (9–11 μm in diameter) to subglobose (6–9) \times (7–11) μm , uninucleate, granulated, intercalary, and are produced singly or, infrequently, in pairs. The hook-to-peg clamp connections are present between the teliospores and the mycelium. The teliospores increase in size to (8–12) \times (9–114) μm after one month. Teliospores germinate at 12–24°C when 2–3-week-old cultures are soaked in distilled water for 8 to 10 weeks and then transferred onto 2% water agar plates. After 3 days on 2% water agar, the teliospores produce a long metabasidium, (1–2) \times (19–140) μm , with 0 to 3 septa and a 2–4 μm -wide terminal swelling. Subglobose to ovoidal (3–4) \times (4–8) μm primary sporidia (up to 10 in number) develop at or near the terminal swelling; they are attached to the apex of the basidium either individually or in pairs (Fig. 314B). For some metabasidia, primary sporidia may be found along the sides of the basidia. One to several basidiospores are produced from the primary sporidia which remain attached to the metabasidium throughout the basidiospore development. Basidiospores detach from the primary sporidia and reproduce by polar budding to form yeast colonies of four different mating types. Some primary sporidia may produce germ-tubes rather than basidiospores (Fig. 314C). In rare cases, the metabasidium may be branched and septate with two “basidial heads.”

Fig. 315. Life cycle of *C. bisporidii* (Fell and Statzell-Tallman 1984).

Metabasidia occasionally develop directly from thick-walled hyphae in the absence of a teliospore. This indicates that karyogamy can occur in the hyphae and in the teliospore. Endospores (1–6 in number) may be present in the metabasidium or in the mycelium.

Fermentation: absent.

Co-Q: 8 (Yamada and Matsumoto 1988a).

Mol% G+C: 60.9 (T_m : Oberwinkler et al. 1983); 64.1 (HPLC: Hamamoto et al. 1986b).

Origins of the strains studied: Marine sources of the Southern Indian and Pacific Oceans (9) (Fell et al. 1973).

Complementary mating types: CBS 6346 (*A1B1*) and CBS 6347 (*A2B2*).

Type strain: CBS 6346.

Allotype strains: CBS 6348 (*A1B2*) and CBS 6349 (*A2B1*).

Comments: *Cystofilobasidium bisporidii* is the only known species in the family Filobasidiaceae that has a tetrapolar mating system. Only two mating types, *A1B1* and *A2B2*, have been isolated from marine sources, but single-basidiospore cultures of *A2B1* and *A1B2* have been obtained from a parental cross (Fell et al. 1973). Mixes of *A1B1*×*A1B2* or *A2B2*×*A2B1* result in conjugation and deformed hyphae but no clamp connections or teliospores. Mixes of *A1B2*×*A2B2* or *A2B1*×*A1B1*, however, fail to show any indication of mating reactions (Fell et al. 1973). Metabasidia of *C. bisporidii* resemble more closely those of *C. capitatum* than any other *Cystofilobasidium* species. *C. bisporidii*, however, produces metabasidia with considerably smaller apices than *C. capitatum*.

80.2. *Cystofilobasidium capitatum* (Fell, I.L. Hunter & Tallman) Oberwinkler & Bandoni (Oberwinkler et al. 1983)

Synonym:

Rhodosporeidium capitatum Fell, I.L. Hunter & Tallman (1973)

Growth in 2% malt extract broth: After 3 days at 12°C, the cells are subglobose to ovoidal or elongate, (1–5)×(2–14)µm, and with or without polar buds. The sediment is light; a ring or pellicle is absent. At one month, a moderate sediment and light film-like ring are present, but without pellicle. Yeast cells grown at 24°C resemble those grown at 12°C, but occasional mycelium and immature teliospores are seen at 24°C. After one month at 24°C, heavy sediment and mycelial clumps are present; a ring may be absent or present, and a pellicle is not produced.

Growth on 2% malt agar: Colonies grown on malt extract agar at 12°C for 3 days are mucoid and light salmon-orange, pinkish, or orange-cinnamon in color. The morphology of cells is similar to that of those grown in malt extract broth (Fig. 316A). At one week, septate true mycelium with terminal, lateral or intercalary teliospores is produced sparsely or abundantly. Conidia are absent on the mycelium. After one month, the colony is deeper in color and usually very mucoid and smooth, although some strains may be convoluted. The colony margin is entire, with areas of dense radiating mycelium.

The teliospores are brown, thick-walled, globose (6–20µm in diameter) to subglobose (5.9–6.5)×(17.4–18.8)µm, and are produced single, double (Fig. 316B), and in multiples up to 12 or more. After one month, there is some increase in number and size of the teliospores.

At 24°C, colonies are of various shades of cinnamon, light to dark pink, orange, or vinaceous-cinnamon with dark brown sections of teliospores. Colony texture may be rugose and dry to smooth, semi-glistening, or glistening with areas of dense mycelium at the margin. The shapes of

Fig. 316. *C. capitatum*. (A) Yeast cells grown on malt agar. Bar = 10 µm. (B) A pair of teliospores. Bar = 5 µm. (C) Metabasidia with basidiospores developed from a teliospore. Bar = 4 µm. (Fell et al. 1973).

Fig. 317. Life cycle of *C. capitatum* (Fell and Statzell-Tallman 1984).

cells in three-day-old culture varies from ovoidal, subglobose, reniform, dumbbell, elongate, and branched with the size range of $1.3 \times 4.7 \mu\text{m}$ to $3.4 \times 16 \mu\text{m}$. Formation of globose (6 to $8 \mu\text{m}$ in diameter) to subglobose ($5.9 \times 6.5 \mu\text{m}$ to $17.4 \times 18.8 \mu\text{m}$) teliospores become evident at one week, but the size of the teliospores is smaller than those at 12°C . The teliospores are produced on a short mycelium developed from the yeast cells and then multiply by yeastlike budding to form a large group of teliospores. Newly formed teliospores may remain attached to the parent spore and continue to replicate. After one month, colonies become darker in color, ranging from flesh-ocher to ochreous-buff or cinnamon-buff. Teliospores are larger in size, measuring 6.7 to $13.4 \mu\text{m}$ or $6.7 \times 10 \mu\text{m}$ to $14.1 \times 14.7 \mu\text{m}$. Endospores are absent in the cultures grown at 24°C .

Dalmau plate culture on corn meal agar: Extensive true mycelium with brown-walled teliospores are produced after incubation for 7 days at 12°C and 24°C . Teliospores are globose (4.7 to $15.4 \mu\text{m}$ in diameter) to ovoidal ($5.4 \times 10.8 \mu\text{m}$ to $6.7 \times 13.4 \mu\text{m}$) and are produced single, double, or in groups of 12 or more intercalary, terminally, or laterally on mycelium. Young developing teliospores (up to $7.4 \times 10.1 \mu\text{m}$), lacking heavy cell walls and the large globuloid inclusions of the developed spores, are also present. Conidia are lacking. After one month, the teliospores show a slight increase in size. Basal projections (2.2 – $2.7 \times 1.1 \mu\text{m}$) that attach to the mycelium have been seen in some teliospores. Endospores, usually fewer than 6 per mycelial cell, are numerous in one-month-old culture, but rare in 7-day-old culture.

Life cycle (Fig. 317): Single yeast cells produce uninucleate hyphae and teliospores without mating.

Clamp connections are absent, but dolipore septa without parentheses are present (Oberwinkler et al. 1983). Teliospores do not germinate unless they are first soaked in water for a prolonged time. To germinate teliospores obtained from 3-week-old malt agar culture, the spores are soaked in distilled water for 11 weeks and then transferred onto water agar at 12°C . Germination can be observed after incubation for 3 days. The metabasidium (Fig. 316C), which is rarely septate, is tubular (8 – $80 \mu\text{m} \times 1.4$ – $2.7 \mu\text{m}$), with an apical swelling, and forms a capitate terminus (4.9 – $7.7 \mu\text{m}$ wide). Primary sporidia ranging from 2 to 10 in number develop on the capitate terminus. Primary sporidia are single or in pairs, subglobose ($4.0 \times 4.7 \mu\text{m}$ to $6.0 \times 7.4 \mu\text{m}$) with one to two basidiospores, or they may produce septate hyphae (germ tubes). In addition to these teliospores, there are considerably smaller teliospores ($2.7 \times 4.0 \mu\text{m}$ – $5.4 \times 6.7 \mu\text{m}$) which germinate to produce short (6.0 – $17.4 \mu\text{m}$) basidia with rarely more than two primary sporidia.

After development of basidiospores or germ tubes, primary sporidia degenerate and remain attached to the basidium. Endospores may be formed within the degenerated teliospores and basidium after the completion of basidiospore formation. A metabasidium with primary sporidia may also arise directly from mycelium, which becomes thick-walled. Such a metabasidium is different from those developed from teliospores by lacking a terminal swelling.

Although cytological studies have not clearly determined whether *C. capitatum* is homothallic or the fruiting body is a result of asexual development, all the basidiospore progeny tested were self-fertile. Evidence of genetic recombination was present among the progeny obtained by micromanipulation. Some progeny

were morphologically distinct from the parent culture and produced rugose, dry colonies composed mainly of teliospores, while others were yeastlike in varying degrees. The rugose, dry isolates produced yeast cells only after several weeks in culture.

Fermentation: absent.

Co-Q: 8 (Sugiyama et al. 1985).

Mol% G+C: 56.6 (T_m : Oberwinkler et al. 1983); 59.2 (HPLC: Hamamoto et al. (1986b).

Origins of the strains studied: Marine sources of the Southern Indian Ocean (13) (Fell 1976) and South Florida (1) (Ahearn and Roth 1966).

Type strain: CBS 6358, isolated from a zooplankton sample in the Southern Indian Ocean.

Comments: The cytology and genetics of *C. capitatum* are extremely difficult to study because the germination of teliospores not only requires a long time and unusual measures (such as soaking in distilled water), but also the rate of germination is low. Oberwinkler et al. (1983) reported that the teliospores can be stimulated to germinate by heating the culture to about 55°C. The details on the growth medium or the length of heating time have not been discussed.

Since the hyphae and teliospores develop directly from a single uninucleate yeast cell, the hyphae are uninucleate with no clamp connections. There is no evidence of nuclear fusion during teliospore formation, and single-basidiospore cultures are self-fertile. Fell et al. (1973) described *C. capitatum* as “self-sporulating” instead of homothallic (Fell and Statzell-Tallman 1984). Because the single-basidiospore cultures vary in morphology and some of them are different from the parent culture, it is

likely that recombination and segregation of the factors controlling colonial morphology had occurred during basidiospore formation. Although conclusive evidence has not been obtained, *C. capitatum* may be naturally diploid and homothallic. A question remains as to when and where the reduction division and subsequent diploidization occur in the life cycle. *C. capitatum* was originally isolated from marine sources, but it also occurs on the gleba of mushrooms such as *Mutinus caninus* and *Phallus impudicus* (Oberwinkler et al. 1983).

80.3. *Cystofilobasidium infirmominiatum* (Fell, I.L. Hunter & Tallman) Hamamoto, Sugiyama & Komagata (1988b)

Anamorph: *Cryptococcus infirmo-miniatus* (Okunuki) Phaff & Fell

Synonyms:

Rhodosporeidium infirmo-miniatus Fell, I.L. Hunter & Tallman (1973)

Torula infirmo-miniata Okunuki (1931)

Rhodotorula glutinis (Fresenius) F.H. Harrison var. *infirmo-miniata* (Okunuki) Lodder (1934)

Rhodotorula infirmo-miniata (Okunuki) Hasegawa & Banno (1964)

Cryptococcus infirmo-miniatus (Okunuki) Phaff & Fell (1970)

Rhodotorula sinensis M.-H. Lee (1974)

Growth in 2% malt extract broth: After 3 days at 12°C, the cells are subglobose (2.0×3.4)–(4.7×8.7) μ m or elongate (1.3×4.0)–(4.7×10) μ m, and single or in short chains. Sediment is light, and a ring or pellicle is absent. After one month, a fragile film and ring have formed.

Growth on 2% malt extract agar: After 3 days at 12°C, the colony is grenadine-pink in color, smooth, glistening, and slightly raised. The border is entire without mycelium. The cells are subglobose to elongate (2.0×3.4)–(4.7×8.7) μ m. After one month, the colony tends to be mucoid and runny. Some strains are dull, dry, and their margin is lighter in color. The cells are oval to elongate (1–5.5)×(2.5–12) μ m or subglobose (2–5.5)×(3–7.5) μ m (Fig. 318A). There are globose (4–8 μ m in diameter) to subglobose (2–6)×(3–7.5) μ m granulated cells with thicker walls than the typical yeast cells.

Dalmat plate culture on corn meal agar: Growth under the coverglass shows abundant yeast cells but no mycelium or pseudomycelium is present at 12°C.

Fig. 318. *C. infirmominiatum*. (A) Yeast cells grown on malt agar. Bar = 10 μ m. (B) Basidium with three basidiospores. Bar = 5 μ m. (Fell et al. 1973).

Fig. 319. Life cycle of *C. infirmominiatum* (Fell and Statzell-Tallman 1984).

Life cycle (Fig. 319): *C. infirmominiatum* is a heterothallic species with a one-locus, multiple-allele system. The mating types known are A1, A2, and A3, and crosses of A1×A2 or A1×A3 produce the same result as the cross of A2×A3. Upon mixture of two compatible strains on corn meal agar, conjugation occurs within 36 hours and mycelial formation becomes evident after 3 days. After one week, mycelium and teliospores are abundant, although there is some strain variation in their rate of formation and degree of abundance. Clamp connections are of the hook-to-peg type, and they are infrequently found. Conidia are rarely produced on the hyphae. Teliospores are found in two morphological forms: the first type is globose (6.5–8 μm in diameter) to subglobose (5–9)×(7–11) μm with numerous granular bodies and is terminal or intercalary and single or double. Teliospores are slightly larger (6.5–10)×(7–11) μm after one month. The second type of teliospore is brown, thick-walled, ovoidal (9–11)×(14–15) μm or subglobose (7.5–17)×(8–18.5) μm with a large globular inclusion and is produced in groups of up to 12.

Germination of the teliospores can be achieved as follows: the teliospores are harvested from dikaryotic cultures grown on corn meal agar for 17 days and soaked in distilled water for 20 weeks before transferring to 2% water agar. The teliospores germinate after 3 days on 2% agar. The morphology of metabasidia is variable and, most commonly, they are pyriform with a large base attached to the teliospore (Fig. 318B). The base of the metabasidia is subglobose (5–7)×(7–9) μm or, occasionally, ovoidal-elongate (3.5–8 μm), and the apex

is globose (1.5–3.5 μm) to subglobose (2–4)×(2.5–5) μm. In some metabasidia, the apex is two-celled, with the terminal cells as large as, or slightly larger than, the basal cell. Sporidia are 1–4 in number and develop terminally on the metabasidium. Lateral sporidia may be found only rarely. Endospores, in numbers of up to 10, may develop within the mycelium. Conjugation does not occur when any of the mating types are mixed with the other species of *Cystofilobasidium*.

Fermentation: absent.

Co-Q: 8 (Yamada and Kondo 1973).

Mol% G+C: 66.3 (HPLC: Hamamoto et al. 1988b).

Origins of the strains studied: Marine waters of the Antarctic, Southern Indian, and Southern Pacific Oceans (14); human source (1) (Fell et al. 1973); air in Tokyo (1) (Okunuki 1931); diseased pears in China as *Rhodotorula sinensis* (1) (Lee 1974).

Complementary mating types: CBS 6350 (mating type *A2*) and CBS 6352 (mating type *A3*), both from marine sources.

Type strain: CBS 323 (mating type *A1*), the type strain of *Torula infirmominiata*.

Comments: *C. infirmominiatum* is the only known species in the family Filobasidiaceae that produces pyriform metabasidia. It is unique in two other ways: it is the only known species in the family that has a unifactorial incompatibility system with three alleles, and it is the only known species in the genus *Cystofilobasidium* that lacks primary sporidia.

In addition to marine water, *C. infirmominiatum* has been isolated from frozen vegetables, raw meat, air, diseased pears, and fecal samples of a man with symptoms of tropical sprue. There is no evidence that the yeast is pathogenic for humans.

80.4. *Cystofilobasidium lari-marini* (Saëz & T.L. Nguyen) Fell & Statzell-Tallman (1992)

Synonym:

Leucosporidium lari-marini Saëz & T.L. Nguyen (1989)

Growth in 2% malt extract broth: Moderate growth with ring and fragile pellicles after one month.

Growth on 2% malt extract agar: After 3 days at 12°C, the cells are ellipsoid or ovoid, (2–5)×(5–12) µm, and single or in pairs (Fig. 320A). Reproduction is by polar budding.

Growth in 2% glucose–peptone agar (Sabouraud agar): Colonies are white, and semi-glossy. Submerged mycelium and pseudomycelium are produced after 2 to 3 weeks. Spheroidal, ovoidal, or pyriform teliospores, (7.5–10)×(10–20) µm, are produced singly or in groups of 2 to 3 on mycelium at either terminal or intercalary position. Teliospores are spheroidal (10.6–13.3 µm) with apical swelling (4–8 µm); 4–8 sessile, oblong basidiospores are produced on the apical portion of the metabasidia (Fig. 320B,C). Basidiospores germinate by budding.

Teliospores germinate one week after soaking in water, heating for one hour at 57°C and incubating at 25°C,

Fig. 320. *C. lari-marini*. (A) Yeast cells grown on malt extract agar. Bar = 10 µm. (B) Basidium with relatively short metabasidium. Bar = 5 µm. (C) Basidium with long metabasidium. Bar = 13 µm. (Fell and Statzell-Tallman 1992).

followed by plating on corn meal agar (Fell and Statzell-Tallman 1992).

Origin of the strain studied: CBS 7420 was isolated from the mouth cavity of a dead sea gull.

Type strain: CBS 7420.

Comments: *Cystofilobasidium lari-marini* was previously classified in the genus *Leucosporidium* because it produces white colonies with teliospores (Saéz and Nguyen 1989). Saéz and Nguyen (1989) did not describe the germination of teliospores or the formation of metabasidia. Studies on the nucleotide sequence of a variable region of the large subunit rRNA, however, indicated the close relationship of *L. lari-marini* with *Cystofilobasidium* rather than with *Leucosporidium* (Fell and Kurtzman 1990). In a subsequent study, Fell and Statzell-Tallman (1992) confirmed the relationship of *L. lari-marini* to *Cystofilobasidium* by demonstrating *C. capitatum*-like metabasidium formation in *L. lari-marini*.

Comments on the genus

Oberwinkler and Bandoni (1983) established the genus *Cystofilobasidium* to accommodate carotenoid-pigmented yeasts which produce hyphae with primitive dolipores and which form teliospores that germinate to produce holometabasidia with terminal basidiospores. They included two species in the genus: *C. bisporidii* and *C. capitatum*; both had been classified in the genus *Rhodospiridium* by Fell et al. (1973). Hamamoto and coworkers (1988b) added another species, *C. infirmominiatum* to the genus on the basis of DNA–DNA homology with the other *Cystofilobasidium* spp., and because of certain biochemical characteristics of the species. *C. infirmominiatum* had also been classified in the genus *Rhodospiridium* by Fell et al. (1973). Fell (1974) was aware of the major differences between these three species and the other *Rhodospiridium* spp., in the context of metabasidium morphology and biochemical characteristics. Unlike the typical species of *Rhodospiridium*, which produce phragmobasidia and mycelium with simple septa, *Cystofilobasidium* species produce holometabasidia and mycelium with dolipores (without parenthesomes). In contrast to *Rhodospiridium* species, *Cystofilobasidium* assimilates inositol and produces starch-like compounds. The two genera can also be distinguished on the basis of their whole-cell sugar composition and coenzyme Q systems. Cells of *Cystofilobasidium* species contain xylose, while

it is lacking in *Rhodospiridium* (Weijman et al. 1982, Weijman and Rodrigues de Miranda 1988, von Arx and Weijman 1979). *Cystofilobasidium* contains ubiquinone Q-8 (Yamada and Kondo 1973, Sugiyama et al. 1985), in contrast to *Rhodospiridium* which forms Q-9 or Q-10. Yamada and Kawasaki (1989a) compared partial sequences of 18S and 26S rRNAs from Q-8-containing species of teliospore-forming yeasts, and reported that the three *Cystofilobasidium* spp. cluster in the same group and are distinguishable from the other groups.

Species of *Cystofilobasidium* share morphological similarities with the other two genera of the Filobasidiaceae, *Filobasidiella* and *Filobasidium*, by producing filobasidiaceous metabasidia; however, the presence of teliospores clearly separates the genus from *Filobasidium* and *Filobasidiella*. Other features that distinguish *Cystofilobasidium* from the other two genera of the Filobasidiaceae include its formation of carotenoid pigment in the yeast phase, formation of endospores in the mycelium, and the non-deciduous nature of primary basidiospores. Unlike *Cystofilobasidium*, species belonging to *Filobasidium* and the Filobasidiaceae have coenzyme Q-10 system. The anamorphs of *Cystofilobasidium* spp. belong to the genus *Rhodotorula* (Fell and Statzell-Tallman 1984) or the genus *Cryptococcus*. Three of the four species produce bright orange, salmon-pink to cinnamon-colored, glistening colonies. *C. lari-marini* can be distinguished from the other three species by the lack of carotenoid pigments. *C. bisporidii* can be distinguished from the other two species with carotenoid pigments by its ability to assimilate melibiose. *C. infirmominiatum* is separated from *C. capitatum* by splitting of arbutin, the inability to assimilate L-sorbose, and the formation of pyriform metabasidia.

Study of the life cycle of *Cystofilobasidium* is impaired because of the low frequency of mating and the difficulty in germinating teliospores. The teliospores may germinate after growing on malt or corn meal agar for three weeks, followed by 8–11 weeks of soaking in distilled water in most species (Fell et al. 1973).

81. *Erythrobasidium* Hamamoto, Sugiyama & Komagata

J. Sugiyama and M. Hamamoto

Diagnosis of the genus

Asexual reproduction is by multilateral budding. Cells are ovoidal to long ovoidal and pseudomycelium is absent. The colony color on solid media is orange-red.

True mycelia are produced from single cells without mating. Clamp connections are present or absent. Septal pores are simple. Teliospores are not formed. Unicellular basidia (holobasidia) arise by the development of the lateral protrusions on the hyphae. The sessile basidiospores are produced terminally on the holobasidia; these are non-apiculate and are not forcibly discharged.

Fermentation is absent. The urease test is positive. The extracellular DNase test is positive (weak). The diazonium blue B color test is positive. Xylose is absent in the cells. The major ubiquinone system is Q-10(H₂). D-Glucuronate and nitrate are assimilated; *myo*-inositol is not assimilated. Starch-like compounds are not produced.

Type species

Erythrobasidium hasegawianum Hamamoto, Sugiyama & Komagata

Species accepted

1. *Erythrobasidium hasegawianum* Hamamoto, Sugiyama & Komagata (1991)

Systematic discussion of the species

81.1. *Erythrobasidium hasegawianum* Hamamoto, Sugiyama & Komagata (1991)

Anamorph: *Rhodotorula hasegawae* Y. Yamada & Komagata

Synonyms:

Erythrobasidium hasegawae (Y. Yamada & Komagata) Hamamoto, Sugiyama & Komagata (1988c), incorrect combination, Art. 59, ICBN

Rhodotorula hasegawae Y. Yamada & Komagata (1983)

Growth in 5% malt extract: After 3 days at 25°C, the cells are ovoidal to long ovoidal, (3.8–5.8) × (6.3–10.5) μm, and single or in pairs. A sediment and a ring are present.

Growth on 5% malt agar: After 3 days at 25°C, the cells are of the same form and almost the same dimensions, (3.3–5.6) × (6.3–12.0) μm, as observed in malt extract. The streak culture is smooth, glistening and pink to reddish-pink. After one month at room temperature, the culture is orange-red.

Dalmay plate culture on corn meal agar: After 10 days at 20°C, there is true mycelium. The mycelium is initially uninucleate; during the process of clamp formation, the clamps are completed but are not always present at each cross wall (Fig. 321A). Hyphae are dikaryotic when clamp connections are formed, and uninucleate when they are not formed (Fig. 321B). After 50–60 days, protrusions are produced laterally on the hyphae and develop into uninucleate basidia (Fig. 321C). These are obovate, 10–18 μm long, 1–2 μm wide near the base, and 3–5 μm wide at the apex, single, and one-celled. They appear to be diploid as their nuclei are twice as large as those of the yeast cells. The basidium produces two to four terminally sessile basidiospores on its apices.

Fig. 321. *E. hasegawianum*, IFO 1058. (A) Hyphae with clamp connections, after 10 days on corn meal agar at 20°C. (B) Uninucleate mycelium stained by the Giemsa method. (C) Basidium after 50–60 days on corn meal agar at 20°C. Arrow indicates a protrusion. (D) Germinated basidium with formation of uninucleate basidiospores, stained by the Giemsa method. (E) Haploid yeasts stained by the Giemsa method. Bar = 10 μm.

These basidiospores apparently are haploid (Fig. 321D, E). Subsequently, basidia repeat the budding.

Life cycle: A dikaryotic mycelium with clamp connections or a uninucleate mycelium without clamps develops from a single cell without mating (Fig. 322). The mycelium produces protrusions laterally. The protrusion develops into uninucleate obovate holobasidia. Karyogamy may take place in the holobasidium. Meiosis may occur during germination, and the resulting sessile haploid basidiospores are terminal on the holobasidium. The basidiospores propagate by budding, thus returning to the yeast phase.

Fermentation: absent.

(Robbins and Ma 1944).**Type strain:** IFO 1058 (ATCC 9536, CBS 8253, IAM 12911, JCM 1545, YK 124), derived from the holotype IAM F-0146; isolated from an old culture of beer yeast, Philadelphia, U.S.A.; received from IFO.**Comments on the genus**

Hamamoto et al. (1988c) discovered the teleomorphic state of *Rhodotorula hasegawae*, which is characterized by unicellular basidia and the lack of teliospores. They proposed the new genus *Erythrobasidium* for the taxon and tentatively placed it in the Filobasidiaceae. Later Hamamoto et al. (1991) replaced the species name *E. hasegawae* (Yamada & Komagata) Hamamoto et al. (1988c) by a new name *E. hasegawianum* Hamamoto et al. (1991) because of an incorrect combination for the teleomorph.

Only one strain (IFO 1058) is known for this species. The strain, isolated from an old culture of beer yeast, was first identified as *Rhodotorula aurantiaca* (Robbins and Ma 1944) and subsequently reidentified as *R. lactosa* (Hasegawa 1965) on the basis of assimilation of lactose and the requirement for *p*-aminobenzoic acid. Later Yamada and Komagata (1983) pointed out that the strain was distinguished from both *R. aurantiaca* and *R. lactosa* by DNA base composition, Co-Q system and the electrophoretic patterns of enzymes. Furthermore, it did not assimilate lactose, contrary to the description of Hasegawa (1965). On the basis of these data, Yamada and Komagata (1983) proposed the new species *R. hasegawae*.

Suh et al. (1993a) have clarified the ultrastructural features of *E. hasegawianum*. They showed the cell wall to be multilayered, conidiogenesis to be enteroblastic and that the septal structure is simple with no septal swelling or parentheses. Such features strongly suggest that *Erythrobasidium* has affinity with the teliospore-forming yeasts rather than with Filobasidiaceous taxa. 18S rRNA gene sequence comparisons among the basidiomycetous yeasts supports conclusions from the ultrastructural data (Sugiyama and Suh 1993, Suh and Sugiyama 1993b). Subsequently, Suh and Sugiyama (1994) suggested a phylogenetically close relationship between *E. hasegawianum* and *Rhodospiridium dacryoideum* using neighbor-joining analysis of 18S rRNA gene sequences. For further discussion, see Suh and Sugiyama (1994).

82. *Filobasidiella* Kwon-Chung

K.J. Kwon-Chung

Diagnosis of the genus

Asexual reproduction is by budding of globose, ovoidal, or apiculate cells. Pseudo- or true mycelium is lacking in haploid cultures. Growth on solid media is white or cream-colored, and commonly mucoid. Visible carotenoid pigments are lacking. Cells are encapsulated by polysaccharide, and the degree of capsulation varies with strains as well as environmental factors.

Sexual reproduction occurs following conjugation between α and a cells. Conjugated cells produce dikaryotic hyphae with clamp connections. The cross walls of the hyphae contain a typical dolipore, but lack parenthesomes (Kwon-Chung and Popkin 1976). Basidiocarps are absent. A slender holobasidium with an abruptly expanded apex arises laterally or terminally from the dikaryotic hyphae. Karyogamy takes place in the metabasidium, and the zygote nucleus undergoes meiosis in the apical area. Repeated mitosis follows meiosis, and uninucleate basidiospores bud basipetally from four spots on the apex of the metabasidium to form four chains of basidiospores.

Fermentation is absent. D-Glucuronate and *myo*-inositol are assimilated, but nitrate is not assimilated. Starch-like compounds are produced. Diazonium blue B and urease reactions are positive. Coenzyme Q-10 is formed. Xylose is present in whole-cell hydrolyzates.

Type species

Filobasidiella neoformans Kwon-Chung

Species accepted

1. *Filobasidiella neoformans* Kwon-Chung (1975)
 - a. *Filobasidiella neoformans* Kwon-Chung var. *neoformans* (1982)
 - b. *Filobasidiella neoformans* var. *bacillispora* Kwon-Chung (1982)

Key to the varieties

1.
 - a Basidiospores spheroidal, oblong, or cylindrical and finely roughened; D-proline is not assimilated; reaction on canavanine-glycine-bromthymol blue (CGB) agar is negative after two to five days *F. neoformans* var. *neoformans*: p. 656
 - b Basidiospores smooth, bacillary and with or without curvature; D-proline is assimilated; CGB agar becomes blue within two to five days *F. neoformans* var. *bacillispora*: p. 657

Systematic discussion of the species

82.1. *Filobasidiella neoformans* Kwon-Chung (1975)

This species has two varieties:

Filobasidiella neoformans Kwon-Chung var. *neoformans* (Kwon-Chung et al. 1982a)

Anamorph: *Cryptococcus neoformans* (Sanfelice) Vuillemin

Synonyms:

***Filobasidiella neoformans* var. *bacillispora* Kwon-Chung (Kwon-Chung et al. 1982a)**

Anamorph: *Cryptococcus neoformans* (Sanfelice) Vuillemin var. *gattii* Vanbreuseghem & Takashio

Synonyms:

Filobasidiella bacillispora Kwon-Chung (1976a)

Cryptococcus bacillisporus Kwon-Chung & Bennett (Kwon-Chung et al. 1978)

Cryptococcus neoformans (Sanfelice) Vuillemin var. *gattii* Vanbreuseghem & Takashio (1970)

Growth in 2% malt extract: After 3 days at 25°C, haploid cells are mostly globose or ovoidal, occurring singly or with buds (Fig. 323C). The cell size ranges from 3–8 μm, but is mostly 3–5 μm in diameter. A slight sediment is present, and a thin ring may be present as well. The sediment increases as the incubation continues.

Growth on 2% malt agar: After 3–5 days at 25°C, haploid cells are globose to ovoidal, measuring 2.5–10 μm in diameter. The colony is white to cream-colored with a smooth, mucoid texture; the margin is entire. In streak culture, the highly mucoid growth runs to the bottom of the slant within one week.

Fig. 323. *F. neoformans* var. *neoformans*. (A) Basidial structure with "hausteriod" hyphae. (B) Basidiospores are released from the basidium. Bar = 10 μm. (C) Yeast cells grown on malt extract agar.

Dalmau plate culture on corn meal agar: Pseudomycelium or mycelium is absent in haploid cells.

Growth on agar medium containing phenolic compounds: Haploid colonies on media containing substances such as extract of niger seed (*Guizotia*

abyssinica) (Staib 1962, Shields and Ajello 1966), caffeic acid (Pulverer and Korth 1971, Hopfer and Blank 1975, Hopfer and Gröschel 1975, Healy et al. 1977, Fleming et al. 1977), chlorogenic acid (Shaw and Kapica 1972) or, L-DOPA (Chaskes and Tyndall 1975) become brown or dark brown to black usually within one to five days, depending on the medium and the isolates. Some strains may require eight days to produce the characteristic pigment on niger seed agar.

Growth on canavanine-glycine-bromthymol blue (CGB) agar: There is no growth, and the color of the medium does not change after two to five days at 25°C.

Life cycle: The life cycle of *F. neoformans* is illustrated in Fig. 324. The majority of isolates are self-sterile and produce basidiospores upon mating with isolates of the opposite mating type. Heterothallism is controlled by a one-locus, two-allele (α and a) system. Cells of α and a mating types conjugate when they are mixed on malt extract agar, V8 juice agar, hay infusion agar, or sucrose yeast extract agar at 25–37°C. V8 juice with 4% agar and hay infusion agar have been the two media most effective for formation of the metabasidia.

Fig. 324. Life cycle of *F. neoformans*.

Dikaryotic hyphae with clamp connections develop within three to five days from the conjugants. After one week, mycelial growth is most evident around the margin of the colony. Hyphae are thin (average 3 μm wide) and hyaline, with a clamp connection at each septum. Regular hyphal branching occurs at clamp connections, and also irregular, thin (1–1.5 μm wide) branches termed "hausterioid" branches originate from clamps. Blastospores bud out from the side or the tip of the hyphae; these are indistinguishable from haploid yeast cells in their size and shape. Mature basidia arise within one to two weeks, singly or in a group, laterally

Fig. 325. Nuclear division and the formation of basipetal basidiospore chains in *F. neoformans* (Kwon-Chung and Fell 1984).

or terminally on the hyphae. Basidia are nonseptate, slender, and uniformly wide in the basal area, but expand abruptly to form oblong to clavate apices (4–10) × (6–13) μm (Fig. 323A,B).

The apical enlargement is often at an angle to the main axis of the basidium. Diploidization occurs in the basidium, and meiosis takes place near the apex of the basidium. Basidiospores are ovoidal, ellipsoidal, cylindroidal, pyriform to globose (1.8–3 × 2–5 μm in diameter), with finely roughened walls and with or without truncate bases. They are produced by basipetal budding directly from four spots on the basidial apex. The chain of basidiospores may contain more than 20 spores per chain. The basidiospore chains collapse into spore balls under humid conditions. Some basidia produce fewer than four initial spores, and these spores are usually twice the size of typical spores. Rarely, more than four initial basidiospores are produced, and extensive chain formation has not been observed in such basidia. Initially, spores are dry and a capsule is not visible until the spores enlarge to twice the original size and undergo profuse budding. Budding of basidiospores results in mucoid colonies of yeast cells representing α , a , or infrequently aa (self-fertile) mating types.

Cytological (Kwon-Chung 1976b) and genetic (Kwon-Chung 1980) studies indicate that the four small nuclei of the first meiotic product remain in the apical part of the basidium and each nucleus divides mitotically. Daughter nuclei migrate into basidiospores, while parent nuclei divide repeatedly during basipetal budding to form uninucleate basidiospores in chains. The spore chains show random distribution of nuclei and, as a result, the spores from a single chain are not genetically identical (Fig. 325).

Monokaryotic fruiting: Shadomy (1970) demonstrated hyphal formation in 11 single cultures (Lurie and Shadomy 1971), and three of the hyphae-forming isolates completed basidial formation without apparent mating (Erke 1976). The isolates were all from human cryptococcosis cases. The isolates first grew in yeast form and produced hyphae with clamp connections either from single yeast cells or from a pair of yeast cells connected by a clamp connection. Hyphal cells were monokaryotic but dikaryons were observed in terminal cells in some strains. In some strains, however, dikaryons were not restricted to terminal cells. The morphological aspects of the basidium and basidiospores produced in self-fertile strains were the same as in the mated cultures except that in the former,

hyphae showed incomplete clamp connections (clamps not fused to the adjoining cells). Colonies developed from single basidiospore cultures obtained from such fruitings were capable of repeating the whole life cycle, but the yeast cells isolated from such colonies became markedly weaker in sporulation in subsequent generations. Erke (1976) suggested that these strains are primarily homothallic; and others designated these strains as self-fertile, though principally heterothallic (Kwon-Chung 1977a). The genetic basis of the self-fertility in these strains was hypothesized to be a diploid state, containing both α and a alleles. Recently, it was found that this so-called self-fertility is a monokaryotic fruiting primarily occurring in the α isolates. Monokaryotic fruiting has been observed in many genera of the Homobasidiomycetes (Stahl and Esser 1976).

Wickes et al. (1996) observed that a majority of α isolates tested can produce monokaryotic fruiting on a medium deprived of nitrogen such as Yeast Nitrogen Base without ammonium sulfate. The association of the α mating type with “self-fertility” had been noted twenty years ago (Kwon-Chung 1977a), when it was found that all the self-fertile cultures eventually behave as α type when the self-fertility becomes suppressed during the prolonged maintenance on rich media. This phenomenon, however, was thought to be due to the loss of the a factor.

Fermentation: absent.

Supplementary description of *F. neoformans* var. *bacillispora*:

This variety can be readily differentiated from the var. *neoformans* by morphological and biochemical characteristics. In contrast to *F. neoformans* var. *neoformans*, *F. neoformans* var. *bacillispora* produces smooth and bacillary-shaped basidiospores measuring (1–1.8) × (3–8) μ m, but produces no haustorioid hyphae. The anamorph of *F. neoformans* var. *bacillispora*, *Cryptococcus neoformans* var. *gattii*, tends to produce more oval and lemon-shaped, (3–5) × (3–7) μ m, yeast cells rather than globose cells. The growth rate of the two varieties is the same at 25°C, but at 37°C, var. *bacillispora* grows slower than var. *neoformans*. Unlike *F. neoformans* var. *neoformans*, the var. *bacillispora* can utilize D-proline as a sole source of nitrogen and changes the color of

CGB medium to blue-green within two to five days. The life cycle of var. *bacillispora* resembles that of *F. neoformans* except that haustorioid hyphae have not been observed (Fig. 326).

F. neoformans var. *bacillispora* has not been isolated from pigeon droppings or soil and does not share an ecological niche with the *neoformans* variety. The natural habitat of this variety is reported to be the Red River gum tree, *Eucalyptus camaldulensis* (Ellis and Pfeiffer 1990).

Mol% G+C of the variety *bacillispora*: 56.3–57.2, three strains (T_m : Aulakh et al. 1981).

Origin of the strains belonging to the variety *neoformans*:

CBS 132 (type strain of *Cryptococcus neoformans*) from peach juice; CBS 6885 (α type) from a human bone lesion; CBS 6886 (α type) and NIH 433 isolated from pigeon excreta in Denmark; CBS 6900 and CBS 6901, single basidiospore progenies obtained from CBS 6885 × NIH 433. The natural habitat is pigeon and other avian excreta and soil.

Complementary mating types and living reference strains:

CBS 6885 (α type) and CBS 6886 (α type).
Holotypes: BPI 71843, a slide mount of basidial structures prepared from the cross CBS 6885 (α) × CBS 6886 (α), was deposited in the herbarium of the National Fungus Collection, Beltsville, MD. The holotype of the type culture of *Cryptococcus neoformans* var. *neoformans* (BPI 72042) has also been deposited at the National Fungus Collection.

Origin of the strains belonging to the variety *bacillispora*:

Eleven strains from human cases of cryptococcosis. CBS 6992 (serotype B) and CBS 6993 (serotype C) were originally received from Dr. Evans.

Complementary mating types and living reference strains:

CBS 6956 (α mating type, serotype B, from sputum) and CBS 6955 (α mating type, serotype C, from spinal fluid).

Holotypes: A slide mount (BPI 71855) of basidial structures prepared from the cross CBS 6992 × CBS 6993 has been deposited in the herbarium, National Fungus Collection, Beltsville, MD. The holotype of *Cryptococcus neoformans* var. *gattii*, and the anamorph or *F. neoformans* var. *bacillispora*, are preserved at the Laboratory for Mycology of the Institute of Tropical Medicine, Antwerp, Belgium (De Vroey and Gattii 1989).

Comments on the genus

The disease caused by *Cryptococcus neoformans*, the haploid state of *F. neoformans*, was first reported by Busse in 1894. Busse was a pathologist who observed the round to oval “corpuscles” in a tumor of the tibia of a woman (Busse 1894) who was diagnosed with a soft sarcoma. Busse isolated a culture from the lesion, and one of his colleagues thought that it was a pathogenic species of blastomycetes (*vide* Sanfelice 1895a). Buschke, a physician who took care of the patient, thought that the etiologic agent was a coccidia (Buschke 1895).

Soon after Busse's report, Sanfelice isolated an encapsulated yeastlike fungus from peach juice and named it *Saccharomyces neoformans* (Sanfelice 1894). In 1895, Sanfelice proved the pathogenicity of *S. neoformans* by inoculating the yeast into experimental animals (Sanfelice 1895a). He recognized the similarity between *S. neoformans* and Busse's isolate. In the same year, he isolated a "*Saccharomyces*" which was thought to be the same fungus as *S. neoformans* from the lymphatic glands of an ox which had died from a primary liver infection (Sanfelice 1895b).

In 1901, Vuillemin transferred the fungus to the genus *Cryptococcus* as *C. hominis*, because he did not find ascospores that characterize the genus *Saccharomyces* (Vuillemin 1901). *Cryptococcus neoformans* had been regarded as a homogeneous species except for the existence of four serotypic variations, A, B, C, and D (Evans 1949, 1950, Wilson et al. 1968) among the isolates. Since the discovery of two morphologically different sexual states among the isolates of *C. neoformans*, it became clear that the isolates of serotypes B and C are fundamentally different from the isolates of serotypes A and D (Bennett and Kwon-Chung 1989). Initially, *C. neoformans* was considered to contain two different teleomorphic species: *F. neoformans* (Kwon-Chung 1975) and *F. bacillispora* (Kwon-Chung 1976a). The *F. neoformans* state was produced by the cross between two mating types of serotype A or D isolates, whereas the *F. bacillispora* state was observed when crosses were made among serotype B or C isolates. Intercrossing between A, D and B, C isolates usually produces basidia with two types of spores: oblong to lemon-shaped spores of *F. neoformans* type, and bacilliform spores of *F. bacillispora* type. In some crosses, however, the spores were predominantly of *F. bacillispora* type (Rogers et al. 1980). The spores produced by the intercrossings between the type cultures of the two species and many other pairs were sterile; however, CBS 6991 (*a* type, serotype D) produced viable basidiospores (30%) when crossed with CBS 6956 (α type, serotype B). The viable basidiospores produced a 1:1 ratio of α and *a* mating types, but all were serotype D. All the α type F_1 isolates assimilated L-malate, while *a* type did not. Since 70% of the basidiospores were nonviable, it was not possible to analyze whether the viable progeny were recombinants or whether the D factor was a dominant cytoplasmic factor. Further genetic analyses between the two species of *Filobasidiella* indicated that they can be more appropriately classified as two varieties of one species. Aulakh et al. (1981) showed 55–63% relatedness between the DNAs of *F. neoformans* and *F. bacillispora*. Furthermore, the type strain of *C. neoformans* var. *gattii* Vanbreuseghem and Takashio (1970) mated with *F. neoformans* and produced basidiospores. The type culture of *C. neoformans* var. *gattii* was physiologically and morphologically indistinguishable from the anamorph of the type strain of *F. bacillispora*. On the basis of these results, *F. bacillispora* was reclassified as *F. neoformans* var. *bacillispora* (Kwon-Chung et al. 1982a).

Cryptococcus neoformans var. *neoformans*, the haploid state of *F. neoformans* var. *neoformans*, and *C. neoformans* var. *gattii*, the haploid state of *F. neoformans* var. *bacillispora*, show considerable differences in their electrophoretic karyotype. Wickes et al. (1994) were able to separate 13 chromosome-sized DNA bands in the reference strains of *F. neoformans* var. *neoformans* and 13–14 bands in the reference strains of *F. neoformans* var. *bacillispora*, but the smallest band of *F. neoformans* var. *neoformans* was approximately 250 kb larger than that of the var. *bacillispora*. The anamorphs of the two varieties also show differences in ecology and epidemiology. Pigeon droppings and, less frequently, other bird droppings have been known as the major environmental source of *C. neoformans* var. *neoformans* (Emmons 1955). Pigeons seem to be a carrier of *C. neoformans* var. *neoformans*, since pigeons caged in different parts of the world contain the fungus in their crops. Our test with 11 isolates obtained by Vanbreuseghem from pigeon crops (caged pigeons) showed all to be serotype A. Isolates of serotype D were frequently found in pigeon droppings collected in northern Europe (Bennett et al. 1977). Although infrequent, *C. neoformans* var. *neoformans* has been isolated from rotting vegetables, fruits and fruit juices, wood, dairy products, and soil contaminated with pigeon droppings.

The ecological niche of *F. neoformans* var. *neoformans* is not known. It is suspected that the natural reservoir of *F. neoformans* var. *neoformans* is different from that of *C. neoformans* var. *neoformans* for the following reason: the isolates of *C. neoformans* var. *neoformans* isolated from pigeon droppings, pigeon nests, and soil in the United States have all been of the mating type α (Kwon-Chung and Bennett 1978). If the primary ecological niche of *F. neoformans* is avian droppings, both α and *a* mating types should have been found from these sources. Similarly, *Tremella* (jelly fungi), another fungus phylogenetically related to *F. neoformans*, is found as a saprophyte on dead tree branches, while its haplophase is isolated from various other substrates besides dead tree branches.

Unlike *C. neoformans* var. *neoformans*, *C. neoformans* var. *gattii* has not been found from a wide range of substrates. It has not been isolated from pigeon or any other bird droppings. Until recently, *C. neoformans* var. *gattii* has only been isolated from clinical specimens collected from humans and animals. An isolation of *C. neoformans* var. *gattii* serotype C from the environment was reported by Denton and DiSalvo (1968), but the isolate was subsequently determined to be an A serotype of the variety *neoformans*. Ellis and Pfeiffer found the natural habitat of *C. neoformans* var. *gattii* serotype B (Ellis and Pfeiffer 1990, Pfeiffer and Ellis 1992). They isolated several strains from wood bark and leaves lying under the canopies of *Eucalyptus camaldulensis* and *E. tereticornis* in Australia. The serotype B isolates of the variety *gattii* were also isolated from materials collected in a koala enclosure in Australia (Pfeiffer and

Ellis 1993). Three strains of *C. neoformans* var. *gattii* isolated from *E. camaldulensis* by Ellis and Pfeiffer were tested in our laboratory and were found to produce fatal infections in mice. When rDNA sequences specific for *C. neoformans* were used to probe RNA extracted from the cultures, the signals of hybridization were equally intense between clinical strains and *Eucalyptus*-originated strains (Kwon-Chung et al. 1992). Attempts to produce the *Filobasidiella* state from these isolates by crossing with type strains of both varieties of *F. neoformans* failed. This was not surprising, since a previous study showed at least 26% of serotype B isolates to be sterile (Kwon-Chung and Bennett 1978). The isolation of *C. neoformans* var. *gattii* from *E. camaldulensis* has epidemiological significance, since the distribution pattern of *E. camaldulensis* corresponded to reported cases of cryptococcosis caused by *C. neoformans* var. *gattii* in Australia (Ellis and Pfeiffer 1990).

Prior to the epidemic of acquired immunodeficiency syndrome (AIDS), cryptococcosis was most commonly reported from patients with leukemia or other kinds of cancer, sarcoidosis, and rheumatoid arthritis (with steroid therapy). Since the early 1980s, AIDS became the leading predisposing condition for cryptococcosis. In the United States, at least 50% of the total cryptococcosis cases reported annually are from AIDS patients, ranking as the fourth most life-threatening infection in these patients. According to one study, in 106 AIDS patients with cryptococcal infection, cryptococcosis was the first manifestation of AIDS in 45% of these patients (Chuck and Sande 1989). The epidemiological studies of the two varieties conducted prior to the AIDS epidemic indicated that infections caused by isolates of *C. neoformans* var. *neoformans* is worldwide in distribution. Infections caused by isolates of *C. neoformans* var. *gattii*, however, were prevalent in tropical and subtropical regions and were rarely found in regions with cold climates (Kwon-Chung and Bennett 1984).

Because cryptococcosis occurs most commonly in AIDS patients, and almost all AIDS patients with cryptococcosis are due to the var. *neoformans* regardless of the geographic location, the overall frequency of infection due to var. *gattii* had diminished drastically since the advent of AIDS. Studies of isolates from two regions previously known as the high-prevalence areas for *C. neoformans* var. *gattii*, Southern California and Brazil, indicated that *C. neoformans* var. *gattii* still causes infection frequently in non-AIDS patients. This indicates that *C. neoformans* var. *gattii* is not disappearing from the environment but that AIDS patients may be more predisposed to infection by *C. neoformans* var. *neoformans* than to var. *gattii*, or they may be less exposed to the source of var. *gattii* than to that of var. *neoformans* (Kwon-Chung et al. 1990).

The holotype strains of *F. neoformans* var. *neoformans* have been proven to be highly virulent for mice. The holotype strains of *F. neoformans* var. *bacillispora* (from clinical source), however, are of low virulence (or

avirulent) in mice (Kwon-Chung et al. 1982a). Isolates of *C. neoformans* var. *gattii* from *Eucalyptus*, on the other hand, are as virulent in mice as those of the var. *neoformans* (Kwon-Chung et al. 1992). The low virulence of the isolates of *F. neoformans* var. *bacillispora* from clinical sources was partly explained by their growth rate at 37°C *in vitro*. *F. neoformans* var. *bacillispora* has a longer doubling time at 37°C than *F. neoformans* var. *neoformans* (Kwon-Chung et al. 1982a). In humans, however, *F. neoformans* var. *bacillispora* causes no less severe infection than *F. neoformans* var. *neoformans*.

Because of the medical importance of *F. neoformans*, various methods for rapid identification were developed. Staib (1962) found that *C. neoformans* was the only tested yeast species to produce dark brown colonies when grown on an agar medium containing niger seed (*Guizotia abyssinica*) extract. Shields and Ajello (1966) developed a medium for selective isolation of *C. neoformans* by incorporating an extract of *G. abyssinica* into an agar medium containing glucose, creatinine, chloroamphenicol, and diphenyl. Pulverer and Korth (1971) found that various *o*- and *p*-diphenols and *o*-triphenols produced results similar to the *G. abyssinica* extract. Strachan et al. (1971) determined that hydroxyl groups in the 3 and/or 4 position of the phenyl ring were common to all compounds which give rise to dark brown pigment. Shaw and Kapica (1972) reported that 3,4-dihydroxyphenylalanine phenoloxidase found in the cells of *C. neoformans* catalyzes melanin synthesis from *o*-diphenols, but not from tyrosine. According to our experience, niger seed agar gave the most consistent results of melanin formation within 1–5 days compared to chlorogenic acid agar or DOPA agar. Isolates of *C. neoformans* var. *gattii* may, on the average, take longer to produce the color, and the intensity of the pigment may be weaker than that of var. *neoformans*. The concentration of the carbon sources in the medium plays a decisive role for the rapid formation of pigment (Nurudeen and Ahearn 1979). Media containing 1% or higher concentrations of glucose delay the formation of melanin compared with media containing 0.1 or 0.05%. Most isolates of the two varieties produce brown colonies within 1–3 days on niger seed agar with 0.1% glucose. Total elimination of glucose from niger seed agar allowed 60 of 89 isolates to develop the pigment within 12 hours (Palawal and Randhawa 1978). Williamson (1994) found that the transcriptional activity of the structural gene coding for diphenoloxidase (*CNLAC1*) is derepressed when *C. neoformans* is grown in the absence of glucose. Biochemical aspects of phenoloxidase and melanin synthesis in *C. neoformans* were studied (Polacheck et al. 1982, Polacheck and Kwon-Chung 1988, Williamson 1994) and were found to be similar to that found in melanoma cells, except that it starts from DOPA instead of tyrosine. The ability to form melanin was shown to be one of the important virulence factors in *C. neoformans*. The mutants lacking phenoloxidase activity were found to have lost the ability to cause fatal infection in mice, and their virulence was

restored when the mutants reverted to show phenoloxidase activity (Rhodes et al. 1982, Kwon-Chung and Rhodes 1986). Employing molecular methods, Salas et al. (1996) confirmed that the *CNLAC1* gene plays a significant role in virulence for mice.

Several one-step diagnostic media to distinguish the isolates of the two varieties have been developed on the bases of their biochemical differences. Only *C. neoformans* var. *gattii* grows on CGB medium and produces a blue color, because it can utilize glycine as the sole source of carbon and nitrogen, in addition to being resistant to L-canavanine (Kwon-Chung et al. 1982b). Only *C. neoformans* var. *gattii* isolates grow on D-proline agar because they can utilize D-proline as a nitrogen source (Dufait et al. 1987). *C. neoformans* var. *gattii* grown on an agar medium containing ethylenediaminetetraacetate (EDTA) produces no urease activity in rapid urea broth, because the enzyme is sensitive to EDTA. The urease of *C. neoformans* var. *neoformans*, however, is resistant to EDTA (Kwon-Chung et al. 1987).

Most isolates of the two varieties are sensitive to $\leq 12 \mu\text{g/ml}$ of cycloheximide and, therefore, agar media containing cycloheximide, such as mycosel agar, should not be used for isolation. Isolates of *C. neoformans* var. *gattii* grow very slowly at 37°C, and the primary isolation tubes or plates should be incubated at 30–35°C. The optimum growth temperature for both varieties is 32°C.

A mechanism of basidiospore formation, similar to *Filobasidiella* species (Kwon-Chung 1976b), is not found in the other genera belonging to the Filobasidiales, and the author is not aware of any comparable situation in the basidiomycetes in general. Species of *Schroeteria* previously considered to belong the Ustilaginales produce spores in chains, but they are produced by acropetal budding (Zundel 1953) rather than basipetal budding as in the case of *Filobasidiella*. Recently, Nagler et al. (1989) concluded that the genus *Schroeteria* should be excluded from the Ustilaginales because the species of *Schroeteria* possessed septal pores, Woronin bodies, and cell walls characteristics of Ascomycetes.

The cytology of basidiospore formation by *F. neoformans* partly resembles that of *Ustilago* species (Alexopoulos and Mims 1979). In *Ustilago maydis*, the nuclei of the first meiotic product divide mitotically and daughter nuclei migrate into the basidiospores (sporidia), while parent nuclei remain in the promycelium. Unlike *Filobasidiella* species, however, the four daughter nuclei are separated from each other by septa of the promycelium, and basipetal chains of sporidia are not produced.

Progress on the molecular biology of *F. neoformans* has been made since a method for spheroplast formation and the isolation of high molecular-sized DNA using Novozyme was described (Rhodes and Kwon-Chung 1985). Mitochondrial restriction patterns of the two varieties have shown a great deal of polymorphism (Varma and Kwon-Chung 1989). Numerous genes, including rDNA (Restrepo and Barbour 1989, Kwon-Chung and

Chang 1994) *URA5* (Edman and Kwon-Chung 1990), *TRYP1* (Perfect et al. 1992), *DHFR* (Sirawaraporn et al. 1993), *HIS3* (Parker et al. 1994), *NMT* (Lodge et al. 1994), *CAP59* (Chang and Kwon-Chung 1994), *CNLAC1* (Williamson 1994), *GAL7* (Wickes and Edman 1995) and various others (Wickes et al. 1994) were cloned from *F. neoformans* var. *neoformans*. The transformation was accomplished in both varieties by using plasmids containing the *URA5* gene or *ADE2* gene as the selection markers (Edman and Kwon-Chung 1990, Toffaletti et al. 1993, Lodge et al. 1994). The *CAP59* and the *CAP64* genes responsible for synthesis of the polysaccharide capsule have been proven by molecular methods to be essential for virulence in *C. neoformans*. Deletion of these genes in a wild type strain resulted in the loss of capsule as well as the loss of virulence in mice. Conversely, acapsular, avirulent mutants with lesions in the *CAP59* and the *CAP64* loci regained capsule and virulence when the strains were complemented with the genes (Chang and Kwon-Chung 1994, Chang et al. 1996).

Malloch et al. (1978) isolated a filamentous fungus from a dead spider and described it as *Filobasidiella arachnophila*. Samson et al. (1983) found that *F. arachnophila* is identical to a fungus previously known as *Aspergillus depauperatus* Petch. Since *A. depauperatus* morphologically resembled *Filobasidiella* rather than *Aspergillus*, Samson et al. (1983) described a new combination *F. depauperata* (Petch) Samson, Stalpers and Weijman. Like *F. neoformans*, *F. depauperata* produces four spore chains on the apex of the basidium; however, *F. depauperata* lacks clamp connections and haustorium-like structures in the hyphae and produces no yeast cells in any part of its life cycle. *F. depauperata* also lacks the key biochemical markers of *F. neoformans*, namely the ability to hydrolyze urea, to oxidize diphenols, to assimilate inositol, and to synthesize starch-like compounds (Khan et al. 1981a). Despite these differences, the phylogenetic trees of Heterobasidiomycetes constructed on the bases of the 18S, 5.8S and 26S rDNA sequences (Kwon-Chung et al. 1995, Mitchell et al. 1992, Guého et al. 1993) indicate that *F. depauperata* is most closely related to *F. neoformans* and that both species have evolved from the *Tremella*-lineage. Ultrastructural studies of *F. depauperata* support its proposed *Tremella*-lineage (Kwon-Chung et al. 1995). The spindle pole bodies of *F. depauperata* and *F. neoformans* are nearly identical to those reported for *Tremella globosa* (Berbee and Wells 1988, Mochizuki et al. 1987). Hyphal septa of *F. depauperata* demonstrate dolipores with parenthesomes consisting of the separate cupulate vesicles typical of *Tremella* species. Some basidia of *F. depauperata* show evidence of partial longitudinal apical division (Kwon-Chung et al. 1995). Such partially septated basidia were seen in *Rhynchogastrea coronata* of the Tremellales (Metzler et al. 1989). *F. depauperata*, however, is not discussed in this chapter because it lacks a yeast stage.

83. *Filobasidium* Olive

K.J. Kwon-Chung

Diagnosis of the genus

Asexual reproduction by budding of globose, ovoidal, ellipsoidal or elongated cells. Pseudomycelium and true mycelium may be produced. Growth on solid media is white, cream-colored, or slightly pinkish, and often mucoid.

Sexual reproduction is heterothallic (Fig. 327), and following mating, the mycelium produces lateral or terminal holometabasidia. Basidiocarps are absent. Sessile basidiospores are produced terminally on the apex of the metabasidium in a petal-like whorl, giving the basidium a flower-like appearance in an apical view. Clamp connections are present at cross walls, and the septa contain typical dolipores with or without parentheses.

Fig. 327. Life cycle of *Filobasidium*.

Fermentation may be present. D-Glucuronate, *myo*-inositol and nitrate are sometimes assimilated. Starch-like compounds are produced. Diazonium blue B and urease reactions are positive. Coenzyme Q-9 or 10 are formed. Xylose is present in whole-cell hydrolyzates.

Type species

Filobasidium floriforme Olive

Species accepted

1. *Filobasidium capsuligenum* (Fell, Statzell, I.L. Hunter & Phaff) Rodrigues de Miranda (1972)
2. *Filobasidium elegans* Bandoni & Oberwinkler (1991)
3. *Filobasidium floriforme* Olive (1968)
4. *Filobasidium globisporum* Bandoni & Oberwinkler (1991)
5. *Filobasidium uniguttulatum* Kwon-Chung (1977)

Key to species

See Table 68.

1. a Basidiospores less than 10 μm long \rightarrow 2
b Basidiospores more than 10 μm long \rightarrow 3
- 2(1). a Basidia with up to 10 reniform to ovoidal (3–5 \times 4–9 μm) basidiospores per basidium *F. uniguttulatum*: p. 667
b Basidia with up to 5 subglobose to apiculate-ovoidal (6–8.5 \times 8–9 μm) basidiospores per basidium *F. globisporum*: p. 667
- 3(1). a Basidia more than 200 μm long; basidiospores 6–9 μm wide *F. floriforme*: p. 666
b Basidia mostly less than 140 μm long; basidiospores mostly less than 6 μm wide \rightarrow 4

<i>F. uniguttulatum</i>	-	-	+	-	-	reniform to ovoidal (3-5)×(4-9)µm

Systematic discussion of the species

83.1. *Filobasidium capsuligenum* (Fell, Statzell, I.L. Hunter & Phaff) Rodrigues de Miranda (1972)

Anamorph: *Candida japonica* Diddens & Lodder

Synonyms:

Leucosporidium capsuligenum Fell, Statzell, I.L. Hunter & Phaff (1969)

Torulopsis capsuligena (as *T. capsuligenus*) van der Walt & van Kerken (1961b)

Candida capsuligena (van der Walt & van Kerken) van Uden & H.R. Buckley (1970)

Torulopsis alba (as *T. albus*) Saito & Oda (1934)

Candida japonica Diddens & Lodder (1942)

Azymoprocandida japonica (Diddens & Lodder) Novák & Zsolt (1961)

Growth in 2% malt extract: After 3 days at 25°C, the haploid cells are subglobose, ovoidal, ellipsoidal to elongated, (2.5-10.7)×(4.0-17.8)µm, single or in pairs. A thin ring and a little sediment are formed. CBS 4736 produced a heavier film than the remaining two strains tested. After one month, there is a moderate to thick slimy ring and a heavy sediment.

Growth on 2% malt agar: After three days, the cells are similar in size and shape (Fig. 328A) to those formed in malt extract, except that elongated pseudomycelial cells occur. The streak culture is white to cream-colored, and the texture varies from dry to mucoid. The colony margin is entire and smooth or with tufts of mycelium. After 3 weeks, mating type α and *a* strains show differences in colony morphology. Strains of α type are mucoid, glistening, cream-colored, with a raised surface and smooth margin; mycelium is lacking. Colonies of mating type *a* have a soft, moist or dry texture and are not mucoid. The margin of the colony is undulate and heavily myceliated. The mycelium consists of branched, septate hyphae.

Dalmau plate culture on corn meal agar: Pseudomycelium or mycelium is absent in mating type α , while true mycelium is present in mating type *a*. Occasionally, a few short chains of undifferentiated, globose cells may be present.

Fig. 328. *F. capsuligenum*. (A) Yeast cells grown on malt agar for 3 days. Bar = 10 µm. (B1) Young basidium. (B2) Mature basidium.

Life cycle: On corn meal agar, conjugation occurs between two mating types within 12 hours of mixing at room temperature. Dikaryotic hyphae with clamp connections grow out from a conjugated pair within 48 hours. After 3 weeks, slender, holometabasidia measuring (3.0-6)×(70-140)µm are produced laterally or terminally on the dikaryotic mycelium (Fig. 328B1); five to nine sessile ellipsoidal to fusiform basidiospores, (4-6)×(9.5-13)µm, bud on the apices of the metabasidia (Fig. 328B2). Occasionally, single isolates may produce mycelium and basidial structures without apparent mating.

Vitamin requirement: Thiamine or thiamine + biotin.**Co-Q:** 10 (Yamada and Kondo 1972a).**Mol% G+C:** 49.8 (T_m : Nakase and Komagata 1971c).

Origin of the strains studied: CBS 1906 (*a* type) described as *Torulopsis albus* by Saito and Oda (1934) and isolated from sake-moto; CBS 4381 (*a* type) from cider by Beech, Bristol; CBS 4736, type culture of *Leucosporidium capsuligenum* (α type) from a wine cellar and described as *Torulopsis capsuligenus* (van der Walt and van Kerken 1961b); CBS 4173 from grapes in Germany; CBS 6122 from forest soil, Braunschweig, Germany.

Complementary mating types: CBS 1906 (*a*) and CBS 4763 (α).

Type strain: CBS 1906.**83.2. *Filobasidium elegans* Bandoni & Oberwinkler (Bandoni et al. 1991)**

Growth on 2% malt agar: The cells multiply by unipolar budding, and are predominantly ellipsoidal, (2.5–5) × (3.5–7.5) μ m, but a few cells may be elongate or spheroidal to subspheroidal. Colonies are mucoid and grayish-white to pale cream in color.

Life cycle: Sexuality of *F. elegans* has not been defined. Thin-walled, hyaline hyphae (2–3 μ m diameter) with clamp connections and haustorial branches produce clavate, thin-walled probasidia singly or arranged in a loose to relatively thin compact hymenium-like aggregation. Each probasidium elongates to become a tubular basidium with an abruptly swollen apex (Fig. 329); mature basidia (65–165 μ m long) have thick walls, especially near the apex (Fig. 329B). The diameter of basidia

Fig. 329. *F. elegans* (Bandoni et al. 1991). (A) Probasidia, a mature basidium with basidiospores and liberated basidiospores (allantoid or reniform). Top view of basidiospores while they are on the basidium (circular arrangement shown on the top left corner). Bars = 10 μ m. (B) Basidia with basidiospores. Bar = 5 μ m.

is 3.5–5.5 μ m in the middle portion and 6–6.5 μ m at the apex bearing basidiospores. Basidia bear 5 to 8 sessile basidiospores that leave minute scars of attachment on the surface of the apex after secession. After the spore secession, basidia collapse inward. Basidiospores, (4.5–7.5 × 8.5–15) μ m, which are reniform or infrequently ellipsoidal, are usually arranged in a circle of 4 or 6 around a single central basidiospore (Fig. 329A). The circular arrangement is usually retained for a short time after release. Basidiospores germinate by budding.

Co-Q: Not determined.**Mol% G+C:** Not determined.

Origin of the strain studies: CBS 7638, 7639, 7640, and 7641 were all isolated from dead inflorescence of *Yucca brevifolia* collected near Gorman, Los Angeles County, California.

Holotype: *F. elegans* on weathered inflorescence scape of *Yucca brevifolia*, collected 10 miles east of Gorman, Los Angeles County, California, was deposited in the herbarium, National Fungus Collection (BPI 118718).

Comments: *Filobasidium elegans* was described by Bandoni et al. (1991) from a fungus collected on a weathered inflorescence scape of various *Yucca* species in California. The anamorph of *F. elegans* is a budding, yeastlike fungus that produces mucoid colonies with a grayish-white to pale cream color. The physiology of *F. elegans* was not characterized by the authors and the carbon assimilation profile was extracted from the CBS data base.

83.3. *Filobasidium floriforme* Olive (1968)

Growth in 2% malt extract: After 3 days at 25°C, the haploid cells are subglobose, ovoidal, or ellipsoidal to long-ovoidal, (2.5–6) × (3–8) μm, single, in pairs, or in small clusters. A small amount of sediment is present. After one month, a moderate ring and sediment are present.

Growth on 2% malt agar: Cell morphology is similar to that in malt extract (Fig. 330A). The streak culture is dull-white to cream-colored and highly mucoid after one month. The colony margin is entire with no mycelium. On corn meal agar, growth is thin, and some strains bear a tinge of pink color.

Dalmau plate culture on corn meal agar: Pseudo- and true mycelium are absent in the haploid state.

Life cycle: Conjugation occurs when cells of two compatible mating types are mixed on V8 juice or hay infusion agar. Soon after conjugation, dikaryotic hyphae with clamp connections are produced from the conjugant.

Fig. 330. *F. floriforme*. (A) Yeast cells grown on malt extract for 3 days. Bar = 10 μm. (B1) Young basidium. (B2) Mature basidium. (B3) Germinating basidiospore. (C) Seven basidiospores released from a single basidium. Bar = 10 μm.

The hyphal septum contains a dolipore but not parenthesomes. Long slender holometabasidia, (3.2–7) × (57–212) μm, arise mostly from branching clusters of hyphae. The thin-walled young metabasidia are slightly broader (Fig. 330B1) than the hyphae bearing them and contain a denser cytoplasm. Six to eight ellipsoidal to ovoidal basidiospores, (6–9) × (10.5–16.5) μm, are formed directly from the expanded apex (Fig. 330B2,C) of the basidia. Basidiospores produce blastoconidia (Fig. 330B3), which continue to bud profusely and form yeast colonies. Occasional isolates have been shown to produce a complete sexual state without mating. Karyogamy and meiosis occur in metabasidia.

Fermentation: absent.

Co-Q: 10 (Sugiyama et al. 1985).

Mol% G + C: Not determined.

Origin of the strains studied: Plume grass (*Erianthus giganteus*) (3); *Hibiscus siriaca* (2); *Yucca* (*Yucca rupicola*) (3).

Complementary mating types: CBS 6241 (*α*) and CBS 6242 (*a*).

Holotype: Herbarium material SC29 was designated as the type by Olive and deposited at the New York Botanical Garden in the Bronx, New York.

Extype strain: CBS 6241, isolated from *Hibiscus siriaca*.

Comments: Although the haploid state of *F. floriforme* is phenotypically similar to *Cryptococcus albidus*, the type strain and many other *C. albidus* strains, including

every variety, failed to mate with α or a mating types of *F. floriforme*.

83.4. *Filobasidium globisporum* Bandoni & Oberwinkler (Bandoni et al. 1991)

Growth on 2% malt agar: The cells, (2.5–5.5×3–9) μm , multiply by budding, and are spheroidal to ellipsoidal or subcylindrical, occasionally with a small extension on one or both ends. The colonies are mucoid and grayish-white to cream in color.

Life cycle: The sexual pattern of *F. globisporum* has not been defined. Hyphae (2–3 μm in diameter) are thin walled with clamp connections and haustorial branches. Basidia are subtended by clamps and produced in dense white patches that are hymenium-like. Mature basidia (35–122 μm long) are 2.5–3.5 μm wide in the middle portion and expanded to 4–5.5 μm apically, and bear 3–5 basidiospores on coarse tubercles (Fig. 331). Some basidia produce 1–3 short lateral branches, which may be sporogenous or remain sterile (Fig. 331A). Basidial walls are thicker immediately below the swollen apex, which shows coarse tubercles that mark the sites of spore attachment. Basidiospores are globose (6–8.5 μm in diameter) or apiculate-ovoidal or broadly ovoidal in side view (6–8.5×8–9 μm). Basidiospores germinate by budding.

Fermentation: absent.

Mol% G+C: Not determined.

Origin of the strains studied: CBS 7642, 7643, 7644, and 7645 were isolated from weathered leaf of *Yucca*

Fig. 331. *F. globisporum*. (A) Fertile hyphae with clamps, young basidia and basidiospores. (B) Mature basidia and basidiospores (Bandoni et al. 1991). Bars = 10 μm .

brevifolia collected 10 miles east of Gorman, Los Angeles County, California.

Holotype: *F. globisporum* on weathered leaves of *Yucca brevifolia*, collected 10 miles east of Gorman, Los Angeles County, California, was deposited at the herbarium, National Fungus Collection (BPI 1108721).

Comments: Bandoni et al. (1991) described *F. globisporum* on the basis of a fungus found on weathered leaves of *Yucca brevifolia* growing in California and Nevada. The anamorph of *F. globisporum* is a budding, yeastlike fungus that produces mucoid colonies with grayish-white to cream color. The description of *F. globisporum* is an excerpt from the original paper by Bandoni et al. (1991), and the assimilation profile was extracted from the CBS database.

83.5. *Filobasidium uniguttulatum* Kwon-Chung (1977b)

Anamorph: *Cryptococcus uniguttulatus* (Zach) Phaff & Fell

Synonyms:

Eutorulopsis uniguttulata Zach (Wolfram & Zach 1934b)

Cryptococcus uniguttulatus (Zach) Phaff & Fell (1970)

Cryptococcus neoformans (Sanfelice) Vuillemin var. *uniguttulatus* (Zach) Lodder & Kreger-van Rij (1952)

Growth in 2% malt extract: After 3 days at 25°C, the haploid cells are globose to ovoidal, single, in pairs, or in small clusters, (3.0–5.5)×(3.5–7.0) μm , rarely up to 9 μm long. A thin ring and a small amount of sediment may be present. After one month, there is a moderate ring and a moderate amount of sediment.

Growth on 2% malt agar: Shape and size of the cells are similar to those grown in malt extract (Fig. 332A). After one month at 25°C, the streak culture is white to cream-colored with an entire margin. Colony texture is smooth, soft, and semiglossy.

Dalmat plate culture on corn meal agar: Pseudo- and true mycelium are not formed in the haploid phase.

Life cycle: On V8 juice or hay infusion agar, cells

produce conjugation tubes, $(1-5) \times (1.5-20) \mu\text{m}$, within 2-3 days after mixing of two compatible mating types. The conjugation tube is usually sinuous and narrower than the dikaryotic hyphae, which arise from the conjugated cells. The dikaryotic hyphae bear clamp connections at each septum. Within 7-10 days, mature metabasidia appear in the margin of mated cultures. Young metabasidia are thin-walled and broader than the hyphae from which they originate. They develop singly or in groups of two to four on the side of hyphae at the clamp or terminally on the hyphae (Fig. 332B). Blastospores are occasionally produced laterally on the hyphae. Metabasidia are elongated, $(4-6) \times (30-90) \mu\text{m}$; they taper apically and expand abruptly to produce a globose apex ($3-5 \mu\text{m}$ diameter) (Fig. 332D) with four to ten sessile terminal basidiospores (Fig. 332C). The basidiospores bud directly from the apex. The spores are ovoidal to kidney-shaped, $(3-5) \times (4-9) \mu\text{m}$. Infrequently, haustorioid branches are produced from the clamp of the dikaryotic hyphae. The liberated basidiospores reproduce by budding and form yeast colonies. Although a detailed cytological study was not carried out, analysis of single basidiospores indicated that meiosis occurred in the metabasidium.

Fermentation: absent.

50% Glucose (w/w)-yeast extract agar	-		

Co-Q: 9 (Yamada and Kondo 1972a).

Mol% G+C: 51.5 (T_m : Storck et al. 1969, Nakase and Komagata 1971c).

Origin of the strains studied: Five strains were from clinical specimens: CBS 1730 (α) and CBS 1727 (α) from diseased nails; CBS 2770 (α) from white spots

Fig. 332. *F. uniguttulatus*. (A) Yeast cells grown on malt extract agar for 3 days. (B) Young basidia. (C) Mature basidia. (D) Basidia after the release of basidiospores. Bars = $10 \mu\text{m}$.

in the mouth; CBS 2994 (α) from a bronchus; and CBS 4257 (α) from sputum. Five strains were single basidiospore cultures obtained by crossing CBS 1730 and CBS 1727.

Complementary mating types: CBS 1727 (α) and CBS 1730 (α).

Type strain: CBS 1730.

Comments: Yamada and Kondo (1972a) studied the Co-Q system of eight species and three varieties in the genus *Cryptococcus*. They found that, except for *C. uniguttulatus*, all had the Q-10 system. The known teleomorphs of species with the Q-10 system belonged either to *Filobasidiella* or *Filobasidium*. The coenzyme Q of *C. uniguttulatus*, the anamorph of *F. uniguttulatus*, however, was Q-9. The question remains whether the isolate that Yamada and Kondo studied produces the *F. uniguttulatus* teleomorphic state. Although *F. uniguttulatus* has been isolated from diseased nails (human) or other clinical specimens, it has not been documented to cause invasive disease.

Comments on the genus

Fell et al. (1969) described the sexual state of *Candida*

japonica (*Candida capsuligena*) as *Leucosporidium capsuligenum*. Basidiospores and basidia were not mentioned, but terminal teliospores connected to the hyphae by clamp connections were described. These were later found to be the initial stage of metabasidium formation. Rodrigues de Miranda (1972) observed the complete sexual life cycle of the species and redescribed the species as *F. capsuligenum*.

Physiologically, *F. capsuligenum* differs from other members of the genus by the ability to ferment glucose and maltose. The extracellular amylolytic systems of *F. capsuligenum* were studied in detail by De Mot and Verachtert (1985). The purified α -amylase (1,4- α -D-glucanglucohydrolase) and two forms of glucoamylase (1,4- α -D-glucanglucohydrolase). The molecular weight of the α -amylase was 64 000, while that of glucoamylase was 60 000. The optimum temperature and pH for α -amylase are 50°C and 5.6, respectively. Although the two forms of glucoamylase had identical molecular weight, their optimum temperature and pH ranges were different.

Ultrastructurally, *F. capsuligenum* differs from *F. floriforme* by having cone-shaped vesicular parenthosomes, while the latter species lacks the parenthosome (Moore and Kreger-van Rij 1972). Such parenthosomes were also observed in *Tremella* species (Khan 1976). *F. uniguttulatum* differs from *F. floriforme* by the inability to assimilate nitrate and lactose. *Cryptococcus uniguttulatus*, the asexual state of *F. uniguttulatum*, was first described as *Eutorulopsis uniguttulata* by Zach (Wolfram and Zach 1934b). Lodder and Kreger-van Rij (1952) redescribed this yeast as *Cryptococcus neoformans* var. *uniguttulatus* on the basis of morphological and physiological similarities with *C. neoformans*, but with reduced capsule formation. In 1961, Kreger-van Rij recognized that isolates of *C. neoformans* assimilated galactitol as a sole carbon source and were able to grow at 37°C, whereas the variety was not able to do so. An

additional difference in creatinine utilization was found between the species and variety by Staib (1963). In 1970, Phaff and Fell reestablished the species status for the variety as *C. uniguttulatus*. With the discovery of the *Filobasidium* state, it is now clear that *C. uniguttulatus* is phylogenetically closer to *Candida japonica* and *Cryptococcus albidus* than to *C. neoformans*. Physiological and morphological characteristics of *C. albidus* fit well with the asexual state of *F. floriforme*; however, we failed to demonstrate successful mating between the type strains of the *C. albidus* varieties with the tester of *F. floriforme*.

The genus *Filobasidium* can readily be separated from *Filobasidiella* by differences in the morphology of their metabasidia. The intergeneric homology of 25S rRNA studied by relative binding of unlabeled 25S rRNA from *F. capsuligenum* and *F. uniguttulatum* with a ³H-labeled cDNA probe of *F. neoformans* showed a minimal difference of 16.11 relative binding% (Baharaeen and Vishniac 1984). The 18S and 25S rRNA sequence analysis supported such observations. Guého et al. (1989) found differences in at least 32 positions within the region of 350 nucleotides in the 25S rRNA and 17 positions within the region of 332 nucleotides in the 18S rRNA.

In 1991, Bandoni et al. described two new species of *Filobasidium*, *F. elegans* and *F. globisporum*, both isolated from weathered inflorescences and leaf parts of several *Yucca* species collected in California, Nevada, and Texas. Bandoni et al. (1991) did not characterize the yeast phases of the species. The description of the two species indicated that they can be distinguished from the three previously known species by the shape and size of the basidiospores and the length of the basidia. Elucidation of their life cycle, biochemical characteristics of the yeast phase, and nucleotide sequence of rRNA are needed to understand the relationship of the two species with the remaining *Filobasidium* species.

84. *Leucosporidium* Fell, Statzell, I.L. Hunter & Phaff

A. Statzell-Tallman and J.W. Fell

Diagnosis of the genus

Growth on solid media is white to cream-colored, often mucoid. Visible carotenoid pigments are not present. Both yeast and mycelial phases may occur. Yeast phase cells are ovoidal to elongate and reproduce by budding; a pseudomycelium may form. The mycelial phase is characterized by true mycelium with or without clamp connections and the formation of terminal and intercalary teliospores. The septal structure is a simple pore. Ballistospores and ballistoconidia are not present.

Sexual mechanisms, although not completely investigated, include unifactorial (bipolar) and bifactorial (tetrapolar) systems. In these heterothallic systems, a dikaryotic mycelium results from the conjugation of a compatible mating pair. A clamp connection is usually present at each cross wall. Intercalary and terminal teliospores develop. Karyogamy takes place in the teliospore (probasidium) which germinates to produce a metabasidium (promycelium) that is septate, usually with four cells (phragmometabasidium). Meiosis takes place during germination and the resulting haploid basidiospores are lateral and terminal on the phragmometabasidia.

Teliospores can be produced, in the apparent absence of mating, by two mechanisms. Uninucleate yeast cells of *L. antarcticum* and *L. scottii* produce uninucleate teliospore-bearing hyphae that lack true clamp connections. In contrast, the uninucleate yeast cells of *L. fellii* are diploid, reduction division takes place with the formation of dikaryotic teliospore-bearing hyphae with clamp connections; karyogamy occurs in the teliospores, which germinate to a metabasidium with diploid basidiospores.

Glucose is not fermented. Nitrate is assimilated. Diazonium blue B and urease reactions are positive. *Myo*-inositol is not assimilated. Starch-like compounds are not produced. Coenzymes Q-9 and Q-10 are present. Xylose is absent from cell hydrolyzates.

Type species

Leucosporidium scottii Fell, Statzell, I.L. Hunter & Phaff

Species accepted

1. *Leucosporidium antarcticum* Fell, Statzell, I.L. Hunter & Phaff (1969)
2. *Leucosporidium fellii* Giménez-Jurado & van Uden (1989)
3. *Leucosporidium scottii* Fell, Statzell, I.L. Hunter & Phaff (1969)

Systematic discussion of the species

84.1. *Leucosporidium antarcticum* Fell, Statzell, I.L. Hunter & Phaff (1969)

Growth in 5% malt extract: After 3 days at 12°C, the cells of self-sporulating strains are ovoidal, (2–4) × (5–22) μm; haploid, heterothallic cells tend to be shorter and wider and are (3–6) × (3–10) μm. Both types of cells are single, in pairs and short chains. There is a light sediment. After one month there is a light ring and a heavy sediment.

Growth on 5% malt agar: After 3 days at 12°C, the cells are approximately the same size as in malt extract. The cells may have a large capsule and refractile inclusions. Growth is cream-colored, smooth, mucoid, runny and glistening; the border is entire. Pseudo- and true mycelium may be present. There is little change after one month.

Dalmau plate culture on corn meal agar: Self-sporulating strains have two types of mycelium: short branched chains of pseudomycelium and long branched chains of true mycelium. After 3 weeks of growth, teliospores develop on the true mycelium and measure (4–6) × (5–8) μm; they occur terminally, singly and occasionally in pairs. The teliospores increase in size and at 7 weeks are (5–8) × (5–10) μm, terminal, intercalary, single and in short chains of two to three. The teliospores usually have one or two bud-like structures that may represent either vestigial clamp connections or undeveloped sister teliospores. Heterothallic strains form true and pseudomycelium.

Life cycle: Self-sporulating strains: septate uninucleate hyphae with teliospores, lacking clamp connections, develop directly from single cells in the absence of mating. Teliospores from a culture grown on corn meal agar at 5°C, germinated on 2% agar after soaking in distilled water. The highest number of germinating teliospores occurred after 3 months; duration of the individual steps varied. For example, growth on corn meal agar for 2 weeks followed by soaking for 10 weeks or growth for 10 weeks with soaking for 2 weeks. Germination then occurred within one week on 2% agar. When the various steps were performed at 5°C, the cells produced less interfering polysaccharides than at 12°C. The metabasidium was four-celled with lateral and terminal basidiospores. Ploidy of the basidiospores has not been determined.

Heterothallism: compatible mating strains *A1* and *A2* mixed on corn meal agar formed spherical to ovoidal, (7–10) × (8–13) μm, teliospores on clamp-bearing mycelium after 3 weeks at 12°C. Teliospore germination occurred after soaking 2-month-old teliospores in distilled water for one month followed by one week on 2% agar. Basidiospores developed laterally and terminally on four-celled metabasidia. Six basidiospores from two teliospores were examined and all progeny were self-sporulating. Neither

self-sporulating, nor heterothallic strains of *L. antarcticum* mated with strains of other *Leucosporidium* species.

Fermentation: absent.

Co-Q: 10 (Yamada and Kondo 1972a).

Mol% G + C: 50.5 (T_m : Sugiyama et al. 1985).

Cell hydrolyzates: Not determined.

Origin of the strains studied: Antarctic marine waters at water temperatures less than 2°C in regions of pack ice adjacent to the Antarctic continent at several locations near the northern tip of the Antarctic Peninsula and at one location (150°E and 64°S) in the Indo-Pacific (46) (Fell et al. 1969, Fell 1976). The majority of the isolations were made at water depths of 100 m or less, however isolates were obtained from depths of 3000 m.

Complementary mating types: CBS 7054 (Fell strain 38-22, mating type *A1*), collected March, 1966 at 64°16'S, 150°06'E at a water depth of 152 m. CBS 7009 (Fell strain 38-107, mating type *A2*), was obtained August, 1966 from 64°10'S and 150°03'E at a water depth of 4 m.

Type strain: CBS 5942 (Fell strain AR 372), a self-sporulating strain isolated August, 1966 in the Weddell Sea near Joinville Island, Antarctica.

84.2. *Leucosporidium fellii* Giménez-Jurado & van Uden (1989)

Growth in 5% malt extract: After 3 days at 19°C, the cells are ovoidal to elongate and obpyriform, (2.7–4.0) × (8–12.7) μm; they occur singly or in pairs, and reproduction is by budding. A slight sediment is present.

Growth on 5% malt agar: After one month at 19°C, the streak culture is white to cream-colored, flat, pasty with

a fringe of true mycelium bearing complete clamps and teliospores which are predominately spherical.

Dalmau plate culture on corn meal agar: After one week at 19°C, mycelium develops with complete and incomplete clamp connections. Intercalary and terminal teliospores form that are spherical, clavate or obpyriform, (8.4–15) × (11.7–15) µm.

Life cycle: The species is homothallic; uninucleate cells develop into a dikaryotic mycelium with complete clamp connections at some, but not all of the septa. Karyogamy appears to take place in the teliospore. The teliospores germinate following 8 weeks of growth and incubation at 19°C on corn meal agar. The metabasidia are club-shaped, 3–8 µm in width and 25–45 µm in length with 2–4 cells. The basidiospores are produced on a swollen pedicel that is terminal on the distal cell and lateral on the remaining cells (Fig. 333). The basidiospores have a bacillary shape, measure (0.8–1.3) × (1.7–5.8) µm, and occur in clusters of up to six in number.

Fermentation: absent.

Co-Q: 10 (Giménez-Jurado and van Uden 1989).

Mol% G+C: 57.7 (T_m : Giménez-Jurado and van Uden 1989).

Cell hydrolyzates: Not determined.

Origin of the strain examined: CBS 7287 isolated from soil collected near Oeiras, Portugal in January 1987.

Type strain: CBS 7287 (Giménez-Jurado and van Uden, I.G.C. 4403).

Comments: *L. fellii* was isolated on a selective L(+)-tartaric acid medium. L(+)-Tartaric acid is the predominant organic acid in grape must and wine and few yeasts have been found to assimilate that organic acid (Fernandez and Ruiz-Amil 1965, Giménez-Jurado and van Uden 1989). The original description reported lactose and sucrose assimilation to be negative, which differs from our results.

Giménez-Jurado and van Uden (1989) reported that the life cycle of *L. fellii* was homothallic; they presumed that the dikaryotic mycelial phase arose from the conjugation of single cells. We examined the life cycle by isolating 26 basidiospores representing progeny from seven teliospores. Based on nuclear staining (modification of Robinow 1961) the basidiospores are uninucleate and germinate to dikaryotic hyphae with complete clamp connections; the teliospores and metabasidia are uninucleate. Mating was not observed prior to teliospore formation. This type of life cycle is present in other basidiomycetous yeasts, specifically in *Sporidiobolus johnsonii*, *Sporidiobolus ruineniae* and *Rhodospodium toruloides*.

According to Giménez-Jurado and van Uden (1989) "... teliospores germinate giving rise to a metabasidium which may form two or more externally located basidiospores ...". This type of basidial formation is typical of the genera *Leucosporidium*, *Rhodospodium* and *Sporidiobolus*, and usually results in spheroidal to ovoid basidiospores, one to two per metabasidial cell. In contrast, we observed that *L. fellii* produced bacillary basidiospores on a swollen pedicel in whorls of six per metabasidial cell. This type of basidiospore formation is unique among the basidiomycetous yeasts although it does resemble the clusters of basidiospores depicted for *Ustilago domesticus*, *U. bistortarum* and *U. lagerheimii* (Fischer and Holton 1957, p. 174). This formation is probably a species-specific (rather than a

Fig. 334. *L. scottii*. Schematic drawing of the life cycle (Fell et al. 1969).

generic) characteristic among the yeasts as *L. fellii* appears to be closely related to *L. scottii* based on partial rRNA nucleotide sequence alignments (Fell and Kurtzman 1990).

84.3. *Leucosporidium scottii* Fell, Statzell, I.L. Hunter & Phaff (1969)

Anamorph: *Candida scottii* Diddens & Lodder

Synonyms:

Candida scottii Diddens & Lodder (1942)

Azymocandida scottii (Diddens & Lodder) Novák & Zsolt (1961)

Vanrija scottii (Diddens & Lodder) R.T. Moore (1980)

Apiotrichum eucryphiae Ramírez & González (1984d)

Growth in 5% malt extract: After 3 days at 25°C, cells are ovoidal to elongate, (1–7) × (4–16) μm, usually single or in pairs. Reproduction is by apical budding. Strands of pseudomycelium are present. Sediment is moderate. After one month there is a ring, some small islets and a heavy sediment.

Growth on 5% malt agar: After 3 days at 25°C, the cells are ovoidal to elongate, (1–4) × (3–12) μm. Some strands of true and pseudomycelium are evident. After one month the growth is cream-colored, extremely mucoid with dense, extensive mycelium at the periphery.

Dalmau plate culture on corn meal agar: After 3–5 days at room temperature, pseudomycelium of the 'Candida' type begins to form. After one month, the pseudomycelium bears large clusters of blastoconidia. True mycelium with endospores is also present. Self-sporulating strains lack clamps on the teliospore-bearing hyphae.

Life cycle (Fig. 334): *L. scottii* has a multiple allelic bifactorial sexual incompatibility system. The mating competency is controlled by two factors designated *A* and *B*, which results in a minimum of four mating types: *A1B1*, *A2B2*, *A1B2*, *A2B1*. Present information suggests that each of the factors consists of two linked loci, designated α and β , which are separable by crossing over, i.e., a cross of $A\alpha_1\beta_1$ strain with $A\alpha_2\beta_2$ strain can result in recombinant progeny $A\alpha_1\beta_2$ and $A\alpha_2\beta_1$. Five *A* and three *B* factors have been identified (Fell and Statzell-Tallman 1982). When compatible strains are mixed on corn meal agar at 25°C, they conjugate within 30 hours at a frequency of less than 1%. A binucleate hypha develops from one of the conjugate cells.

After 72 hours, the hyphae develop extensively with clamp connections at each septum. After 4–7 days intercalary and terminal teliospores develop with one or more clamp structures between the spore and hypha. The teliospores are spherical, thick-walled, have a granular content and range in size from (7–15) × (7–16) μm. Karyogamy in the teliospores precedes germination. After 5 days, the teliospore (Fig. 335) germinates and the diploid nucleus migrates into the metabasidium. Meiosis occurs in the metabasidium, which partitions into four cells. Each metabasidial cell contains one nucleus, which reproduces mitotically, resulting in one nucleus in the cell and one in the developing basidiospore. Basidiospores form near the septa and terminally on the distal metabasidial cell. Budding of the basidiospores results in mucoid yeast cells that represent either parental mating types or self-sporulating strains.

Fig. 335. *L. scottii*, CBS 5930×CBS 5931. Cells of opposite mating types were mixed on corn meal agar and incubated at 25°C for 5 days; the resulting teliospores germinated to a four-celled metabasidium with lateral basidiospores. Bar = 10 µm.

Some strains are capable of monokaryotic formation of teliospores: a hypha with uninucleate cells develops from a uninucleate yeast cell. The hyphae do not have clamp connections, although incomplete clamp-like structures may be present. Monokaryotic fruiters will mate with heterothallic mating strains resulting in binucleate clamped hyphae with teliospores. Progeny of matings of monokaryotic×heterothallic strains are 50% heterothallic fruiters and 50% monokaryotic fruiters. Similar results have been obtained with heterothallic×heterothallic fruiters. This segregation suggests that there are one or more separate genes for fruiting that may be repressed in some heterothallic strains. This gene may not be associated with a specific mating type as suggested by the mating of monokaryotic *A3B1*×heterothallic *A2B2* → heterothallic *A3B1* progeny (Fell and Statzell-Tallman 1982). Strains of *L. scottii* do not mate with strains of other species in the genus.

Co-Q: 9 and 10 (Yamada and Matsumoto 1988a); 8, 9 and 10 as minor subunits (Yamada and Nakagawa 1990); 9 (CBS 5931) and 10 (CBS 614) (Sugiyama et al. 1985, Yamada and Kondo 1972a).

Mol% G+C: 60.9, 61.1 (T_m : Giménez-Jurado and van Uden 1989).

Cell hydrolyzates: Glucose, mannose and galactose (Gorin and Spencer 1970).

Origin of the strains studied: 65 strains were examined: Southern Pacific Ocean (59) (Fell 1976); Antarctic soil and seawater strains from di Menna (3); soil in Australia (1) (Lodder and Kreger-van Rij 1952); unreported sources (2).

Complementary mating types: CBS 6562 (*A1B2*) and CBS 6561 (*A2B1*) are progeny from *A1B1*×*A2B2* matings (Fell 1974). CBS 5932 (a self-sporulating strain) was collected August 1966 at 134°53'W, 34°59'S from Antarctic seawater at a water depth of 155 m, temperature of 2.59°C and salinity of 34.61‰.

Type strain: CBS 5930 (mating type *A2B2*) collected August 1966 from Antarctic seawater at 129°59'W, 41°58'S at a water depth of 1364 m, temperature of 3.0°C, salinity of 34.44‰.

Allotype: CBS 5931 (mating type *A1B1*) was collected August 1966 from Antarctic seawater (134°30'W, 36°00'S) at a water depth of 1902 m, temperature of 2.3°C and salinity of 34.62‰.

Comments: *L. scottii* inhabits low temperature environments, generally in polar regions or in temperate regions during the cold weather seasons. There have been no reports from tropical or sub-tropical environments. Summerbell (1983) reviewed the ecology of *L. scottii* and recorded the various isolation sources. These included soil and frozen beef from Australia (Scott 1936); apple fruit in Canada (Clark et al. 1954), soil in New Zealand (di Menna 1955a,b, 1958a, 1960, 1965a); grapevines in South Africa (Van Zyl and du Plessis 1961); plant blossoms in Czechoslovakia (Kocková-Kratochvílová 1964); wild mushroom in Czechoslovakia (Kocková-Kratochvílová et al. 1965); soil and grapes in New Zealand (Parle and di Menna 1966); polluted rivers in the northern United States (Woollett and Hedrick 1970), Quebec (Simard and Blackwood 1971) and France (Hinzelin and Lectard 1978); marine fish in Scotland (Bruce and Morris 1973); Antarctic soils (di Menna 1960, 1966b); Antarctic seas (Fell et al. 1969, Fell 1974); Antarctic mosses and saline lakes (Goto et al. 1969); soils in East Greenland (di Menna 1966b); Soviet Arctic tundra soils (Bab'eva et al. 1976, Bab'eva and Azieva 1980). Summerbell (1983) isolated *L. scottii* in southern British Columbia,

Canada from snow and decomposing plant materials in terrestrial locations, foam, living and decomposing plant material in fresh water and plants and driftwood in marine locales.

Yamada and Nakagawa (1990) examined the coenzyme Q systems and partial nucleotide sequences of the SSU and LSU rRNA of 19 strains of *L. scottii*. They found one strain IFO 9474 (UBC 670 from Bandoni) with Co-Q 7 and a sequence which differed from the other *L. scottii* strains – apparently this strain is a distinct species from *L. scottii*. The remaining strains were either Co-Q 9 or Co-Q 10. Eight strains had Co-Q 9 as the major component; three of these strains were isolated by Fell et al. (1969) from Antarctic sea water, the remaining 5 strains were progeny isolated from conjugants that included those marine strains (Fell and Statzell-Tallman 1982). The Co-Q 10 containing strains were isolated either from terrestrial sources or from temperate marine regions. Nucleotide sequence alignments of rRNA from Co-Q 9 and Co-Q 10 containing strains indicated a single species (Yamada and Nakagawa 1990, Fell and Kurtzman 1990).

Comments on the genus

Based on septal morphology, polysaccharide composition of the cell hydrolyzates and molecular phylogeny (see Moore, Chapter 5, Kurtzman and Blanz, Chapter 10, and Boekhout et al., Chapter 74, this volume), *Leucosporidium* is a teliospore-forming member of the Sporidiales. Three species are included in the genus, all have white to cream-colored colonies and appear to have low optimal growth temperatures. Two of the species (*L. antarcticum* and *L. scottii*) have been isolated from polar and other cold temperature regions. The species differ in their methods of teliospore formation: self-sporulation, homothallic uni- and bi-allelic systems; however in all cases a phragmometabasidium with basidiospores is formed. *L. fellii* produces distinctive basidiospores: bacillary basidiospores on a swollen pedicel in whorls of six per metabasidial cell (see Fig. 333). The *Leucosporidium* species can be separated from each other and from other teliospore-forming yeasts by standard fermentation and assimilation tests (Table 69).

85. *Mrakia* Y. Yamada & Komagata

J.W. Fell and A. Statzell-Tallman

Diagnosis of the genus

Growth on solid media is white to cream-colored, often mucoid. Visible carotenoid pigments are not present. Both yeast and mycelial phases occur. In the yeast phase, the cells are ovoid to elongate and reproduce by budding; a pseudomycelium may form. Formation of the mycelial phase occurs in the absence of mating. Teliospores are produced terminally or intercalarily on the mycelium. Yeast cells are uninucleate and produce uninucleate teliospore-bearing hyphae without clamp connections. Teliospore germination results in phragmo- or holometabasidia. Ballistoconidia are not present in either the yeast or mycelial phase. The septal pore is a dolipore without a parenthesome.

Glucose is fermented. Nitrate is assimilated. *Myo*-inositol is not assimilated. Maximum temperature for growth is below 20°C. Xylose is present in cell hydrolyzates. Starch-like compounds are produced. Diazonium blue B and urease reactions are positive. Coenzyme Q-8 system is present.

Type species

Mrakia frigida (Fell, Statzell, I.L. Hunter & Phaff) Y. Yamada & Komagata

Species accepted

1. *Mrakia frigida* (Fell, Statzell, I.L. Hunter & Phaff) Y. Yamada & Komagata (1987)

Systematic discussion of the species

85.1. *Mrakia frigida* (Fell, Statzell, I.L. Hunter & Phaff) Y. Yamada & Komagata (1987)

Synonyms:

Leucosporidium frigidum Fell, Statzell, I.L. Hunter & Phaff (1969)

Candida frigida di Menna (1966a)

Vanrija frigida (di Menna) R.T. Moore (1980)

Leucosporidium gelidum Fell, Statzell, I.L. Hunter & Phaff (1969)

Mrakia gelida (Fell, Statzell, I.L. Hunter & Phaff) Y. Yamada & Komagata (1987)

Candida gelida di Menna (1966a)

Leucosporidium nivalis Fell, Statzell, I.L. Hunter & Phaff (1969)

Mrakia nivalis (Fell, Statzell, I.L. Hunter & Phaff) Y. Yamada & Komagata (1987)

Candida nivalis di Menna (1966a)

Vanrija nivalis (di Menna) R.T. Moore (1980)

Leucosporidium stokesii Fell, Statzell, I.L. Hunter & Phaff (1969)

Mrakia stokesii (Fell, Statzell, I.L. Hunter & Phaff) Y. Yamada & Komagata (1987)

Candida curiosa Komagata & Nakase (1965)

Cryptococcus curiosus (Komagata & Nakase) Rodrigues de Miranda & Weijman (Weijman et al. 1988)

Growth in 5% malt extract: After 3 days at 12°C, the cells are short-ovoidal to ovoidal-elongate, (2.6–8.0) × (3–14) μm, and occur singly or in pairs. Occasionally septate cells are observed. A sediment is formed and sometimes a slight ring. After one month, a ring, which may be thick and myceliated, and a light to heavy sediment may be present.

Growth on 5% malt agar: After one month at 12°C, the streak culture is cream-, yellowish-white to light brownish-gray, raised, dull, mucoid and smooth or wrinkled. The margin may be fringed with true mycelium bearing ovoid to ovoid-elongate teliospores but

no clamp connections. The teliospores may be intercalary or terminal and spherical (5–8 μm in diameter) or elongate (5.4–11.9) × (6.5–13.5) μm.

Dalmay plate culture on corn meal agar: After one week, pseudo- and true mycelium are abundantly developed. Blastosporidia are short-ovoid to ovoid and occur singly, in chains, in clusters or in verticils. Teliospores form occasionally or abundantly, usually in greater numbers after 3 weeks when they are smaller in size, (3–7) × (4–8) μm, as compared to their larger size at 9 weeks, (4–11) × (5–16) μm.

Life cycle: Mycelium and teliospores develop directly from a single cell and no clamp connections form. Nuclear stains indicate that the mycelium is uninucleate. Teliospores may germinate to a one to three celled metabasidium, 8–12 μm long (Fig. 336). Germination has not been observed in all strains. Teliospores of certain strains germinate in response to different regimes of varied temperatures (5°C–12°C) and time of growth on corn meal agar or 2% glucose Sabouraud agar, soaking in distilled water and streaking on 2% agar devoid of added nutrients. Basidiospores are terminal and/or lateral (Fig. 336).

Co-Q: 8 (Yamada and Kondo 1972a).

Mol% G+C: 54.1, *M. frigida* (T_m : Nakase and Komagata 1971f); 56.1, *M. gelida* (T_m : Nakase and Komagata 1971f); 52.9, CBS 5688, *Candida curiosa* (T_m : Meyer et al. 1984).

Cell hydrolyzates: Xylose present (Sugiyama et al. 1985).

Origin of the strains studied: Di Menna (1966b) obtained approximately 80 isolates from Antarctic soil samples collected in the vicinity of Campbell-Mawson, Mawson-Koettlitz, Beardmore-Nimrod, Shackleton-Axel Heiberg Glaciers and from Scott Base. She also obtained 20 isolates from Greenland soil samples near Mastersvig airstrip. The common constituent of the Greenland

samples was plant material such as mosses, lichens and algae. Di Menna's strains, used as type strains in the description of *Leucosporidium* spp., were: 5A1 (CBS 5270) *L. frigidum*; 2AH10 (CBS 5272) *L. gelidum*; 2AH2 (CBS 5266) *L. nivalis*. Sinclair and Stokes (1965) isolated a strain (P-16, CBS 5917), from an Antarctic snow core, which was described as *L. stokesii*. Komagata and Nakase (1965) isolated two strains, P-6 (CBS 5688) and P-13, from frozen food (*Sillago japonica*) in Kawasaki, Japan, 1963, which the authors described as *Candida curiosa*. M. Parish (Univ. Florida) obtained a strain from orange juice in cold storage (5°C) in Florida.

Type strain: CBS 5270, isolated from soil at Scott Base, Antarctica, by M. di Menna.

Comments on the genus

Di Menna (1966a,b) isolated a group of low temperature yeasts from Antarctic and Greenland soil samples and described several species of *Candida*: *C. frigida*, *C. gelida* and *C. nivalis* based on differences in assimilation patterns. These species were placed in the genus *Leucosporidium* due to the observation of teliospore formation, which was a result of self-sporulation. The species were retained as separate *Leucosporidium* species, based on physiological properties as per di Menna's recommendations. Yamada and Komagata (1987) studied the Co-Q system of the genus *Leucosporidium* and found that the original di Menna species, and *L. stokesii*, differed from other members of *Leucosporidium*, by the presence of the Co-Q 8 system. Sugiyama et al. (1985) reported the presence of xylose in the cell hydrolyzates of these species; in contrast, xylose is absent in other species of *Leucosporidium*. Based on these differences Yamada and Komagata (1987) created the genus *Mrakia* consisting of four species that they transferred from *Leucosporidium*. Yamada and Matsumoto (1988a) examined the electrophoretic pattern of 7 enzymes of strains of *Mrakia* spp. and concluded that *M. nivalis* was a synonym of *M. frigida* and that *M. stokesii* was a synonym of *M. gelida*. Molecular sequence analysis (Yamada and Kawasaki 1989a, Fell et al. 1992) suggests that all four nomenclatural strains represented a single species, *M. frigida*.

We also include *Candida curiosa* in the list of synonyms. Van Uden and Buckley (1970) recognized the synonymy of *C. curiosa* and *C. nivalis* based on physiological properties. Because teliospores had not been observed in *C. curiosa*, the species was retained in *Candida* (Meyer et al. 1984) and subsequently transferred to *Cryptococcus* as *C. curiosus* (Weijman et al. 1988). During the examination of *C. curiosus* for the present treatise, we were able to induce teliospore formation by incubating a culture on 2% dextrose Sabouraud agar at 12°C to confirm the synonymy recommended by van Uden and Buckley (1970).

86. *Rhodospordium* Banno

J.W. Fell and A. Statzell-Tallman

Diagnosis of the genus

Colony color on solid media includes shades of yellow, orange and red due to the presence of carotenoid pigments. Yeast and mycelial phases may occur. In the yeast phase the cells are ovoid to elongate and reproduce by budding; a pseudomycelium may form. Formation of the mycelial phase can result from sexual reproduction and may develop by two methods of self-sporulation. True mycelium with or without clamp connections is formed. The septal structure consists of a simple pore. Teliospores may be terminal, lateral on stalks or intercalary on the mycelium.

Sexual mechanisms, although not completely understood, are both homothallic and heterothallic. Heterothallism includes unifactorial biallelic (e.g., *R. toruloides*) and bifactorial (*R. dacryoideum*) systems. In these heterothallic systems a dikaryotic mycelium results from the conjugation of a compatible mating pair. A clamp connection is usually present at each cross wall. Intercalary and terminal teliospores develop. Karyogamy takes place in the teliospore (probasidium), which germinates to produce a two to four celled, septate metabasidium (phragmometabasidium). Meiosis takes place during germination and the resulting haploid basidiospores are lateral and terminal on the phragmometabasidium.

Homothallism, or self-fertility, consists of the development of hyphae with teliospores from a single yeast cell in the apparent absence of mating. The yeast phase is diploid and reduction division takes place with the formation of a dikaryotic mycelium with clamp connections. Karyogamy occurs in the teliospore. Germination of the teliospore results in a metabasidium with diploid basidiospores (strains of *R. dacryoideum* and *R. toruloides*).

In contrast to the homothallic life cycle, the hyphal cells of some self-sporulating species (e.g., *R. fluviale* and *R. kratochvilovae*) remain uninucleate and clamp connections are lacking. Teliospore formation has not been studied in detail, although the process may be monokaryotic fruiting rather than a sexual cycle. Neither ballistospores nor ballistoconidia are present in any of the phases.

Sugars are not fermented. Diazonium blue B and urease reactions are positive. Extracellular starch is not produced. Among the species currently included in the genus, none assimilate lactose, melibiose, D-glucosamine, erythritol, or inositol. Galactose, trehalose and glycerol are assimilated. Xylose is absent in the cells. Coenzymes Q-9 and Q-10 are present.

Type species

Rhodospordium toruloides Banno

Systematic discussion of the species

86.1. *Rhodosporidium babjevae* Golubev (1993)

Growth in glucose–yeast extract–peptone water: After 3 days at 25°C, the cells are spheroidal to ovoidal (the width/length ratios are from 1.0 to 2.0), (2.5–6.0) × (4.2–8.5) μm, with small capsules, and single or in pairs. After one month, a sediment, a ring and also islets or a pellicle sometimes form.

Growth on yeast morphology agar: After one month, the streak cultures are red, smooth, glistening, mucoid or soft; the margin is entire to undulating.

Slide cultures on corn meal agar: After 10 days, neither pseudomycelium nor true mycelium is produced. Short lengths of true hyphae without clamp connections may be present on month-old cultures. No ballistoconidia are observed.

Life cycle: Conjugation of mating types on corn meal agar at 20°C, results in the formation of true mycelium with clamp connections at the septa. Two mating types were found (Golubev 1993, Bab'eva and Kartintsev 1974), which suggests a unifactorial mating system. The teliospores are subglobose, globose (6.0–12.8) × (7.6–13.6) μm, usually single, terminal, thick-walled, and granular. After soaking 2 week-old cultures in distilled water

for 3 days, teliospores germinate to produce 1 or 2-celled metabasidia with 1 to 3 terminal ovoid basidiospores (Figs. 337, 338). *R. babjevae* does not mate with other species included in the genus *Rhodosporidium*, or with the type strain of *Rhodotorula glutinis*.

Fermentation: absent.

Co-Q: 10 (Golubev 1993).

Mol% G+C: 66.2 (PC: Golubev 1993).

Monosaccharide composition of extracellular polysaccharides: Mannose, galactose, glucose, and fucose (Golubev 1993).

Origin of the strains studied: Herbaceous plants, Moscow Region, Russia, from Bab'eva et al. (1973).

Complementary mating types: CBS 7808 (VKM Y-2275, mating type *A1*) and CBS 7809 (VKM Y-2276, mating type *A2*).

Type strain: CBS 7808.

Comments: This species came to our attention after the completion of this generic review, therefore the data recorded above are from the original description. We briefly examined teliospore germination from mixes of compatible mating types on corn meal agar for 2 weeks at 25°C. After soaking the teliospores in sterile deionized water for one week and moving them to 2% agar, germination occurred and 1–2 celled metabasidia (6 μm×2.6 μm) form (Fig. 337). More measurements of metabasidia are required to assure an accurate assessment of size. The basidiospores formed on small persistent pedicels and up to 3 pedicels were observed at different sites on the terminal cell of 2-celled metabasidia. We also observed single basidiospores on pedicels from the basal cell. These basidiospores may grow parallel to the basal

cell (Fig. 338). Additional strains were collected from soil, Krasnodar Region, Russia, by Golubev and Vdovina (1973) (2); silage, Kiev Region, Ukraine, by Shchelokova (1964) (1) and from peat, birch leaves, soils in Novgorod, Nizhni Novgorod regions and East Pamir by Bab'eva and Kartintsev (1974).

86.2. *Rhodosporidium dacryoideum* Fell, I.L. Hunter & Tallman (1973)

Synonym:

Sakaguchia dacryoides (Fell, I.L. Hunter & Tallman) Y. Yamada, Maeda & Mikata (1994a)

Growth in 5% malt extract: After 3 days at 24°C, the haplophase cells are ovoid, (1–5)×(3–9) μm, single, in pairs and short chains; budding may occur on a short stalk. A ring and film are not present; there is a light sediment. After one month, there is a light to heavy ring and moderate sediment.

Growth on 5% malt agar: After 7 days at 24°C, the growth is red-orange, smooth, creamy, glistening, and slightly raised; the margin is entire. Cell morphology is similar to that in malt extract. After one month, the growth is slightly darker in color, glistening, creamy to pasty; occasionally the edge is slightly wrinkled.

Dalmu plate culture on corn meal agar: After one week at 24°C, mycelial growth may be absent or there may be long thin true mycelium or short primitive pseudomycelium.

Life cycle (Fig. 339): The species is heterothallic (bifactorial), although a self-sporulating strain has been observed. Mating pairs with dissimilar *A* and *B* factors (*A1B1*×*A2B2*, *A1B2*×*A2B1*) produce the complete life cycle. Mixing of strains with similar *A* and dissimilar *B* factors results in mating and formation of short,

Fig. 339. Life cycle *R. dactyloideum*, CBS 6353×CBS 7142 (Fell et al. 1973).

distorted, true hyphae lacking both clamp connections and teliospores. There is no mating reaction with pairs having similar *B* factors. Conjugation between mating types with opposite *A* and *B* factors is usually within 24 hours of mixing on corn meal agar at 24°C; this may be variable, mating may not occur for one week or longer. After one week binucleate mycelium is sparse to abundant with hook-to-peg clamp connections. Conidia have not been observed on the hyphae. Teliospores are lateral or occasionally terminal on the hyphae. The lateral teliospores develop either directly from the hypha on a short sporophore or from clamp connections. After one week the teliospores are subglobose and slightly dacryoid (4–10)×(5–14) μm, or more pronounced dacryoid with a subglobose base (4–8)×(7–10) μm and an apical tip measuring (0.3–3)×(0.8–6) μm. After one month most teliospores exceed 6×11 μm. The apical tip may be wider than long (1–2)×(2–3) μm. Basal clamp connections join the teliospore to the hypha or to the sporophore. Germination of the teliospores is often difficult to obtain. The best results were obtained by soaking one month old cultures in distilled water at 24°C. After 10–25 days of soaking, germination (Fig. 340) was observed directly from the distilled water preparation. The metabasidium was 2 to 4-celled, (3–4)×(24–59) μm with lateral and terminal basidiospores.

Progeny were isolated by micromanipulation of basidiospores derived from *A1B1*×*A2B2*. Resulting F₁ mating types were *A1B1*, *A2B2*, *A2B1*, and one strain similar to the *A ≠ B =* heterokaryons of *Coprinus lagopus* and *Schizophyllum commune* (see Raper 1966, for a discussion

of this behavior). The yeast cells of the *A ≠ B =* strain were generally uninucleate, although binucleate cells were present. A mycelium developed that was initially binucleate; during the process of clamp formation and nuclear segregation, the clamps were not completed and one nucleus remained in the clamp and one nucleus was in the subterminal cell. The terminal cells were uninucleate. Teliospores were formed. Conjugation was not observed when the individual mating types were mixed with strains of the other species in the genus.

Fermentation: absent.

Fig. 340. *R. dactyloideum*, CBS 6353×CBS 7142. A teliospore, which developed from a mix of opposite mating type cells after 4 weeks on corn meal agar, was soaked for 2 weeks at 24°C; it germinated to a 2-celled metabasidium with lateral basidiospores. Bar = 10 μm.

Co-Q: 10 (Sugiyama et al. 1985).

Mol% G + C: 57.8, 58.1, 58.4, 58.9 (T_m : Hamamoto et al. 1986b).

Cell hydrolyzates: Xylose absent (Sugiyama et al. 1985).

Origin of the strains studied: Marine waters of the southern Indian and Pacific Oceans (10) in surface waters to depths of 4156 m at water temperatures from 0.6°C to 8.0°C (Fell et al. 1973).

Complementary mating types: CBS 6353 (mating type *A1B1*) was collected April 1966, at 61°31'S latitude, 95°56'W longitude, at a water depth of 1738 m, temperature of 1.8°C and salinity of 34.72‰; CBS 6354 (mating type *A2B2*) collected July 1966, 43°00'S, 139°59'W, 156 m deep, 80°C and 34.40‰; CBS 6355 (mating type *A2B1*) collected April 1966, 61°31'S, 95°56'W, 3929 m deep, 0.61°C, 34.71‰; CBS 6356 (mating type *A1B2*) collected April 1966, 61°31'S, 95°56'W, 3 m deep, 4.02°C and 33.96‰ (Fell et al. 1973). CBS 6357 is an *A* ≠ *B* strain from parental strains CBS 6353 and CBS 6354.

Type strain: CBS 6353.

Comments: The species is widespread in Antarctic marine waters; we are not aware of any other sources of isolates. Haploid strains of *R. dacryoideum* fit the description of *Rhodotorula minuta*, however the type strain of *Rhodotorula minuta* does not mate with the mating types of *R. dacryoideum*. Nucleotide sequence analysis of a partial region of the LSU rRNA also indicates that they are separate species (Fell et al. 1992).

86.3. *Rhodospidium diobovatum* Newell & I.L. Hunter (1970)**Synonym:**

?*Torulopsis terrestris* Verona (1935)

Growth in malt extract: After 3 days at 22°C, the haplophase cells are round to ovoid (1–6) × (2–9) μ m, and occur singly or in pairs. A slight sediment is formed. After one month, there is a heavy sediment and a thin to moderate film of cells; large round cells (to 9–11 μ m diameter) with large oil globules are present.

Growth on malt agar: Cell morphology is similar to that in malt extract. The streak colony is coral-red, raised, mucoid, the border entire.

Dalmau plate culture on corn meal agar: Some strains produce only budding cells, whereas other strains produce, in addition to budding cells, a primitive pseudomycelium or fine, true hyphae (diameter 2 μ m) bearing blastoconidia with dimensions similar to the yeast-phase cells. These blastoconidia are often formed at septa, on structures homologous to clamp connections, but aberrant and incomplete. Each primary hypha is formed by a single yeast-phase cell.

Life cycle: The species is heterothallic; a biallelic (*A1* and *A2*) system of sexual incompatibility factors exists. Mixing of yeast-phase strains of *A1* and *A2* on corn meal agar results in conjugation within 24 hours. Plasmogamy takes place, and binucleate hyphae (diameter 3 μ m) are formed from one of the conjugant cells, or from the conjugation tube joining them. Clamp connections are hook-to-peg or peg-to-peg. After 3 days of hyphal growth, unicellular, round to obovate, diobovate, or diclavate, (6–11) × (6–22) μ m, heavy-walled terminal teliospores form. The teliospores have clamp connections at the basal septum and are binucleate at first, but become uninucleate at maturity. In addition to teliospores, blastoconidia form on the binucleate hyphae. Additional incompatibility factors may exist as several isolates have been examined

Fig. 341. *R. diobovatum*, CBS 6084 × CBS 6085. Teliospore, which developed from a mix of opposite mating type cells after 5 days on corn meal agar at 22°C, developed a lateral metabasidium with lateral and terminal basidiospores, within 10 days of soaking in distilled water. Bar = 10 μ m.

Fig. 342. *R. diobovatum*, CBS 6084×CBS 6085. Teliospore, which developed from a mix of opposite mating type cells after 5 days on corn meal agar at 22°C, developed a terminal metabasidium with lateral and terminal basidiospores, within 10 days of soaking in distilled water. Bar = 10 µm.

which mate with *A2* strains to produce mycelium but fail to develop teliospores. Germination of the teliospores occurs after 5–10 days of soaking in distilled water. A lateral (Fig. 341) or terminal (Fig. 342) club-shaped phragmometabasidium, (3–5)×(13–22) µm develops from the teliospore with lateral and terminal basidiospores, which are either *A1* or *A2* mating types.

Fermentation: absent.

Mol% G + C: 67.3 (T_m : Nakase and Komagata 1971c), 64.8–66.1 (T_m : Hamamoto et al. 1986b).

Cell hydrolyzates: Xylose absent (Sugiyama et al. 1985).

Origin of the strains studied: Marine sources in southern Florida (14) including water over a southeast Florida reef with a water temperature of 29°C and a salinity of 36.2‰ and from mangrove detritus in the Florida Everglades, water temperature 20°C, salinity 19‰ (Newell and Hunter 1970).

Complementary mating types: CBS 6084 (Newell strain FR 4, mating type *A2*) and CBS 6085 (Newell strain FR 5, mating type *A1*). Both strains were collected from water over a southeast Florida reef.

Type strain: CBS 6085.

Comments: *R. diobovatum* is prevalent in near shore marine waters of South Florida, the Caribbean and the Bahamas. The species is often found in the vicinity of coral reefs (Fell and Statzell-Tallman, unpublished data). The species was reported from terrestrial plants and soils (Kvasnikov et al. 1975, Bab'eva and Kartintsev 1974), although those strains may belong to the newly described *R. babjevae* (Golubev 1993). Strains of *R. diobovatum* fit the description of *Rhodotorula glutinis*, although the type strain of *Rhodotorula glutinis* does not mate with either mating type of *R. diobovatum*. Nucleotide sequence analysis of a partial region of the LSU rRNA indicates that these two species are distinct and closely related (Fell et al. 1992). Barnett et al. (1990) list *Torulopsis terrestris* Verona (CBS 994) as a synonym of *R. diobovatum*, however, that strain was not included in the present study.

86.4. *Rhodosporidium fluviale* Fell, Kurtzman, Tallman & Buck (1988)

Growth in 5% malt extract: After 3 days at 25°C, cells are ovoidal to spheroidal, (3.5–8.0)×(5.4–9.4) µm. Cells occur singly or in pairs. After one month there is a heavy sediment and a light ring, but not a pellicle.

Growth on 5% malt agar: After 3 days at 25°C, cells are similar to those in malt extract with a few larger cells to 10.5 µm. The streak culture is light scarlet orange, smooth, glistening, slightly raised and the border is entire. Teliospores form in patches at the edge of the colony and they are slightly larger than those formed on corn meal agar.

Dalmat plate cultures on corn meal agar: After 6 days at 25°C, true mycelium forms with incomplete (rarely complete) clamps at the septa and at the teliospores. Nuclear stains indicate that the hyphae are uninucleate suggesting that formation of teliospores is the result of monokaryotic fruiting. The teliospores are spheroidal to subglobose, (7.4–10.7)×(8.7–12.1) µm, usually single or in pairs. A short, hyphal-like tip may form on the teliospores. In month old cultures, teliospores form in groups of up to 12. The walls are smooth but may become warty in older cultures. Teliospores are intercalary, rarely terminal or lateral on short branches.

Fig. 343. *R. fluviale*, CBS 6568. Teliospore, which formed on corn meal agar at 25°C within one month, germinated to a 4-celled metabasidium with lateral basidiospores, after soaking for 2 weeks in deionized water. Bar = 10 µm.

Life history: Thick-walled teliospores form on the hyphae in the apparent absence of mating. These teliospores may germinate after one month on corn meal agar; germination in higher frequencies occurs after soaking 1-month-old teliospores for 2 weeks in distilled water followed by transfer to 2% aqueous agar. The resulting metabasidium is club-shaped (Fig. 343), consisting of 4 cells that break up into individual cells (a characteristic also observed in *R. sphaerocarpum*). Ovoid basidiospores, (~2.5 × 4.0) µm, form laterally on the metabasidium on short sporophores. Single basidiospores isolated by micro-manipulation develop into homokaryotic fruiting strains similar to the parental strain.

Fermentation: absent.

Co-Q: Not determined.

Mol% G + C: 61.4 (BD: Fell et al. 1988).

Cell hydrolyzates: Not determined.

Origin of the strains studied: Collected in October 1972, from brackish water of the Miami River, Florida (Fell et al. 1988).

Type strain: CBS 6568 (Fell strain ML 1580, NRRL Y-12922).

Comments: This species has only been isolated from one location. Nucleotide sequence analysis of a partial region of the LSU rRNA (Fell et al. 1992) suggests that *R. fluviale* may be related to strains of *Sporidiobolus ruineniae*.

86.5. *Rhodosporidium kratochvilovae* Hamamoto, Sugiyama & Komagata (1988a)

Growth on 5% malt extract: After 3 days at 25°C, the cells are encapsulated, ovoidal, (3–6) × (4–10) µm, occurring singly and in pairs. Growth is pink. After one month, a ring and sediment are present.

Growth on 5% malt extract agar: After one month at 25°C, the colony is peach- to orange-colored, slightly raised, the surface is semiglossy becoming rugose, while the margin is smooth, entire and fringed with true mycelium. The mycelium, which develops within one week, bears teliospores that are intercalary, terminal, or lateral on short stalks and false clamps at the septa.

Dalmau plate culture on corn meal agar: After one week at 19°C, septate hyphae have formed bearing false clamps and spheroidal or obpyriform teliospores (7–9 µm).

Life cycle: Mycelium with teliospores and false clamps at the septa develops from a single cell. Hamamoto et al. (1988a) reported that the hyphal cells are uninucleate and as growth occurs one nucleus remains in the incomplete clamp and one in the subterminal cell. They found that the teliospores were uninucleate and rarely germinated when 10-day-old cultures were soaked for 10 days in distilled water at 17°C followed by transfer to 2% aqueous agar for 10 days. Our investigations found that germination would occur after incubating for 8 weeks at 19°C on corn meal agar. A four-celled metabasidium (20–37) × (4–5) µm formed that produced lateral and terminal basidiospores, one basidiospore per metabasidial cell (Fig. 344).

Fermentation: absent.

Fig. 344. *R. kratochvilovae*, CBS 7436. Teliospore formation after 7 days at 19°C on corn meal agar and germination after 2 months. Bar = 10 µm.

Co-Q: 10 (Sugiyama et al. 1985).

Mol% G+C: 64.7–64.9 (T_m : Hamamoto et al. 1986b).

Cell hydrolyzates: Xylose absent (Sugiyama et al. 1985).

Origin of the strains studied: A record of the original isolation data of this species was not found. Two strains were included in the original description: the type strain and CBS 7293 (IAM 13073, CCY 62-3-2, YK 219).

Type strain: CBS 7436 (IAM 13072, CCY 62-3-1, YK 218).

Comments: Our results of assimilation tests based on CBS 7436 differed from the original description on cellobiose, D-xylose, L-arabinose and galactitol. Our results agreed with those of Barnett et al. (1990) who studied CBS 7293. Nucleotide sequence analysis of a

region of LSU rRNA (Fell et al. 1992) indicates that *R. kratochvilovae* is related to *Rhodospiridium diobovatum* and *Rhodotorula glutinis* which is in agreement with the similarities in physiological characteristics of these species.

86.6. *Rhodospiridium lusitaniae* A. Fonseca & Sampaio (1992)

Growth in 5% malt extract: After 3 days at 25°C, the cells are ovoidal or bacilliform, measure (2.5–5.9) × (5.9–20.1) µm, and occur in pairs or chains of three to four. There is a sediment present. After one month, neither a ring nor pellicle was observed.

Growth on 5% malt extract agar: After one month at 25°C, the colony is peach-colored, the surface is glossy and smooth, the texture is soft, the cross section is slightly raised and the border is fringed with mycelium. The latter bears clamps at the septa and spheroidal teliospores that may be intercalary, lateral on stalks or terminal. The teliospores are 9.5–13.3 µm in diameter and occur singly or in clusters of two to four.

Dalmau plate culture on corn meal agar: After one month at 25°C, true mycelium with teliospores and clamp connections form in abundance.

Life cycle (as described by Fonseca and Sampaio 1992): The life cycle was observed on corn meal agar and potato dextrose agar. Mating between cells did not take place. Uninucleate cells germinated to produce dikaryotic hyphae with complete clamp connections and terminal, intercalary and lateral uninucleate teliospores (Fig. 345).

Teliospores were transferred in small pieces of the agar to demineralized water and allowed to soak for 2 weeks at room temperature. At this time slender protrusions (measuring 5–20 µm) arose from the teliospores. The teliospores were transferred to 2% agar and, after 2 months at room temperature, 2–4-celled metabasidia (3.2–4.3 × 16–22 µm) emerged from the protrusions. Photographs by Fonseca and Sampaio (1992) show the teliospore with an elongate stalk terminated by a 4-celled

Fig. 345. *R. lusitaniae*, CBS 7604. Teliospore formation after 2 weeks on corn meal agar at 19°C. Bar = 10 µm.

metabasidium. One to four basidiospores (2.2–2.7×4.3–8.1 μm) arose from a single site at each cell of the phragmometabasidium.

Fermentation: absent.

Co-Q: 9 (Fonseca and Sampaio 1992).

Mol% G + C: 62.0–62.1 (T_m : Fonseca and Sampaio 1992).

Cell hydrolyzates: Xylose absent (Fonseca and Sampaio 1992).

Origin of the strains studied: Fonseca and Sampaio (1992) isolated three strains: IGC 4641 from soil collected in a wood, Lisbon, Portugal, Spring 1987; IGC 4599 and IGC 4642 from dried leaf material collected in a natural park, south of Lisbon (Arrábida) in the summers of 1989 and 1990.

Type strain: CBS 7604 (IGC 4641).

Comments: In contrast to our results, Fonseca and Sampaio (1992) reported that the species was unable to utilize L-arabinose and cellobiose. The strains were

isolated using media containing lignin-related phenolic compounds as the sole carbon source.

86.7. *Rhodsporidium malvinellum* Fell & I.L. Hunter (Fell 1970b)

Synonym:

Kondoa malvinella (Fell & I.L. Hunter) Y. Yamada, Nakagawa & Banno (1989a)

Growth in 5% malt extract: After 3 days at 12°C, the ovoidal to spheroidal haplophase cells measure (2–7)×(3–7) μm; they are single, occasionally in pairs with budding on short necks. A light sediment is formed. After one month there is a moderate sediment.

Growth on 5% malt agar: After 3 days at 12°C, the cell sizes are as above. The streak is creamy white, smooth and semi-glistening. The periphery is entire and the cross section is raised. At 2 weeks, the streak is light mauve and at one month the color has intensified.

Dalmat plate culture on corn meal agar: Pseudo-mycelium is generally absent; occasionally short branched chains of cells are present.

Life cycle: The species is heterothallic (biallelic, unifactorial); when compatible mating types are mixed on corn meal agar at 12°C, conjugation and binucleate mycelium with clamp connections are present within 3 days. Teliospores are rare after 7 weeks and abundant after 3 months. The teliospores are subglobose (5–10)×(7–12) μm. They develop singly and are attached to the hyphae by a short stalk (Fig. 346). Germination has only been observed once. The phragmometabasidium was 2-celled with lateral and terminal basidiospores.

Fermentation: absent.

Fig. 346. *R. malvinellum*, CBS 6082×CBS 6083. Cells of opposite mating types were mixed on corn meal agar and grown at 12°C for 3 months; teliospores formed on a short stalk. Bar = 10 μm.

Co-Q: 9 (Yamada and Kondo 1973).

Mol% G + C: 50.5 (T_m : Nakase and Komagata 1971c).

Cell hydrolyzates: Xylose absent (Sugiyama et al. 1985).

Origin of the strains studied: Marine waters of the southern Pacific, Indian and Antarctic Oceans (17) (Fell 1970b).

Complementary mating types: CBS 6082 (mating type *A1*), collected April 1966 at 60°29'S, 94°56'W at 53 m deep; CBS 6083 (mating type *A2*), collected on the same date and location at a water depth of 16 m with approximately the same temperature and salinity (Fell 1970b).

Type strain: CBS 6082.

Comments: The species appears to be restricted to marine habitats; in addition to the isolations from the southern oceans, Laurenvichene et al. (1989) isolated this species from coastal areas of the Baltic Sea. *R. malvinellum* has the physiological and life cycle characteristics typically found in other species of *Rhodospiridium*. The distinctive colony color is useful for species identification. Based on nucleotide sequence data the species does have distinctive genetic differences from other species of *Rhodospiridium*. Blanz and Gottschalk (1984, 1986) and Blanz and Unseld (1987) through examination of the nucleotide sequences of the 5S rRNA of 49 species of basidiomycetes found that *R. malvinellum* was more closely related to the Hymenomycetes, *Atractiella solani* and *Phleogena faginea*, than to *R. toruloides*. Blanz and Gottschalk suggested that *R. malvinellum* should be transferred to a separate genus. Yamada et al. (1989a) examined partial regions of the large and small subunits

of rRNA of *R. malvinellum*, *R. toruloides*, *Leucosporidium scottii* and *Rhodotorula lactosa*. Based on the comparative differences in nucleotide sequences, Yamada et al. (1989a) described the genus *Kondoa* with the single species *Kondoa malvinellum*. Using the description of *R. malvinellum* published by Fell (1970b), Yamada et al. considered that *Kondoa* was morphologically unique through the production of teliospores attached by short stalks and 2-celled phragmometabasidia. However, other species, such as *R. toruloides* and *R. dacryoideum* produce lateral teliospores on short stalks or sporophores and their phragmometabasidia are 2–4-celled. Whether or not 2-celled phragmometabasidia are characteristic of *R. malvinellum* is unknown as germination has only been observed one time (Fell 1970b). Yamada et al. (1989a) also point out that *R. malvinellum*, as a psychrophile, is distinct from the other species of *Rhodospiridium*. It should be noted that *R. malvinellum* was collected from low temperature environments and that psychrophilic characteristics are also found in other species (e.g., *Leucosporidium scottii*, *L. antarcticum*, *Mrakia frigida*) collected from cold habitats.

Although it is difficult to distinguish phenotypic differences between *Kondoa* and *Rhodospiridium*, the genetic differences were confirmed by Fell et al. (1992) who examined a partial region of the LSU rRNA for 117 species of basidiomycetous yeasts. Based on the species examined, *R. malvinellum* appears to be more related to species of *Bensingtonia* than to *Rhodospiridium* spp. This suggested relationship, and that presented by Blanz and Unseld (1987), indicates the need for more in depth examination of nucleotide sequence analyses and their phylogenetic significance at the generic level. For taxonomic purposes, the only distinctive phenotypic character appears to be color, and separation of genera based on shades of color does not seem either warranted or practical. Therefore, we have tentatively maintained the taxonomic binomial *R. malvinellum* with the suggestion that further investigations may confirm *Kondoa* as a distinct genus.

86.8. *Rhodospiridium paludigenum* Fell & Statzell-Tallman (1980a)

Growth in 5% malt extract: After 3 days at 25°C, the cells are ovoidal to elongate, (2–4) × (3–11) μ m. They occur singly and in pairs. There is a light sediment. After one month, there is a heavy ring with light to heavy sediment.

Growth on 5% malt agar: After 3 days at 25°C, the cell morphology is similar to that in malt extract. The one-month-old streak culture is salmon-orange, smooth, glistening, slightly raised or rugose and the border entire.

Dalmay plate culture on corn meal agar: After 6 days at 25°C, there are short chains of budding cells, and short lengths of true mycelium may be present.

Life cycle: The species is heterothallic. When opposite

mating types were mixed on corn meal agar (prepared with 20% seawater) and incubated at 22–25°C, true hyphae, bearing spheroidal (13–17 µm diameter) teliospores, developed within 6 days. The teliospores were in clusters of 2 to 4, intercalary and rarely terminal on the hyphae. Teliospore germination after 4 weeks on corn meal agar, resulted in 2- to 4-celled metabasidia (Fig. 347). Basidiospores were of the two parental types, indicating a unifactorial sexual system. *R. paludigenum* does not mate with the other species included in the genus.

Fermentation: absent.

Co-Q: 10 (Sugiyama et al. 1985).

Mol% G + C: 64.9–65.3 (Fell et al. 1988).

Cell hydrolyzates: Xylose absent (Sugiyama et al. 1985).

Origin of the strains studied: Intertidal black rush (*Juncus roemerianus*) marsh and mangrove (*Rhizophora mangle*) swamp waters bordering Card Sound near Miami, Florida, April 1973 (3) (Fell and Statzell-Tallman 1980a); seawater, Florida by Ahearn (1).

Complementary mating types: CBS 6567 (mating type *A1*, Fell strain ML 2226) and CBS 6566 (mating type *A2*, Fell strain ML 2225).

Type strain: CBS 6566.

Comments: Haploid strains of *R. paludigenum* fit the description of *Rhodotorula graminis*, however, the type strain of *Rhodotorula graminis* does not mate with either mating type of *R. paludigenum*. Additionally, nucleotide sequence analysis indicates that the two species are distinct, but closely related.

Fig. 347. *R. paludigenum*, CBS 6566×CBS 6567. Cells of opposite mating types were mixed and incubated on corn meal agar for 6 days; resulting teliospores germinated after 4 weeks to form a phragmotetbasidium with lateral and terminal basidiospores. Bar = 10 µm.

86.9. *Rhodotoridium sphaerocarpum* Newell & Fell (1970)

Anamorph: *Rhodotorula glutinis* (Fresenius) Harrison var. *salinaria* Hirosawa & Takada

Synonym:

Rhodotorula glutinis (Fresenius) Harrison var. *salinaria* Hirosawa & Takada (1969)

Growth in 5% malt extract: After 3 days at 20°C, the cells are spheroidal to ellipsoidal, (3–5)×(5–7) µm, single or in pairs. Often newly divided cells form on very short necks <0.5 µm long. There is an orange to pink-orange sediment. After one month the sediment becomes thick and a weak ring has formed; spheroidal cells (7 µm) may be present.

Growth on 5% malt agar: Cell morphology at 20°C, is similar to that in malt extract. The streak culture at 3 days is smooth, glossy, orange to pink-orange; texture is highly mucoid; cross section is raised, spreading and the border is entire. After one month the culture becomes extremely mucoid; if kept at 5°C for one month, the culture does not become as mucoid as observed at 20°C, and develops a yellow pigmentation.

Dalmu plate culture on corn meal agar: Some strains produce no mycelium, others produce, from individual cells, short, fine, primary hyphae (diameter 1–3 µm) with 1 or 2 septa; self-sporulating strains develop extensive, larger (diameter 3.4–5.4 µm) septate hyphae, bearing large, spherical, thick-walled, terminal or intercalary teliospores.

Life cycle: *R. sphaerocarpum* has a biallelic unifactorial mating system. Mixing of haploid mating types *A1* and *A2* on corn meal agar at 25°C results in conjugation followed by hyphal development from the conjugation tube, or from one of the two conjugate cells (Fig. 348). The mycelium is dikaryotic; clamp connections form at the septa and thick-walled teliospores develop terminally and intercalary on the hyphae. The teliospores are at first binucleate and eventually become uninucleate. They are spheroidal,

Fig. 348. Diagrammatic representation of the life cycle of *R. sphaerocarpum* (after Newell and Fell 1970).

smooth, and dark in color at maturity, occurring singly, in pairs, and in branched chains of as many as 12 or more. When teliospores are present in large quantities the culture becomes dark brown. The teliospores germinate if placed in distilled water at 25°C for one month followed by transfer to malt agar at the same temperature. The teliospore germinates to a 4-celled metabasidium, each cell capable of repeated mitotic divisions for the formation of several basidiospores. The metabasidium eventually breaks up into individual cells (Fig. 349). The basidiospores are haploid; a haplo-lethal effect occurs in some strains: examination of progeny from germination of teliospores indicated that all colonies were of mating type *A1*; apparently mating type *A2* did not survive.

Some strains produce teliospores in the absence of mating. The yeast cells are uninucleate and produce uninucleate teliospore-bearing hyphae without clamp connections. The mycelial formation is less extensive than the dikaryotic mycelium produced by the conjugating strains. Teliospores of the self-sporulating strains germinate under the same conditions as described above for the heterothallic strains to produce phragmometabasidia with haploid basidiospores (Fig. 347). Although Newell and Fell (1970) postulated that the haploid cells were the result of a meiotic division in the basidium, it is likely that these strains are homokaryotic fruiters similar to those of *Leucosporidium scottii*. Studies have not been undertaken to confirm either possibility.

Strains of *R. sphaerocarpum* fit the description of *Rhodotorula glutinis*: The type strain of *Rhodotorula glutinis* does not mate with mating types of *R. sphaero-*

carpum. Similarly, nucleotide sequence analysis indicates that the two species are separate (Fell et al. 1995).

Fermentation: absent.

Mol% G + C: 64.9–65.4 (T_m : Nakase and Komagata 1971c); 64.0–64.1 (BD: Fell et al. 1988); 62.2–62.7 (T_m : Hamamoto et al. 1987).

Cell hydrolyzates: Xylose absent (Sugiyama et al. 1985).

Fig. 349. *R. sphaerocarpum*, CBS 5939×CBS 5940. Teliospores formed from a mix of cells of opposite mating types after 2 weeks on corn meal agar at 25°C. After soaking in distilled water for 1 month, germination occurred within one day of placing the teliospores on V8 agar. Bar = 10 μm.

Origin of the strains studied: Marine sources near the Antarctic (Palmer) Peninsula and Palmer Archipelago, Jan.–Feb. 1966, from waters whose temperatures ranged from -1.68 to 1.33°C and salinities of 32.48‰ to 34.72‰ (33) and from the Caribbean Sea, Jan.–Feb. 1967, 100–150 miles off the coasts of Columbia and Panama, over the Columbian Basin in water depths of 184–297 meters where temperatures ranged from 12.90 to 17.72°C and salinities of 35.62 to 36.42‰ (4) (Fell et al. 1973); salt farm in 1967 at Yashima along the shore of Seto Inland Sea, Japan (1) (Hirosawa and Takada 1969).

Complementary mating types: CBS 5940 (Newell and Fell strain AR-74, mating type *A1*) collected from the Gerlache Straits near Anvers Island, Antarctica. CBS 5939 (Newell and Fell strain AR-3, mating type *A2*) collected from Marguerite Bay, Antarctica. Self-sporulating strain: CBS 5941 (Newell and Fell strain AR-77, strain from the Gerlache Straits near Brabant Island, Antarctica).

Type strain: CBS 5939.

Comments: *R. sphaerocarpum* is a commonly occurring species in marine habitats. In addition to the sources previously listed, we found this species to be prevalent in near shore waters of the Caribbean, Bahamas and Florida, often in association with coral reefs. J. Buck (personal communication) reports that *R. sphaerocarpum* is abundant in freshwater lakes in Connecticut, U.S.A.

86.10. *Rhodosporeidium toruloides* Banno (1967)

Anamorph: *Rhodotorula rubescens* (Saito) F.C. Harrison

Synonyms:

Torula rubescens Saito (1922)

Mycotorula rubescens (Saito) Ciferri & Redaelli (1925)

Rhodotorula rubescens (Saito) F.C. Harrison (1928)

Rhodotorula glutinis (Fresenius) F.C. Harrison var. *rubescens* (Saito) Lodder (1934)

Rhodotorula longissima Lodder (1934)

Rhodotorula gracilis Rennerfelt (1937)

Rhodotorula glutinis (Fresenius) F.C. Harrison var. *rufusa* Iizuka & S. Goto (1965)

Growth in 5% malt extract: After 4 days at 25°C, heterothallic haploid cells are spheroidal to elongate, $(2-7) \times (4-12)$ μm. The homothallic cells are ovoidal to obtuse oblong, $(3-7) \times (6-30)$ μm, and may form true mycelium and teliospores.

Growth on 5% malt agar: After 4 days at 25°C, the cells are similar in size to those in malt extract. The streak culture is pink to orange, the border is entire, the surface is smooth and glistening, the texture is soft to slightly mucoid. After one month, the color becomes scarlet. The homothallic cultures have dark brown areas consisting of true mycelium and teliospores.

Dalmat plate culture on corn meal agar: After 2 weeks at 25°C, pseudomycelium of heterothallic strains may be absent or range from short branched chains of pseudomycelium to abundant clusters of pseudomycelium. The homothallic strains have extensive true mycelium with clamps and teliospores.

Life cycle: The species is homothallic and heterothallic (Fig. 350). Heterothallism: On malt agar at 25°C cells of compatible mating types (*A1* and *A2*) conjugate within 24 hours and plasmogamy occurs. From one cell of the conjugate pair, a septate hypha develops with clamp connections at the septa. Angular, irregularly shaped, thick-walled teliospores develop terminally or laterally on short, clamped sporophores (Fig. 351).

After 1–2 weeks the spores germinate to produce club-shaped metabasidia with 2–4 cells. Basidiospores bud laterally and terminally. Some of the basidiospores are heterothallic and capable of mating and repeating the life cycle.

Homothallism: In addition to the heterothallic basidiospores, homothallic basidiospores are produced on the metabasidium. These are uninucleate cells that develop directly into a dikaryotic mycelium with clamp connections and teliospores. The teliospores germinate to produce

Fig. 351. *R. toruloides*, CBS 14×CBS 349. Teliospores formed from a mix of cells of opposite mating types on corn meal agar at 25°C after 2 weeks. Bar = 10 μm.

Fig. 350. Diagrammatic representation of the life cycle of *R. toruloides* (Fell et al. 1970).

metabasidia with both heterothallic and homothallic basidiospores.

The heterothallic and homothallic basidiospores are uninucleate, the hyphae with clamp connections, produced by both heterothallic and homothallic phases, are binucleate. The teliospores are initially binucleate, and become uninucleate through karyogamy. At germination the diploid nucleus undergoes reduction division into the four haploid nuclei of the metabasidium. Anamorphic strains of *R. toruloides* fit the description of *Rhodotorula glutinis*. The type culture of *Rhodotorula glutinis* does not mate with mating types of *R. toruloides*.

Fermentation: absent.

Co-Q: 9 (Yamada and Kondo 1973).

Mol% G+C: 60.0–61.0 (T_m : Nakase and Komagata 1971c, Nakase 1972b); 59.3–60.5 (T_m : Hamamoto et al. 1987).

Cell hydrolyzates: Xylose absent (Sugiyama et al. 1985).

Origin of the strains studied: Conifer pulp in Sweden (CBS 14) (Rennerfelt 1937); soil in Japan (CBS 349) (Okunuki 1931); air, Japan (CBS 315, type strain of *Torula rubescens* Saito; Southern Pacific Ocean (Fell strain 27-51, 1967); gut of a dead porpoise, Bimini, Bahamas (2); unknown (2).

Complementary mating types: IFO 0559 (CBS 14) mating type A1 and IFO 0880 (CBS 349) mating type A2.

Type strain: Banno designated the mycelial conjugate of IFO 0559 (CBS 14) and IFO 0880 (CBS 349) as the type strain. He deposited the conjugate in the IFO collection as IFO 11588. We recommend the living type strains as the holotype CBS 14 (mating type A1) and the allotype CBS 349 (mating type A2). Self-sporulating strain: CBS 6016 (IFO 8766).

Comments: In addition to the sources listed above, we isolated the species from tropical marine waters in South Florida, the Caribbean and Bahamas, usually in regions of coral reefs. The species, although widespread in the marine habitats, was not abundant. *Rhodotorula*

glutinis var. *rufusa*, an anamorph of *R. toruloides*, was isolated (Iizuka and Goto 1965) from soil of the Nishiyama oil field, Niigata Prefecture, Japan. Joo et al. (1988) found a colorless variant of *R. toruloides* and questioned the use of color in separating *Leucosporidium* from *Rhodospodium*. Sequence analysis of the LSU rRNA indicates that these two genera are phylogenetically distinct (Fell et al. 1992).

Comments on the genus

A sexual life cycle involving mating between two strains of *Rhodotorula glutinis* was first reported by Banno (1967) with the description of the genus *Rhodospodium* and the species *R. toruloides*. Although a basidiomycetous life cycle had been established for *Sporidiobolus johnsonii* Nyland, Banno's observation confirmed the basidiomycetous nature of strains of *Rhodotorula* and opened the door to further exploration into sexual cycles in *Rhodotorula*. Nine additional species followed and we predict that many more will be found. This prediction is based on the presence of numerous anamorphic strains and species of *Rhodotorula* with unknown teleomorphic states.

Some *Rhodospodium* species (*R. babjevae*, *R. kratohvilovae*, *R. diobovatum*, *R. paludigenum* and *R. toruloides*), based on sequence analysis of the large subunit rDNA, are related to the anamorphs *Rhodotorula graminis*, *R. araucariae*, *R. mucilaginoso* and *R. glutinis*. Mating

reactions between these teleomorphs and anamorphs has not been observed. Another species, *R. fluviatile*, appears related to *Sporidiobolus ruineniae*. Sequence analysis indicates that *R. dacryoideum* and *R. malvinellum* are not related to the above mentioned species, instead *R. malvinellum* appears close to *Bensingtonia yuccicola*, and *R. dacryoideum* is in a large cluster of species that includes *Rhodotorula lactosa* and *Erythrobasidium hasegawae* (Fell et al. 1992, 1995). Because of these nucleotide sequence differences, recommendations have been made (Yamada et al. 1989a, 1994a) to create new genera for *R. malvinellum* (*Kondoa*) and *R. dacryoideum* (*Sakaguchia*). The difficulty with these recommendations is that the genera do not have sufficient classical taxonomic differences to separate them from *Rhodospodium*, or distinguish them as separate genera. The paramount character is derived from nucleotide sequence analysis, which currently is an impractical technique for routine identification. Therefore, we have maintained the present integrity of *Rhodospodium*, recognizing the polyphyletic nature of the genus. As our knowledge of the relationships of species and genera in the Heterobasidiomycetes becomes more acute, a stronger basis for generic separations will emerge. Currently, species within the genus can readily be separated by teliospore shape, colony color and a limited number of assimilation tests (Table 70).

87. *Sporidiobolus* Nyland

A. Statzell-Tallman and J.W. Fell

Diagnosis of the genus

Colony color on solid media includes shades of pink and red due to the presence of carotenoid pigments. Vegetative reproduction by budding, formation of pseudomycelium and true mycelium, and by ballistoconidia. Ballistoconidia develop on simple and branched sterigmata that arise from yeast and mycelial cells. The septal structure consists of a simple pore.

Sexual mechanisms are homothallic and heterothallic. In the heterothallic system a dikaryotic mycelium results from the conjugation of a compatible mating pair. A clamp connection is usually present at each cross wall. Intercalary and terminal teliospores develop. Karyogamy takes place in the teliospore (probasidium) which germinates to produce a metabasidium (promycelium). Meiosis takes place during germination with the formation of haploid basidiospores.

Homothallism consists of the development of hyphae with teliospores from a single yeast cell in the absence of mating. The yeast phase is diploid; reduction division takes place with the formation of a dikaryotic hypha with clamp connections. Karyogamy occurs in the teliospore. Germination of the teliospore results in a metabasidium with diploid basidiospores. Strains of some species produce teliospores on uninucleate hyphae that lack clamp connections (self-sporulation). The ploidy of the nucleus is unknown.

The metabasidia are one-celled (holometabasidia) or septate with two or more cells (phragmometabasidia). The basidiospores are terminal on the holometabasidium and lateral and terminal on the phragmometabasidium. In some species the metabasidium is connected to the teliospore by an aseptate stalk that ranges in length from 3 to 26 μm .

Sugars are not fermented, starch formation is negative, Diazonium blue B and urease are positive, xylose is absent from cell hydrolyzates, D-glucuronate and *myo*-inositol are not assimilated. Coenzyme Q-10 is present.

Type species

Systematic discussion of the species

87.1. *Sporidiobolus johnsonii* Nyland (1949)

Anamorph: *Sporobolomyces holsaticus* Windisch ex Yarrow & Fell

Synonyms:

Prosporobolomyces holsaticus (Windisch) Novák & Zsolt (1961)

Sporobolomyces holsaticus Windisch ex Yarrow & Fell (1980)

Growth in 5% malt extract: After 3 days at 25°C, the cells are ovoidal and elongate, (2–7) × (5–27) µm, single, in pairs and in short chains. The cells are budding and may have simple or branched sterigmata bearing kidney-shaped ballistoconidia, (4–7) × (8–14) µm. Short hyphal strands develop from single cells. A thick, dull, corrugated grenadine-pink pellicle or a thick ring and a light sediment are present. After one month, there is a moderate sediment and a strongly wrinkled pellicle. There may be extensive formation of mycelium with complete clamp connections and teliospores.

Growth on 5% malt agar: After 5 days at 25°C, the streak culture is yellowish-pink colored with a convoluted surface. The streak is shiny in the center to dry and powdery at the periphery; true mycelium forms at the edge of the colony. After one month the colony is peach-colored. By 3 weeks, there is an extensive formation of mycelium with clamps and teliospores.

Dalmáu plate culture on corn meal agar: After 5 days at 25°C, there are budding yeast cells as well as cells with simple and branched sterigmata bearing ballistoconidia; extensive true mycelium with clamp connections and spherical teliospores, 10–15 µm in diameter may be produced.

Formation of ballistoconidia: Asymmetric, reniform, (2–4) × (5–10) µm, ballistoconidia form on simple or branched sterigmata after 3 days on malt agar or corn meal agar.

Life cycle: As described by Laffin and Cutter (1959a,b) the species is homothallic. The yeast phase is diploid; reduction division occurs with the formation of dikaryotic hyphae with clamp connections. Karyogamy occurs in the teliospore. Germination of the teliospore results in a holometabasidium with terminal diploid basidiospores. To obtain germination, the cultures were grown on malt agar (22°C) for 4 weeks and then the teliospores were transferred to 2% agar where they germinated after 10 days of incubation.

Fermentation: absent.

Co-Q: 10 (Yamada et al. 1983, Nakase and Suzuki 1986d).

Mol% G+C: 63.5 (BD: Holzschu et al. 1981); 62.0, 64.0 (BD: Storck et al. 1969).

Cell hydrolyzates: Mannose, glucose, galactose, fucose (von Arx and Weijman 1979).

Origin of the strains studied: Pustule of *Phragmidium rubi-idaei* (DC.) Karst. on a living leaf of *Rubus idaeus* L. in the State of Washington, U.S.A. (1) (Nyland 1949); fodder yeast (1) from Windisch 1949.

Type strain: CBS 5470 (Nyland 1949).

Comments: The majority of the strains labeled *Sporobolomyces holsaticus* that we studied were found to mate with strains of *Sporobolomyces salmonicolor*. One exception was the type strain of *S. holsaticus* (CBS 1522), which was maintained as a separate species in the last edition of "The Yeasts". Subsequent studies of CBS 1522 concluded that *S. holsaticus* is a synonym of *Sporidiobolus johnsonii* based on morphological and physiological similarities, DNA–DNA hybridization (93.1%) between the type strains of these species (Boekhout 1991a), the electrophoretic pattern of enzymes (Yamazaki and Komagata 1983a) and nucleotide sequence analysis (Fell et al. 1992). CBS 1522, therefore, represents an anamorphic strain of *S. johnsonii*, viz., hyphae with clamps and teliospores are not formed.

87.2. *Sporidiobolus pararoseus* Fell & Tallman (Fell and Statzell-Tallman (1981)

Anamorph: *Sporobolomyces shibatani* (Okunuki) Verona & Ciferri

Synonyms:

Torula shibatana Okunuki (1931)

Sporobolomyces pararoseus Olson & Hammer (1937) nom. nud.

Sporobolomyces shibatani (Okunuki) Verona & Ciferri (1938)

Sporobolomyces marcellae Santa Maria (1958b)

Prosporobolomyces marcellae (Santa Maria) Novák & Zsolt (1961)

Sporobolomyces ruber Yamasaki & Fujii (1950)

Sporobolomyces carnicolor Yamasaki & Fujii (1950)

Sporobolomyces japonica Iizuka & Goto (1965)

Growth in 5% malt extract: After 3 days at 25°C, there is considerable variation in cell shape; the cells may be ovoidal, spherical, elongate or allantoid, (3–9)×(4–21)µm. They occur singly, in pairs, small clusters and short chains. A thin ring and light to moderate sediment are present. After one month a thick corrugated pellicle may form and the sediment may be heavy.

Growth on 5% malt agar: After one month at 25°C, the streak culture is pale salmon, grenadine, coral-red or peach-red in color with a rugose or smooth, glossy or semidull surface. The texture is soft. The cross section is low convex to flat and the border entire, occasionally with a mycelial fringe.

Dalmat plate culture on corn meal agar: The strains vary considerably; pseudo- and true hyphae are absent in some strains, whereas other strains will produce light to extensive amounts of both.

Formation of ballistoconidia: Although some strains form ballistoconidia on corn meal agar, Phaff (1970c) found that a medium, which consisted of Yeast Nitrogen Base agar with either ribose, glycerol or glucono-δ-lactone was more suitable for ballistoconidium production for other strains. The ballistoconidia are asymmetric, measuring (2–5)×(5–12)µm, with 1–5 or more sterigma.

Life cycle: When compatible mating types were mixed on corn meal agar at 22°C, conjugation was followed by formation of hyphae with hook-to-peg clamps and teliospores. The latter are elliptic-fusiform or spherical, (9–13)×(13–24)µm, occurring singly, in pairs or rarely in chains of three. After 35 days on corn meal agar at 22°C, the teliospores germinated on the corn meal agar by forming branched hyphae with buds. Continued growth of either the buds or hyphae was not successful. Two mating types were found, suggesting a unifactorial mating system with two alleles.

One strain, identified as *S. pararoseus* (CBS 5541), produced extensive true mycelium with elliptic-fusiform to spherical teliospores, (10–12)×(12–20)µm. The teliospores were single and in chains, located intercalarily and terminally on the hyphae and on short lateral branches. Clamp connections were not formed. This self-sporulating strain did not mate with either the *A1* or *A2* mating types of *S. pararoseus*. DNA sequence analysis indicates that this strain maybe related to *Sporobolomyces roseus* rather than to *S. pararoseus*.

Fermentation: absent.

Co-Q: 10 (Yamada and Kondo 1973).

Mol% G+C: 50.0–53.7 (T_m : Boekhout 1991b); 51.5–55.0 (BD: Storck et al. 1969).

Cell hydrolyzates: Glucose, mannose, galactose and fucose (Gorin and Spencer 1970).

Origin of the strains studied: Sources include soil (Okunuki 1931), air (Olson and Hammer 1937), flower, plants and seawater.

Complementary mating types: CBS 491, mating type *A2*, and CBS 499 (Olson and Hammer 1937), mating type *A1*, from air in a dairy, USA, isolated by B.W. Hammer. Additional mating strains: CBS 484, mating type *A1*, type strain of *Sporobolomyces pararoseus*, from air, USA, B.W. Hammer; CBS 4216, type strain of *Sporobolomyces ruber* Yamasaki & Fujii, mating type *A2*; CBS 5329 and CBS 5330, mating type *A2*, from seawater in Atlantic Ocean, USA by D. Ahearn. Self-sporulating strain: CBS 5541, from flower of *Fumaria* sp., France by J. Villoutreix.

Type strain: CBS 491, type strain of *Sporobolomyces shibatanus*, mating type *A2*, from soil, Japan, isolated by K. Okunuki.

Comments: Two strains identified as *Sporobolomyces pararoseus*, CBS 4217 (type strain of *S. marcellae* and CBS 2637, did not mate with either of the mating types of *S. pararoseus*. Storck et al. (1969) found that the G+C content of the type strain of *S. pararoseus* (CBS 484) is 51.5%, whereas the G+C content of CBS 4217 is 55.0% and CBS 2637 is 60.5%. Apparently these two strains belong to one or more species distinct from *S. pararoseus*.

87.3. *Sporidiobolus ruineniae* Holzschu, Tredick & Phaff (1981)

Synonyms:

Sporobolomyces coprophilus Sugiyama & S. Goto (1967)

Sporidiobolus ruineniae Holzschu, Tredick & Phaff var. *coprophilus*

Kurtzman & Fell (1991)

Sporidiobolus microsporus Higham (1970) nom. nud.

Growth in 5% malt extract: After 3 days at 25°C, the cells are cylindrical or ovoidal, (2–9) × (6–13) μm, and single or in pairs. Some cells have sterigmata with several bud scars. Short hyphal strands develop from single cells. A light ring and a moderate pellicle may be present. Hyphae with clamp connections and spherical teliospores (4–20 μm in diameter) develop.

Growth on 5% malt agar: After 3 days at 25°C, the streak culture is cream to light buff or peach-colored (see comments). The surface is smooth, rugoid, slightly raised, and slightly glistening. The border is entire with tufts of mycelium formed by some strains; clamp connections (incomplete, rarely complete) may or may not be present on the mycelium; teliospores may occur. After one month, there is a more extensive development of hyphae and teliospores and the colony is orange-luteolus or peach-red.

Dalmou plate culture on corn meal agar: After 6 days at 25°C, true and pseudomycelium may be present. By 6 weeks, teliospores develop on true mycelium. Complete or incomplete clamp connections may be present; spherical teliospores are present that resemble those on malt agar.

Formation of ballistoconidia: Asymmetric ballistoconidia, (2–7) × (6–10) μm, form on most growth media, with the exception of one strain (CBS 5811, *Sporobolomyces coprophilus*) that appears to have lost this ability.

Life cycle: The species is homothallic; teliospores develop from single cells in the absence of mating. *S. ruineniae* and *S. microsporus* strains develop hyphae with complete and incomplete clamp connections and germination of teliospores at 19°C results in a metabasidium that connects to the teliospore by an aseptate stalk, which ranges in length from 3–26 μm. Rates of teliospore germination vary. Teliospores from a streak culture of a *S. ruineniae* strain (Figs. 352, 353) on corn meal agar for 1.5 to 5 weeks, which were moved in a block of agar to distilled water for 4–12 weeks, germinated within 3 days of being transferred onto 2% aqueous agar; the *S. microsporus* strain teliospores, from a streak on a corn meal agar Dalmou plate for 8 weeks, were soaked for 2 weeks in distilled water; germination occurred after one week on 2% agar. The metabasidia were two- and four-celled with lateral and terminal basidiospores. Ploidy of the basidiospores was not determined. The third strain, *S. coprophilus*, produced teliospores on mycelium that lacked complete clamps, although sparse incomplete clamps were present. Teliospore germination occurred in a 7-week-old culture on malt agar, which was soaked for

Fig. 352. *S. ruineniae*, CBS 5001. Teliospore, which formed from cells grown on corn meal agar at 19°C after 5 weeks, germinated after soaking in deionized water for 5 weeks. The 3-celled metabasidium is attached to the teliospore by an aseptate basal cell. Basidiospores, often in clusters of 2–4 cells, are on small pedicels. Bar = 10 μm.

2–4 weeks in distilled water and transferred to 2% agar for 3 days. The club-shaped phragmometabasidium lacked the aseptate basal cell present in the other two species (Fig. 354); the resulting basidiospores formed in two to four-spore clusters on a short pedicel and developed a parental-type life cycle: teliospores formed on hyphae that lacked clamp connections.

Fermentation: absent.

Co-Q: 10 (Nakase and Suzuki 1986d).

Mol% G+C: CBS 5811, 64.5; CBS 5001, 64.9 (BD: Holzschu et al. 1981; BD: Kurtzman and Fell 1991).

Cell hydrolyzates: Xylose absent (Suzuki and Nakase 1988a).

Fig. 353. *S. ruineniae*, CBS 5001. Teliospore, which formed on corn meal agar at 19°C after 5 weeks, germinated after soaking in deionized water for 5 weeks. The 2-celled metabasidium, is attached to the teliospore by an aseptate basal cell. Basidiospores, often in clusters of 2-4 cells, are on small pedicels. Bar = 10 μ m.

Fig. 354. *S. ruineniae* (*S. coprophilus* type strain), CBS 5811. Teliospore formed on malt agar after 7 weeks and then soaked in deionized water for 2 weeks. Germination to a club-shaped metabasidium lacking an aseptate basal cell occurred within 4 days on 2% aqueous agar. Bar = 10 μ m.

Origin of the strains studied: Four strains of *S. ruineniae* (CBS 4998, 4999, 5000 and 5001, type) were isolated from the phyllosphere of tropical foliage of *Malpighia coccigera* at Bogor, Indonesia (Ruinen 1963). The type strain of *Sporobolomyces coprophilus* (CBS 5811) was isolated from goat dung in Pakistan (Sugiyama and Goto 1967). This strain lost the ability to produce ballistoconidia and was considered to be a strain of *Rhodotorula graminis* (Phaff and Ahearn 1970). *Sporidiobolus microsporus* (CBS 7041) was studied by June Higham (Higham 1970), a student of R.J. Bandoni, however, a formal description was not published (Bandoni, personal communication).

Type strain: CBS 5001 (isolated by Ruinen 1963).

Comments: The three species (*S. ruineniae*, *S. coprophilus* and *S. microsporus*) have been placed in synonymy (Boekhout 1991a) based on their similar physiological and morphological properties. Our morphological and molecular studies suggest that this decision should be examined in greater detail. *S. ruineniae* (Figs. 352, 353) and *S. microsporus* (no photograph included) strains have complete and incomplete clamp connections on the hyphae and their metabasidia form on stalks. In

contrast the *S. coprophilus* strain has incomplete clamp connections (very rarely complete) and the few teliospores that germinated revealed a metabasidium that lacks a connecting stalk (Fig. 354). *S. microsporus* differs from the other strains by colony color, i.e., after 3 days on malt extract *S. microsporus* is cream to buff and at one month is orange-luteolus; the other strains are peach-colored with an increase in intensity to peach-red. *S. microsporus* does not utilize maltose; the other strains utilize maltose, sometimes slowly. Nucleotide sequence studies of a partial region of the LSU rRNA (Fell et al. 1992) indicate that the *S. ruineniae* and *S. coprophilus* strains have identical sequence alignments and that *S. microsporus* differs by 11 base positions (~4% of positions sequenced). This would suggest that *S. microsporus* is a distinct species. Kurtzman and Fell (1991) examined the G + C contents of *S. ruineniae* (64.9%) and *S. coprophilus* (64.5%) and determined that DNA reassociation between the two strains was 63% which led them to suggest that the two strains represented varieties of the same species. As far as we are aware there have not been any G + C content or hybridization studies on the *S. microsporus* strain. The nucleotide sequence studies indicate that *Rhodospiridium fluviale* is related to these three species; the *S. ruineniae* strain differs from *R. fluviale* at nine base positions. Species separations of *R. ruineniae* and *R. fluviale* are confirmed by 0% DNA hybridization (Fell et al. 1992). The *S. microsporus* strain appears more closely related to *R. fluviale*, differing at five base positions; DNA hybridization studies between these two strains have not been reported.

87.4. *Sporidiobolus salmonicolor* Fell & Tallman (Fell & Statzell-Tallman 1981)

Anamorph: *Sporobolomyces salmonicolor* (Fischer & Brebeck) Kluver & van Niel

Synonyms:

- Rhodomyces kochii* von Wettstein (1885)
- Blastoderma salmonicolor* Fischer & Brebeck (1894)
- Monilia kochii* (von Wettstein) Saccardo (1892)

- Sporobolomyces rubicundulus* (Okunuki) Verona & Ciferri (1938)
- Sporobolomyces hispanicus* Peláez & Ramírez (1956a)
- Prosporobolomyces hispanicus* (Peláez & Ramírez) Novák & Zsolt (1961)
- Sporobolomyces coralliformis* Tubaki (1958)
- Sporobolomyces salmonicolor* (Fisher & Brebeck) Kluver & van Niel var. *fischerii* Misra & Randhawa (1976)
- Sporobolomyces philippou* Krasil'nikov (1933)
- Sporidiobolus veronae* Balloni, Florenzano & Materazzi (1974)

Fig. 355. *S. salmonicolor*. CBS 2630×CBS 5937. Opposite mating type cells were mixed on corn meal agar at 22°C; the resulting teliospores germinated within 18 weeks to a metabasidium connected to the teliospore by an aseptate basal cell. Bar = 10 µm.

Fig. 356. *S. salmonicolor*. CBS 2630×CBS 5937. Opposite mating type cells were mixed on corn meal agar at 22°C; the resulting teliospores germinated within 18 weeks to a metabasidium connected to the teliospore by an aseptate basal cell. Bar = 10 µm.

Growth in 5% malt extract: After 7 days at 25°C, there may be a light to thick ring; when present the pellicle ranges from a thin film, or small islets, to thick and corrugated. Film and pellicle colors are off-white, light-salmon, yellowish-pink and peach. After one month the ring and pellicle have increased in size.

Growth on 5% malt agar: There is considerable strain variation in cell and colony morphology. After 7 days at 25°C, the cells are ovoid to elongate, (2–12)×(3–35) µm, single and in pairs; pseudo- and true hyphae may occur. Cells and hyphae may have sterigmata up to 50 µm or more in length. The streak cultures are shades of yellowish-pink, salmon and peach. The edges may be entire or heavily myceliated. The surface is smooth, powdery or deeply corrugated. The texture varies from pasty to tough. After one month, there is little change in the cell size, while the streak cultures become deeper in color.

Dalmau plate culture on corn meal agar: There is considerable strain variation, ranging from an absence of pseudo- and true hyphae to extensive growth of both types of hyphae.

Formation of ballistoconidia: Most strains form kidney-shaped, (3–5)×(5–10) µm, ballistoconidia on corn meal agar. Some strains produce ballistoconidia on malt agar.

Life cycle: The species is heterothallic. Conjugation of opposite mating types on corn meal agar at 22°C results in the formation of true mycelium with clamp connections at the septa. As noted by Bandoni et al. (1975) the mating reactions are not consistent, due possibly to such factors as types of media, age and condition of the strains. Two mating types have been recorded, indicating that the species is unifactorial with two alleles. The teliospores are spheroidal (10–14) µm or ovoidal (8–10)×(10–17) µm, terminal, intercalary and lateral on hyphal branches. The teliospores germinate after 18 weeks on corn meal agar at 22°C. The metabasidium is one-celled (5–7)×(13–47) µm and is borne on a connecting cell (1–3)×(3–13) µm (Fig. 355). One to two basidiospores form terminally on the metabasidium (Fig. 356). Hyphae may develop

from the metabasidium. Endospores may be present in the metabasidium.

Fermentation: absent.

Co-Q: 10 (Nakase and Suzuki 1986d).

Mol% G+C: 63.5–65.0 (BD: Storck et al. 1969); 62.0 (BD: Holzschu et al. 1981).

Cell hydrolyzates: Mannose, glucose, galactose, and fucose (von Arx and Weijman 1979); xylose absent (Suzuki and Nakase 1988a).

Origin of the strains studied: *Aessosporon salmonicolor* CBS 5937 (type strain, mating type A1); CBS 5937.3 (A1); *Sporobolomyces coralliformis* CBS 4209 (type), A2; *Sporobolomyces hispanicus* CBS 2873 (type), A1; *Sporobolomyces odoratus* CBS 483 (type), A2; CBS 487 (A1); *Sporobolomyces salmonicolor* CBS 490 (type), A1; *S. salmonicolor* var. *fischerii* CBS 6832 (type), A1; CBS 1039 (A1); CBS 2630 (A2); strains UBC 949 (A1), UBC

950 (A1), UBC 958 (A2) from R.J. Bandoni; strains 5Y (A1) and 7Y (A1) from S.A. Meyer.

Complementary mating types: CBS 490, mating type A1, and allotype strain CBS 2630, mating type A2.

Type strain: CBS 490, type strain of *Sporobolomyces salmonicolor* (Kluyver & van Niel 1924), mating type A1.

Comments: Strains were isolated from sources as diverse as tanning fluid (Peláez Campomanes and Ramírez Gómez 1956a), seawater, atmosphere (Bandoni et al. 1971), mixed cultures (Kluyver and van Niel 1924); humans (Misra and Randhawa 1976, van der Walt 1970f) and plants (Tubaki 1958, Derx 1930).

Boekhout (1991a) reported a 75.8% DNA–DNA similarity between the type strains of *Sporobolomyces johnsonii* and *Sporidiobolus salmonicolor* and consequently placed *S. salmonicolor* into synonymy with *S. johnsonii*. LSU rRNA sequence analyses (Fell et al. 1992) of one mating strain of *S. salmonicolor* (UBC 949) and the type strain of *S. johnsonii* (CBS 5470) found that the two strains differed at 5 nucleotides (2% of the sequence examined). This result agrees with the conclusion that the two species are closely related, but questions the synonymy, and therefore we have retained the two taxa as separate species.

Comments on the genus

Nyland (1949) described a ballistoconidial yeast with clamp connections and thick-walled chlamydospores as the genus *Sporidiobolus*, a genus that represents the teleomorphic states of *Sporobolomyces*. The importance of this first observation of a sexual state for the basidiomycetous yeasts was probably overlooked as the genus was not mentioned in Lodder and Kreger-van Rij's (1952) review. With the discovery of a sexual state in *Rhodotorula* (Banno 1967), the significance of *Sporidiobolus* became apparent and Phaff (1970e) presented a detailed discussion of the genus and included a second species (*S. ruineniae*) in the genus. As currently viewed, the genus consists of the pigmented, teliospore- and ballistoconidia-forming members of the Sporidiales. There are four accepted species, which, based on nucleotide sequence analysis (Fell et al. 1992, 1995), are closely related. Species are differentiated by the method of teliospore formation (self-sporulation or heterothallic) and a limited number of assimilation tests (Table 71). Increased interest in the ballistoconidia-forming yeasts, as evidenced by the number of recently described species of *Sporobolomyces*, should result in the discovery of their teleomorphic states and consequently the addition of new species of *Sporidiobolus*.

88. *Sterigmatosporidium* Kraepelin & Schulze

A. Statzell-Tallman

Diagnosis of the genus

Growth on solid medium is white to cream-colored, either butyrous or rough. Both yeast and mycelial phases occur. Haploid yeast cells are polymorphic, ovoid to cylindrical, and reproduce by polar budding, usually on spiny denticles or thin sterigmata with the septa at the distal end. Pseudohyphae are present.

Heterothallic sexual reproduction occurs following conjugation of haploid cells of opposite mating types; dikaryotic hyphae with clamp connections form; clavate or lageniform cells develop with whorls of terminal dikaryotic basidia-like structures on clamps. Septal pores have not been examined. Self-sporulating strains occur which develop dikaryotic hyphae with clamp connections. Teliospores are absent. Monokaryotic haustorial branches form from subglobose cells on the hypha.

Fermentation is absent. D-Glucuronate and *myo*-inositol are assimilated. Starch-like compounds are synthesized. Diazonium blue B and urease reactions are positive. Coenzyme Q-10 is present. Xylose is present in whole-cell hydrolyzates.

Type species

Sterigmatosporidium polymorphum Kraepelin & Schulze

Species accepted

1. *Sterigmatosporidium polymorphum* Kraepelin & Schulze (1982)

Systematic discussion of the species

88.1. *Sterigmatosporidium polymorphum* Kraepelin & Schulze (1982)

Growth in 5% malt extract: After 3 days at 20°C, the cells are polymorphic, from oval, cylindrical, elongate to irregular and measure (1.1–3.7) × (1.6–10.1) μm. They occur singly, or bud on spiny denticles (Fig. 357) or sterigmata (Fig. 358) which are 0.5–3.7 μm long and 0.5 μm wide. New buds, which are ovoidal to spheroidal, separate from the distal end of the sterigmata or occasionally a sterigma breaks in the middle. A sediment is present. After one month, a sediment and sometimes islets or a pellicle are present.

Growth on 5% malt extract agar: After one month at 20°C, the streak colonies of the haploid and the dikaryon are white to cream-colored, raised, butyrous, smooth with buds forming on short stalks, or the colonies may be rugoid in which the buds form on long sterigmata (Fig. 358). The margin is entire, with the haploid strain fringed by pseudomycelium and the dikaryon fringed with both pseudomycelium and true mycelium with clamps at each septum.

Dalmau plate culture on corn meal agar: After one month at 20°C, pseudomycelium is formed by the haploid strains and dikaryotic strains. True mycelium is also formed by the dikaryotic strain.

Fig. 358. *S. polymorphum*, CBS 8089 × CBS 8090. Formation of blastoconidia (arrow) on long sterigmata. Bar = 25 μm.

Fig. 359. *S. polymorphum*. Life cycle proposed by Kraepelin and Schulze (1982), pg. 479. (A) Haploid cells on long sterigmata. (B) Conjugation of haploid cells. (C) Dikaryotic conidia bud from dikaryotic hypha. (D) Chlamydospore-like cells with paired nuclei form with clamps on hypha. (E) Monokaryotic haustoria form from subglobose cells which develop on clamps from the dikaryotic hypha. (F) Refractive cells on whorl of clamp-like structures on lageniform sporogenous cell with basal clamp. (G) Refractive, dikaryotic basidia-like structures. (H) Haploid cells bud from basidia-like cells.

Life cycle (from Kraepelin and Schulze 1982):

Both haploid and dikaryotic self-sporulating strains may be isolated from nature. Mixing of opposite mating type haploid cells (Fig. 359A) on malt extract agar or corn meal agar results in conjugation (Fig. 359B) and the formation of hyphae with clamps at the septa. Lageniform to subglobose sporogenous cells form laterally or terminally with a clamp at the basal septum (Figs. 359F, 360).

These sporogenous cells develop whorls of an indeterminate number of cells, $(2.9-3.8) \times (4.8-6.7) \mu\text{m}$, possibly sexual, each on a clamp-like or a stalk-like structure (Figs. 361, 362).

In the life cycle as presented by Kraepelin and Schulze (1982) the nuclei in these refractive, dikaryotic, basidia-like structures (Fig. 359G) are transversely paired. The authors suggested that karyogamy and meiosis occur in these cells, not in typical basidia, and that haploid cells of the two parental mating types bud from these sexual (?) cells (Fig. 359G,H). Self-sporulating strains may be derived from budding of dikaryotic conidia from

Fig. 360. *S. polymorphum*. CBS 8089 \times CBS 8090. Hypha with immature lageniform cell (1) on clamp and chlamydospores (2). Lageniform sporogenous cells on clamps with terminal whorls of clamps (3). Bar = 10 μm .

Fig. 362. *S. polymorphum*. CBS 8089 \times CBS 8090. Refractive cells formed on whorl of clamp-like or stalk-like structures on lageniform sporogenous cell with basal clamp. Bar = 10 μm .

the dikaryotic mycelium (Fig. 359C). Spherical, refractive chlamydospore-like cells, $(4.3-4.8) \times (4.3-5.8) \mu\text{m}$, with paired nuclei form with clamps on the hyphae (Figs. 359D, 360); germination of these cells is unknown. Monokaryotic haustoria form from subglobose cells which develop with clamps (Fig. 359E) from the dikaryotic hyphae.

Fermentation: absent.

Type strain: CBS 8088 (Kraepelin strain Ra 18), dikaryon.

Comments on the genus

The formation of blastoconidia on sterigmata initially linked *S. polymorphum* to *Sterigmatomyces* (Fell et al. 1984a). However there was little nucleotide complementarity (Kurtzman 1990a) between this species and the species accepted in the genus *Sterigmatomyces*. Subsequently, nucleotide sequence analyses (Guého et al. 1989, 1990, Fell et al. 1995), and electrophoretic comparisons of enzymes (Yamada et al. 1986a) indicated a close relationship with the genus *Fellomyces*, which clusters with the tremellaceous fungi. Further investigations on the life cycle and the relationship to other tremellaceous fungi are required.

89. *Tilletiaria Bandoni & Johri*

T. Boekhout

Diagnosis of the genus

Hyphae are septate, narrow, hyaline, and monokaryotic with retraction septa. Septal pores are primitive dolipores without parenthesomes. Ballistoconidia are allantoid and falcate, and formed on sterigmata. Chlamydospores are brown. Colonies are tough and grayish-brown.

Teliospores occur intercalarily or terminally, and are echinulate, brown, and germinate with 1–4-celled basidia. Clamp connections are absent.

Sugars are not fermented. Urease reaction is positive. Xylose is absent from whole-cell hydrolyzates. Major ubiquinone is Q-10.

Type species

Tilletiaria anomala Bandoni & Johri

Species accepted

1. *Tilletiaria anomala* Bandoni & Johri (1972)

Systematic discussion of the species**89.1. *Tilletiaria anomala* Bandoni & Johri (1972)**

Growth on 5% malt extract agar: After 7 days at 25°C, hyphae are narrow, 1.0–3.5 µm wide, usually largely lysed with retraction septa, and with lateral sterigmata. Chlamydospores are subglobose to ellipsoidal, brown, (6.0–20.0) × (5.0–8.0) µm. Colonies are firm to tough, pruinose, dull dark grayish-brown, and with the margin entire or eroded.

Growth on the surface of assimilation media: Islets, a ring and a sediment are formed.

Dalmeu plate culture on morphology agar: After 7 days at 17°C, hyphae are abundantly present. Aerobic growth is pale yellow-brown, ochraceous-brown to dark brown, firm, flat, irregular to pustulate, and the margin entire, eroded or crenulate.

Formation of ballistoconidia: Ballistoconidia are allantoid to falcate, (5.0–15.0) × (1.5–4.0) µm (Fig. 363).

Fig. 363. *T. anomala*, CBS 436.72. Ballistoconidia and teliospores on morphology agar. Bar = 5 µm.

Formation of teliospores: Teliospores are subglobose, brown, echinulate, somewhat thick-walled, (6.0–12.5) × (6.0–12.5) µm, and with spines usually up to ca. 3.0 µm long (Fig. 363). Germination of teliospores occurs when transferred to water agar (1–3 days at 20–25°C), forming 1–4-celled basidia which form ballistospores (Bandoni and Johri 1972). The species is homothallic.

Fermentation: absent.

Comments on the genus

Tilletiaria is characterized by the presence of narrow hyphae without clamp connections, allantoid to falcate ballistoconidia, and brown, echinulate teliospores (Bandoni and Johri 1972, Boekhout 1991a). Prior to teliospore

formation, outgrowths of two adjacent cells are formed near a septum, which after fusion, give rise to the teliospore.

Tilletiaria was tentatively placed in the Tilletiales, because of the presence of teliospores, basidiospores that are ballistospores, and from morphological, biochemical and ultrastructural similarities (Boekhout et al. 1992a).

The dark colonies hampered reading of the Diazonium blue B test, which is expected to be positive.

90. Tremelloid genera with yeast phases

Fibulobasidium Bandoni, *Holtermannia* Saccardo & Traverso, *Sirobasidium* de Lagerheim & Patouillard, *Tremella* Persoon, *Trimorphomyces* Bandoni & Oberwinkler

R.J. Bandoni and T. Boekhout

1. Introduction

The Tremellales and Filobasidiales are the only known taxa with both dolipore septa and yeast states. As noted in the introduction to heterobasidiomycetes, biochemical characteristics suggest a very close relationship of the two groups of fungi and maintaining the two as separate orders is primarily a matter of convenience here. The Tremellales in this sense includes only three families, the Tetragoniomycetaceae, Sirobasidiaceae, and Tremellaceae. The families Filobasidiaceae, Syzygosporaceae and Rhynchogastremaceae are presently placed in the Filobasidiales.

Although budding was first observed and illustrated in Tremellaceous fungi by Brefeld (1888) and by Möller (1895), later students mostly mentioned this trait as one of several methods of basidiospore germination, i.e., yeast states were not discussed. Dimorphism in heterobasidiomycetes, other than in smuts and their relatives, remained essentially unknown until the 1960's, when studies were carried out on species of *Tremella* Persoon (Bandoni 1961, 1963, Kobayasi and Tubaki 1965).

2. Classification

Taxa in two of the three families in the Tremellales, Tremellaceae s. str. (Bandoni 1984) and Sirobasidiaceae, have known yeast states. *Tetragoniomyces uliginosus* (Karsten) Oberwinkler & Bandoni, the only species in the Tetragoniomycetaceae, has deciduous basidia that function as disseminules and germinate directly (Oberwinkler and Bandoni 1981); the species is not considered further here. Basidia in the Sirobasidiaceae and Tremellaceae produce basidiospores, ballistospores and yeast states. All taxa in the order are thought to be mycoparasites, but the evidence for this largely rests upon association with specific fungi in nature, and experimental evidence for parasitism is lacking for most taxa. The Sirobasidiaceae and Tremellaceae are not sharply delimited morphologically, as noted below, and analyses of other types have not yet dealt with sufficient species to be of help at this level.

2.1. Life history

A life-history diagram typical of many Tremellales is shown in Fig. 364; it is based primarily upon studies of *Tremella mesenterica* Retzius:Fries (Bandoni 1963, 1965, Wong et al. 1985). Information from cultural studies of other taxa has been incorporated, including those of *T. globispora* Reid, *T. rhytidhysterii* Bezerra & Kimbrough (Bezerra and Kimbrough 1978), *Fibulobasidium inconspicuum* Bandoni (Bandoni 1979), and

Trimorphomyces papilionaceus Bandoni & Oberwinkler (Oberwinkler & Bandoni 1983).

In culture, isolated basidiospores of heterothallic species give rise to yeast states, with mycelia typically developing only when compatible strains are paired. Pairing of suitable cells yields a rapid response to complementary pheromones; budding ceases, conjugation tubes develop and fuse, and the dikaryotic hyphal state is initiated. Under conditions suitable for fruiting, basidiome development commences soon after dikaryon initiation in *T. globispora* and *Sirobasidium magnum* (i.e., a long assimilative period is not required before basidiocarp production commences (Brough 1974, Flegel 1976). The basidiocarp typically is gelatinous and 2–4-celled basidia are produced in an amphigenous surface hymenium. Each basidial cell produces a fusiform, passively released spore (in Sirobasidiaceae) or a tubular epibasidium tipped by a sterigma and ballistospore (in most Tremellaceae). Basidiospores of both groups can germinate either by ballistospore production or by budding. Not infrequently, closely situated compatible basidiospores conjugate directly on culture media and, presumably, also in nature.

Differences in life histories and development are found in 1) dikaryotic hyphae, 2) basidiocarp features, 3) basidia, 4) basidiospore germination, 5) yeast states and conjugation, and 6) conidial production, as follows.

2.2. Dikaryotic hyphae

With few exceptions, dikaryotic hyphae in the Tremellales have clamp connections and characteristic haustorial branches. The latter, first recognized by Olive (1947) in *Tremella mycophaga* var. *obscura* Olive, and designated by him as haustoria, are known in many species of that genus. They have not been reported in *Sirobasidium* and are unknown in some species of *Tremella*. Each haustorial branch consists of a basal cell and filament; the latter contacts hyphal walls of associated fungi (Olive 1947, Bandoni 1961, Bezerra and Kimbrough 1978, Oberwinkler et al. 1984, Bandoni and Oberwinkler 1983, Metzler et al. 1989), the tip penetrating the wall. Bauer and Oberwinkler (1990a) showed direct, cytoplasm-to-cytoplasm connections between haustorial filaments of *Tetragoniomyces uliginosus* and its host, as well as in *Christiansenia pallida* Hauerslev (Syzygosporaceae) and its host (Bauer and Oberwinkler 1990b). Zugmaier et al. (1994) have found similar cytoplasmic connections between haustorial filaments of *Tremella mesenterica* and several associated basidiomycetes. Similar observations were made with *T. encephala* and *T. mycetophiloides*

Fig. 364. Life cycle typical of the majority of Tremellales. (A) Basidiome on wood. (B) Basidia. (C) Basidiospores which can bud (D) or germinate by repetition (E). Budding initiates the yeast phase (F), which can continue indefinitely. If compatible cells are closely situated, complementary pheromones trigger tube development (G), and conjugation (H) occurs. Cells which fail to mate may revert to budding or produce conidia that bud. Conidia are also formed in many basidiomes (I). These include both dikaryotic conidia, which germinate by dikaryotic hyphal production, and haploid conidia which yield a yeast phase.

(as *T. mycophaga* Martin) with hyphae of *Stereum sanguinolentum* (Albertini & Schweinitz:Fries) Fries and *Aleurodiscus amorphus* (Persoon:Fries) Schröter, respectively. In *T. mycetophiloides* (Fig. 302D), which produces minute basidiomata on the host hymenium, the structures almost certainly function in absorption, as with haustoria in other parasites. Haustorial filaments in *Tremella mesenterica* can be found attached to hyphae of a variety of basidiomycetes, as noted by Zugmaier et al. (1994) and also to dematiaceous hyphae often growing in the basidiocarps. Contact commonly results in what appears to be a necrotrophic response, and the attack of many different types of hyphae by haustoria of this species may suggest a defensive function in addition to parasitism. In *Trimorphomyces papilionaceus* and *Tremella fuciformis* Berkeley, haploid yeast cells can also produce minute haustoria (Fig. 365) in the presence of suitable host hyphae (R.J. Bandoni, unpublished observation).

2.3. Basidiocarp features

Tremella penetrans (Hauerslev) Jülich, *T. mycophaga* Martin var. *obscura* Olive and several similar taxa grow as endoparasites of other basidiomycetes, e.g., dacrymycetaceous fungi and polypores. They do not have discrete basidiocarps, but produce basidia and often conidia in hymenia of their hosts. Basidiocarps in other species range from tuberculate structures under 1 mm in

diameter in some lichen parasites to extensive masses reaching 20 cm in diameter in *Tremella brasiliensis* (Möller) Lloyd, *T. foliaceae* Persoon and others. A large size range also occurs in the Sirobasidiaceae. Basidiocarps in *Holtermannia* Saccardo & Traverso are composed of dense aggregates of erect simple or branched clavarioid structures.

Basidiocarps (Fig. 302) are entirely gelatinous in most species, but a tough fleshy core of host hyphae is present in those of *Tremella aurantia* Schweinitz:Fries, *T. encephala* Persoon (Bandoni 1961), and related taxa, and in some taxa overgrowing ascomycetous stromata, e.g., *T. moriformis* Smith & Sowerby. The structure is monomitic in species described to date; the usually amphigenous hymenial layer consists of basidia and, often, conidiogenous cells. Paraphysoids are present in a few species, e.g., *Tremella coalescens* Olive and in species closely related to *T. mesenterica*.

Two species, *T. fuciformis* and *T. aurantialba* Bandoni and Zang Mu, are cultivated commercially. *T. aurantialba* is grown in dual culture with a species of *Stereum* (Bandoni and Zang Mu 1990); basidiocarps contain zones of host hyphae as in *T. aurantia*. *T. fuciformis* (Fig. 365) also appears to be grown in mixed culture commercially, but the literature on the subject is unclear. Basidiocarps of this species are homogeneous and gelatinous; they are often associated with ascomata of *Hypoxylon* spp.

Fig. 365. *T. fuciformis* Berkeley. (A) Basidiome on dead branch. Bar=10 mm. A-A & RJB 9832, Thailand. Photo courtesy of Dr. T.W. Flegel). (B) Mixed yeast strains of unknown compatibility growing with mycelium of *Hypoxylon stygium* (Lév.) Sacc., one cell (arrow) with haustorial branch. Bar=10 μ m. Cultures: UBC 7122-1(4), Hawaii; 7694-8, China. (C) Haustorial branch arising from short hypha (?haploid) out of focus below cell, the haustorial filament growing along a *Hypoxylon* hypha (UBC 7122-1, 7122-2, RJB, Thailand). *Hypoxylon stygium*, UBC 7668-C, RJB, China, used in both cultures shown in (B) and (C).

in nature. Culture studies suggest parasitism of these ascomycetes (R.J. Bandoni, unpublished observation). Xu Biru (1986) reported dependence upon an unnamed associate for fruiting in artificial culture. Cultivated basidiocarps of both species are dried and are widely sold as food; they are also used in traditional medicine in parts of Asia.

2.4. Basidia

Basidia in *Sirobasidium* occur in linear chains, which mature basipetally; those in *Fibulobasidium* Bandoni are in terminal clusters and are united to one another laterally. Here, basidia form successively, the first from a terminal cell subtended by a clamp connection; the second by direct inflation of that clamp connection, and the third by inflation of the basal clamp of the second, and so on. Basidia in the Tremellaceae are predominantly or all single and terminal, but scattered catenate ones occur in species of *Sirotrema* Bandoni and, less frequently, in *Tremella indecorata* Sommerfelt (Bandoni 1984).

Tremella simplex Jackson & Martin, *T. rhytidhysterii*, *Sirobasidium brefeldianum* Möller, and a few other taxa have 2-celled basidia, and 2-celled basidia sometimes occur in species characterized by 4-celled basidia. Basidial

form, which is highly variable among species and within any single basidiome, ranges from globose to obovoid, pyriform, clavate, capitate, or subcylindric. The “septation pattern” (see Bandoni 1984, for an alternative concept) is regularly “cruciate” in most taxa, but is highly variable in others. Cylindric basidia with transverse septa are characteristic of *Phyllogloea tremelloidea* Lowy (F. Oberwinkler, personal communication) and *Phragmozenidium mycophilum* Oberwinkler & Schneller (Oberwinkler et al. 1990c). Basidia in *Sirobasidium* spp. are often fusiform and with 1 or 3 transverse to diagonal septa, i.e., they can be 2- or 4-celled, each cell budding off a fusiform primary basidiospore. Tremellaceous basidial cells develop tubular extensions (epibasidia), most of which are tipped by sterigmata and bear ballistospores. Passive release of epibasidia or basidiospores occurs either regularly or from time to time in some Tremellas, in *Sirotrema* spp., in *Bulleromyces albus* Boekhout & A. Fonseca (Boekhout et al. 1991a), and in the species of *Xenolachne* Rogers.

2.5. Basidiospore germination

The passively released basidiospores of *Sirobasidium* and *Fibulobasidium* spp., are probably homologues of epibasidia of most Tremellaceae; they are elongate, typically

fusiform, and germinate either by ballistospore formation or by budding. Basidiospores in the Tremellaceae are mostly ballistospores, but they also germinate either by producing another ballistospore (repetitive germination) or by budding. Details of basidiospore budding differ among the species, and there can also be differences among spores of a single basidiome. Budding can occur directly, with the buds falling free at maturity; in *T. mesenterica*, primary buds remain attached to the basidiospore (Fig. 290) and produce buds that are freed (as illustrated, e.g., by Ingold 1982a,b, 1985, Bandoni 1987). These two types may be combined with another, in which a short broad tube is produced and buds or sessile budding cells develop at its apex.

2.6. Yeast states and conjugation

Haploid yeast states in species of *Tremella* (Figs. 290, 365) were noted almost 30 years ago to resemble asporogenous yeasts classified in the genus *Cryptococcus* (Kobayasi and Tubaki 1965, Slodki et al. 1966). More recent studies of coenzyme Q (Yamada and Kondo 1973, Yamada et al. 1983) and carbohydrate composition also show similarities between tremelloid and cryptococcoid yeasts. Comparison of the above two characteristics, as well as septal pore ultrastructure, ballistospores, and haustoria by Boekhout et al. (1992b) suggests a close relationship of *Bullera* Derx, *Bulleromyces* Boekhout & Fonseca, *Kockovaella* Nakase et al., and *Itersonilia* Derx to the Tremellales. The classification of *Bulleromyces* and the *Bullera* anamorphs definitely should be in the Tremellales, but the relationship of *Kockovaella* and *Itersonilia* species are not yet firmly established. Similarly, a definite link between *Tremella* and *Cryptococcus* species has not been established, i.e., no *Cryptococcus* strains have been found to yield a *Tremella*-like teleomorph. Although Baharaeen and Vishniac (1984) suggested that 25S ribosomal RNA homology data did not support a close relationship, studies by Guého et al. (1993), Fell et al. (1992, 1995), and Swann and Taylor (1993) have found otherwise. *Tremella* yeasts examined to date all have the coenzyme Q-10 system, as do closely related species of *Filobasidium* (Yamada et al. 1983) and some species placed in *Cryptococcus* (Yamada and Kondo 1973). The Q-10 system does not appear to be definitive, however, in that it is widespread in hemiascomycetes as well as other heterobasidiomycetes (Yamada et al. 1982, 1983).

An unusual and striking feature is the occurrence of a morphologically distinct dikaryotic yeast phase in *Trimorphomyces papilionaceus* (Oberwinkler and Bandoni 1983). This phase is initiated following conjugation of haploid yeast cells, or it can develop at germination of dikaryotic conidia produced on conidiophores. The dikaryotic yeast phase is usually characterized by colonies of H-shaped, binucleate cells, that are morphologically identical to the conidia. Dikaryotic cells superficially similar to the haploid ones are produced in rare strains. The cells produce pairs of closely situated "twin" buds

synchronously, and conjugation occurs between the two individuals of a pair before their release. A similar development in species of *Syzygospora* Martin involves conjugation of adjacent buds from paired (separate) conidiogenous cells, but no dikaryotic yeast states are known in that group.

In heterothallic species of *Tremella*, *Sirobasidium*, *Holtermannia*, *Fibulobasidium*, and *Trimorphomyces* examined to date, isolated basidiospores germinate by budding (Fig. 290), and this then continues indefinitely under laboratory conditions. Mating is initiated by an allelic pair, the A's controlling production of complementary pheromones; independent alleles, the B's (multiple alleles at one locus) determine dikaryon viability (Bandoni 1963, 1965, Brough 1974, Flegel 1976, Wong et al. 1985, Fox and Wong 1990, Okuda et al. 1981). To be compatible, pairs must be heterozygous for both sets of alleles, the first to initiate the conjugation process, and the second in order to yield a dikaryotic mycelial phase. Pairing strains heterozygous for A's and homozygous for B's (common B) often results in plasmogamy, yielding cells which are usually vesiculose and abortive. The pheromones produced by *Tremella mesenterica* and *T. brasiliensis* are peptides (Reid 1974, Sakagami et al. 1978a,b, 1979, Ishibashi et al. 1983a,b) similar to those in species of *Rhodotorula* Harrison. When compatible cells are mixed, short tubes can often be seen after 4 hours; extensive tube development and short dikaryotic hyphae are visible within 12 hours. Conjugation tubes in *Trimorphomyces papilionaceus* are extremely inconspicuous; in the absence of host hyphae in culture, conjugation can be detected by the presence of the dikaryotic H-shaped yeast cells. Canadian isolates of the species show strong sexual agglutination (R.J. Bandoni, unpublished observation), but this is absent in Japanese strains.

Secondary homothallism, in which binucleate basidiospores give rise directly to dikaryotic hyphae, is known in *Sirobasidium magnum* and *Tremella rhytidhysterii*. Many basidia in young basidiomes of *S. magnum* are two-celled, and the basidiospores from such basidia produce fertile mycelia directly (R.J. Bandoni, unpublished observation). The two-celled basidia of *T. rhytidhysterii* produce basidiospores that give rise to dikaryotic mycelia; the latter sometimes dedikaryotize to yield haploid yeast states (Bezerra and Kimbrough 1978). Homothallism has also been found in stocks of *T. fuciformis* from Hawaii and Panama, although most isolates of the species are heterothallic (Fox and Wong 1990). Many strains in this species also have limited development of haploid hyphae with false clamps and occasional haustorial branches.

2.7. Conidial production

Dikaryotic conidia are produced on growing hyphae of *Tremella mesenterica* in culture, as is the production of scattered pockets of haploid budding cells in this species and others (Brough 1974, Bezerra and Kimbrough 1978).

In basidiocarps, conidia may develop before basidia, or concurrently with them in the hymenium of *T. mesenterica* (Fig. 300). They also occur concurrently with basidia in *T. mycetophiloides* Kobayasi, *T. australiensis* Lloyd, and *Trimorphomyces papilionaceus* (Fig. 304). Hymenial conidia appear to be mainly blastic, but combinations of arthric and blastic development are characteristic of some taxa. Frequent pockets of budding cells within the basidiome tissue, sometimes in the absence of visible basidia and spores, suggests occasional dikaryotization similar to that occurring in culture.

3. Descriptions and keys to representative yeast states

The number of species known in the families Sirobasidiaceae and Tremellaceae exceeds 150, but many species remain to be described in both temperate and tropical

regions. Biochemical analyses and morphological studies indicate that *Tremella*, the largest genus, is heterogeneous. However, very few taxa have been examined carefully by either approach. Among the undescribed taxa are many growing on lichens (Diederich 1986, 1996, and personal communication). In this treatment, yeast states of 17 common temperate and tropical species are described. For convenience, haploid yeast states of the various species are referred to by their teleomorph names. The same species are also mentioned in the keys to similar anamorphic yeast genera (e.g., *Cryptococcus*, *Bullera*, etc.). Detailed descriptions of the teleomorphs are available in taxonomic works dealing with these fungi, e.g., Bandoni 1958, Bandoni and Oberwinkler 1983, Bourdot and Galzin 1928, Kobayasi 1937, 1939, Martin 1952, Pilat 1957, Torkelsen 1968, Raitvir 1967, Lowy 1971, 1980, Wojewoda 1981, and in references cited in these works.

5. Taxa described

5.1. Sirobasidiaceae

1. *Fibulobasidium inconspicuum* Bandoni (1979)
2. *Sirobasidium intermedium* Kundalkar & Patil (1986)
3. *Sirobasidium magnum* Boedijn (1934)

5.2. Tremellaceae

4. *Bulleromyces albus* Boekhout & Fonseca (1991)
5. *Holtermannia corniformis* Kobayasi (1937)
6. *Tremella aurantia* Schweinitz:Fries (1822)
7. *Tremella brasiliensis* (Möller) Lloyd (1922)
8. *Tremella cinnabarina* (Montagne) Patouillard (1900)
9. *Tremella coalescens* Olive (1951)
10. *Tremella encephala* Persoon (1822)
11. *Tremella foliacea* (Persoon:S.F. Gray) Persoon (1822)
12. *Tremella fuciformis* Berkeley (1856)
13. *Tremella globispora* Reid (1970)
14. *Tremella indecorata* Sommerfelt (1826)
15. *Tremella mesenterica* Retzius:Fries (1822)
16. *Tremella moriformis* Smith:Berkeley (1856)
17. *Trimorphomyces papilionaceus* Bandoni & Oberwinkler (1983)

6. Systematic discussion of the species

90.1. *Fibulobasidium inconspicuum* Bandoni (1979)

Growth on malt agar: After 3 days at 25°C, the cells are subglobose to globose, (2.5–5.5) × (2–5.5) µm, and single or in pairs. After one month at 20°C, the streak culture is gray-brownish-yellow, pasty, partly wrinkled and partly smooth with a lobate edge.

Dalmu plate culture on potato agar: Pseudohyphae and hyphae are absent.

Formation of ballistospores: Ballistospores are fusiform to ellipsoidal, and measure (2–8) × (1.5–3.5) µm.

Fermentation: absent.

Assimilation (25°C):

50% Glucose	–	Growth at 25°C	+
Starch formation	+	Growth at 30°C	v
Urease	+	Growth at 37°C	–
Nitrite	+		

Co-Q: Not determined.

Mol% G+C: Not determined.

Origin of the strains studied: CBS 6963, CBS 7672, CBS 7679, CBS 7680, CBS 8237, CBS 8238, all from oak (*Quercus virginiana*), USA.

90.2. *Sirobasidium intermedium* Kundalkar & Patil (1986)

Growth on 5% malt extract agar: After 5 days at 25°C, the cells are ellipsoidal to subglobose, (4.0–7.5) × (2.3–7.0) µm, and single. Budding is polar or occasionally multilateral, sessile or on short denticles, and with sympodial proliferation. Colonies are yellowish to yellowish-cream, mucoid, smooth, shiny, pale and with the margin entire.

Growth on the surface of assimilation media (glucose): Some flocks, a fragile ring and a sediment are formed.

Dalmu plate culture on morphology agar: After 5 days at 25°C, primitive pseudohyphae may be present.

Fermentation: absent.

Assimilation (25°C):

Glucose	+	<i>N</i> -Acetyl-D-glucosamine	n
Galactose	v	Methanol	–
L-Sorbose	l	Ethanol	+
Sucrose	+	Glycerol	l

Starch formation	+	Growth at 30°C	s
Urease	+	Growth at 37°C	–
Nitrite	–		

Co-Q: Not determined.

Mol% G+C: Not determined.

Origin of the strain studied: CBS 7805, from *Eutypella leprosa* on elm (*Ulmus* sp.), Devon, UK, also reported from India (Kundalkar and Patil 1986).

90.3. *Sirobasidium magnum* Boedijn (1934)

Growth on malt agar: After 3 days at 25°C, the cells are globose to subglobose, (2–4.5)×(2.5–6) µm, and single or in pairs. After one month at 20°C, the colonies are yellowish or yellowish-white, smooth or with a finely reticulate border, shiny or dull in the middle of the streak, and with a smooth or undulating edge.

Dalmau plate culture on potato agar: Pseudohyphae and hyphae are absent.

Formation of ballistospores: Ballistospores on corn meal agar are spherical, ovoidal or apiculate, and measure (4–9)×(3.5–5) µm.

Fermentation: absent.

Assimilation (25°C):

Glucose	+	<i>N</i> -Acetyl-D-glucosamine	n

Starch formation	+	Growth at 30°C	v
Urease	+	Growth at 37°C	–
Nitrite	–		

Co-Q: Not determined.

Mol% G + C: Not determined.

Origin of the strains studied: CBS 6803, CBS 6804, CBS 6805, CBS 6964, on decaying wood and oak (*Quercus* sp.), USA, Japan and Philippines.

90.4. *Bulleromyces albus* Boekhout & A. Fonseca (1991)

See *Bulleromyces albus*: p. 641

90.5. *Holtermannia corniformis* Kobayasi (1937)

Growth on malt agar: After 3 days at 25°C, the cells are short ellipsoidal to elongate, (5–15)×(2.5–5) µm, and short hyphal elements may occur. Budding is polar, and sometimes on a broad base. After one month at 20°C, the colonies are yellowish-white, smooth, shiny and mucoid.

Dalmau plate culture on potato agar: Pseudohyphae and extensive hyphae are absent, but occasionally a few hyphal cells, sometimes with septa, are present.

Fermentation: absent.

Assimilation (25°C):

Glucose	+	<i>N</i> -Acetyl-D-glucosamine	n
Galactose	s	Methanol	–

Nitrite	–		

Co-Q: Not determined.

Mol% G + C: Not determined.

Origin of the strains studied: CBS 6979, CBS 7088, CBS 7675, CBS 7676, from dead wood, Japan.

90.6. *Tremella aurantia* Schweinitz:Fries (1822)

Growth on malt agar: After 3 days at 25°C, the cells are ellipsoidal, (3–5.5)×(2.5–4.5)µm, and single or in pairs. Budding occurs on a rather broad base. After one month at 20°C, the colonies are yellowish-brown, smooth, shiny, and slimy.

Slide culture on potato agar: Pseudohyphae and hyphae are absent.

Fermentation: absent.

Assimilation (25°C):

Glucose	+	<i>N</i> -Acetyl-D-glucosamine	n
Galactose	+	Methanol	–
L-Sorbose	v	Ethanol	+
Sucrose	+	Glycerol	s

2-Keto-D-gluconate	+	Nitrite	–
50% Glucose	w/–	Diazonium blue B	+
Starch formation	+	Growth at 25°C	+
Urease	+	Growth at 30°C	–

Co-Q: Not determined.

Mol% G+C: Not determined.

Origin of the strains studied: CBS 6965, CBS 8203, CBS 8213, on angiosperm wood, widely distributed, Canada.

Comments: The yeast stage of *Tremella aurantia* is very similar to that of *T. encephala* and *T. indecorata*. With the set of identification tests currently used, these species can hardly be differentiated. However, *T. aurantia* does not assimilate melibiose and lacks growth at 30°C, whereas the other species show a variable or a slow response.

90.7. *Tremella brasiliensis* (Möller) Lloyd (1922)

Growth on malt agar: After 3 days at 25°C, the cells are ellipsoidal, (2.5–5.5)×(1.5–4.0)µm, and single or in pairs. After one month at 20°C, the colonies are whitish-brown, smooth, shiny, somewhat slimy, and with a smooth edge.

Slide culture on potato agar: Pseudohyphae and hyphae are absent, but cells may adhere in short chains.

Fermentation: absent.

Assimilation (25°C):

Starch formation	+	Growth at 25°C	+
Urease	+	Growth at 30°C	–

Co-Q: Not determined.

Mol% G+C: Not determined.

Origin of the strains studied: CBS 6966, CBS 8209, CBS 8212, CBS 8231, from Costa Rica.

90.8. *Tremella cinnabarina* (Montagne) Patouillard (1900)

Growth on 5% malt extract agar: After 5 days at 25°C, the cells are subglobose to ellipsoidal, (5.0–8.0)×(3.0–8.0)µm, and single. Budding is polar or occasionally multipolar, usually on a short denticle, and with sympodial proliferation. Colonies are grayish-cream, shiny, smooth, somewhat mucoid and with the margin entire.

Growth on the surface of assimilation media (glucose): A fragile ring and a sediment are formed.

Dalmau plate culture on morphology agar: Pseudo-hyphae and hyphae are absent.

Fermentation: absent.

Assimilation (25°C):

Co-Q: Not determined.

Mol% G + C: Not determined.

Origin of the strains studied: CBS 6968, CBS 8207, CBS 8217, CBS 8218, CBS 8220, from conifer wood (rarely on angiosperms, cosmopolitan in temperate conifer forests), Canada.

Comments: The yeast stage of this species is difficult to differentiate from the yeast stages of *T. aurantia* and *T. indecorata* using the present set of characteristics (see also under *T. aurantia* and *T. indecorata*).

90.11. *Tremella foliacea* (Persoon:S.F. Gray) Persoon (1822)

Growth on malt agar: After 3 days at 25°C, the cells are globose, subglobose to short ellipsoidal, (3–8.5)×(2–8) µm, and single or in pairs. After one month at 20°C, the colonies are whitish-brown, smooth, shiny, somewhat slimy, and with an entire margin.

Slide culture on potato agar: Pseudohyphae and hyphae are absent.

Fermentation: absent.

Origin of the strains studied: CBS 6970, CBS 6971, CBS 8225, CBS 8226, from, e.g., the fruiting bodies of commercially grown strains, Taiwan and Japan; pantropical and extending onto warm temperate areas.

90.13. *Tremella globispora*¹ Reid (1970)

Growth on malt agar: After 3 days at 25°C, budding yeast cells and true hyphae are present. The yeast cells are globose to ellipsoidal, (4–8)×(3–5.5) µm, and single or in pairs. The hyphae have a diameter of ca. 2 µm. After one month at 20°C, the colonies are yellowish-white to brown, smooth, shiny, and very slimy.

Slide culture on potato agar: Pseudohyphae and true hyphae are absent.

Fermentation: absent.

Origin of the strains studied: CBS 6976, CBS 8232, from willow (*Salix* sp.), Canada.

Comments: The yeast stage of this species is difficult to differentiate from the yeast phases of *T. aurantia* and *T. encephala*. However, it may be differentiated from the former by variable growth responses with melibiose and at 30°C, and from the latter by lack of growth at 37°C.

90.15. *Tremella mesenterica* Retzius:Fries (1822)

Growth on malt agar: After 3 days at 25°C, the cells are globose to subglobose or short ellipsoidal, sometimes cylindrical, (2.5–6) × (2–5) μm, occasionally up to 16 μm long, single, and in pairs or in short chains. After one month at 20°C, the colonies are yellowish-white to brown, smooth, shiny, and somewhat slimy.

Slide culture on potato agar: Pseudohyphae and true hyphae are absent.

Fermentation: absent.

Origin of the strains studied: CBS 6973, CBS 6974, CBS 6975, CBS 8211, CBS 8214, from dead wood of angiosperms, e.g., alder (*Alnus* sp.), Canada, Costa Rica.

**90.16. *Tremella moriformis* Smith:Berkeley
(Berkeley 1860)**

Growth on 5% malt extract agar: After 5 days at 25°C, the cells are ellipsoidal, (4.5–9.0)×(3.0–6.0) µm, and single; larger cells, (9.0–16.0)×(4.0–6.5) µm, occur as well, and may form short branched or unbranched chains. Budding is polar, on short denticles and sometimes with sympodial proliferation. Colonies are whitish, shiny, smooth, mucoid and with the margin entire.

Growth on assimilation media (glucose): A thin film and ring, and a sediment are formed.

Dalmau plate culture on morphology agar: After 5 days at 25°C, filaments are present, which may form primitive pseudohyphae.

Fermentation: absent.

Assimilation (25°C):

Origin of the strain studied: CBS 7810, on a dead branch of an alder (*Alnus rubra*), Canada.

90.17. *Trimorphomyces papilionaceus* Bandoni & Oberwinkler (1983)

Growth on 5% malt extract agar: After 5 days at 25°C, the cells are subglobose, ellipsoidal, somewhat triangular, oblong or subcylindric, (4.5–7)×(3–6) µm, and single. Budding is polar, but sometimes multipolar, usually on a short denticle, and the cells may adhere in short chains. Cells up to 10.0 µm long occur, which bud on a broad base, leaving distinct scars. Colonies are pale pinkish-yellow to pale pinkish-brown, smooth, shiny, butyrous, and with the margin entire. Colonies of the dikaryotic yeasts are superficially similar, but the cells are H-shaped to irregularly butterfly-shaped; budding is usually polar, twin buds developing synchronously on closely situated points; conjugation occurs between these paired cells early in their development, and they are released as H-shaped cells.

Growth on the surface of assimilation media (glucose): Absent, but a sediment is formed.

Dalmau plate culture on morphology agar: Pseudohyphae and hyphae are absent.

Fermentation: absent.

Origin of the strains studied: CBS 443.92, CBS 445.92, CBS 200.94, on the stem of *Arundinaria*-like cane, on culms of *Sasa* sp. and on the stem of bamboo, Japan and Canada.

91. *Xanthophyllomyces* Golubev

W.I. Golubev

Diagnosis of the genus

Cells are encapsulated and reproduce by enteroblastic budding. True mycelium is absent; chlamydospores may be present. Slender cylindrical holobasidia arise mainly after conjugation between a cell and its bud. Basidiospores are produced terminally on minute pegs. They are not forcibly discharged and germinate by budding. Carotenoid pigments are synthesized, which give cultures an orange to salmon-red color. Xylose and rhamnose are present in extracellular polysaccharides. The urease and diazonium blue B tests are positive. Glucuronate assimilation is variable.

¹Fermentation is present. *myo*-Inositol and nitrate are not assimilated. Starch-like compounds are produced. Coenzyme Q-10 is formed.

Type species

Xanthophyllomyces dendrorhous Golubev

Species accepted

1. *Xanthophyllomyces dendrorhous* Golubev (1995)

Systematic discussion of the species

91.1. *Xanthophyllomyces dendrorhous* Golubev (1995)

Anamorph: *Phaffia rhodozyma* Miller, Yoneyama & Soneda²

Synonyms:

?*Rhodomyces dendrorhous* Ludwig (1891)

Rhodomyces montanae Phaff, Miller, Yoneyama & Soneda (1972)
nom. nud.

Phaffia rhodozyma Miller, Yoneyama & Soneda (1976b)

Cryptococcus rhodozyma (Miller, Yoneyama & Soneda) Weijman,
Rodrigues de Miranda & van der Walt (1988)

Growth in glucose–yeast extract–peptone water:

After 3 days at 18°C, the cells are spheroidal to ovoidal (width/length ratios are 1.0 to 2.5, av. 1.4), 3.5–10.0×5.0–13.5 µm, (av. 6.0×8.5 µm) with small capsules, and single, in pairs, or occasionally in short chains. A very thin creeping pellicle may be present. After 1 month, there is a sediment, a ring, and sometimes islets.

Growth on Difco yeast morphology agar: After 1 month at 18°C, the streak culture is orange to salmon-red, nearly smooth, glossy to semi-dull, soft; the margin is entire or undulating. Spheroidal chlamydospores with refractile granules may be formed.

Slide cultures on corn meal agar: After 10 days at 18°C, a rudimentary pseudomycelium may occur. No true mycelium is formed. Ballistospores are not observed.

Life cycle: Formation of basidiospores is observed on agar media containing polyols (ribitol, D-glucitol, L-arabitol or D-xylitol), pentoses (D-ribose, D-xylose or D-arabinose) or D-lyxose, except for D-mannitol and L-arabinose, after 2–3 weeks at 18°C. Following conjugation between a cell and its bud, a slender cylindrical holobasidium forms which is 2 to 3.5 µm in diameter,

Fig. 366. *X. dendrorhous*. After 2 weeks at 20°C on Difco yeast nitrogen base agar with 0.5% glucitol. (A) Basidium with basidiospores formed following conjugation between a cell and its bud. (B) Basidium with terminal pegs that are attachment sites for basidiospores. (C) Attached basidiospores germinating by budding. Bars = 10 µm.

and 30–165 µm (usually, 70–80 µm) in length (Fig. 366A). Rarely does conjugation occur between independent cells nor does a basidium form without apparent conjugation. Usually 3–4 (up to 6) thin-walled oval or ellipsoidal spores, 3.4–6.0×5.0–12.0 µm (av. 4×8 µm), are produced

¹ The information in this paragraph was added by the Editors to allow comparison with other genera.

² Golubev (1995) proposed, on the basis of descriptions by Ludwig (1891, 1896), that *Rhodomyces dendrorhous* represents the anamorph of *X. dendrorhous*. With the exception of drawings in the original publications, type material of *R. dendrorhous* is not available for comparison. Because the name *Phaffia rhodozyma* is of current economic importance, a proposal is being made to conserve this name against *R. dendrorhous* as the anamorphic name of *X. dendrorhous*. In view of this development, the editors have listed *P. rhodozyma* as the anamorph of *X. dendrorhous*.

terminally on the apex of the basidium giving it a flower-like appearance in apical view. Basidiospores are not forcibly discharged. They are formed on minute pegs (Fig. 366B) but appear sessile and germinate by budding (Fig. 366C).

Co-Q: 10 (Sugiyama et al. 1985).

Mol% G + C: 48.3 (BD: Miller et al. 1976b).

Extracellular polysaccharide hydrolyzates: Mannose, xylose, glucose, galactose and rhamnose.

Synthesis of carotenoid pigments: Positive, approximately 85% is astaxanthin (Andrewes et al. 1976).

Origin of the strains studied: Slime fluxes of deciduous trees: alder (*Alnus japonica*) (1), birch (*Betula*

maximowicziana) (1), *B. tauschii* (1), dogwood (*Cornus brachypoda*) (2), beech (*Fagus crenata*) (1), all from Japan; *B. verrucosa* from Russia (10); *B. papyifera* (1) from Alaska; *Betula* sp. (1) from Finland.

Type strain: VKM Y-2786 (CBS 7918, JCM 9681), isolated from *Betula verrucosa* flux, Russia.

Comments on the genus

Xanthophyllomyces dendrorhous is an inhabitant of spring sapwood flows of deciduous trees and due to the abundant development of the yeast, the flowing sap assumes a salmon-red color (Golubev et al. 1977b). Ludwig (1891, 1896) reported a similar phenomenon caused by a yeast that he described as *Rhodomycetes dendrorhous*, and which Golubev (1995) considered to be the anamorph of *X. dendrorhous*. Placement of *X. dendrorhous* among the basidiomycetous yeasts has been determined from comparisons using the strains designated as *Phaffia rhodozyma*, hence, the ensuing discussion will use this latter name. From the primary and secondary structure of 5S rRNA (Gottschalk and Blanz 1985), presence of xylose in the capsular polysaccharide (Sugiyama et al. 1985, Weijman and Rodrigues de Miranda 1988), sensitivity to mycocins produced by *Cystofilobasidium bisporeidii* and *Cryptococcus laurentii* (Golubev and Kuznetsova 1989, Golubev 1990b), ability to synthesize starch-like compounds (pH independent) and assimilation of D-glucuronate, a tremellaceous (filobasidiaceous) affinity is suggested for *P. rhodozyma*. Based on these observations, the name *Phaffia* was regarded by Weijman et al. (1988) as a synonym of *Cryptococcus*. However, comparisons of partial 18S and 26S rRNA sequences showed that *Phaffia* does not cluster with *Cryptococcus*, but that it is close to *Cystofilobasidium* (Guého et al. 1989, Nakase et al. 1993, Yamada and Kawasaki 1989b, Yamada et al. 1990a) and *Mrakia* (Fell et al. 1995).

Golubev (1995) established that polyols and pentoses induce conjugation between a cell and its bud (pedogamy) in *X. dendrorhous*, and the subsequent formation, without production of mycelium, of a slender holobasidium that forms oval basidiospores at the apex. Cultivation on polyol-containing media appears to simulate the natural habitat when spring sapwood flow ceases and the flux appears dry. In response to water stress, eukaryotic microorganisms, which are inhabitants of the spring sap flows, accumulate high concentrations of polyhydric alcohols (Brown 1978), and this change in physiology appears to trigger sexual reproduction in *X. dendrorhous*.

The strains of this species that were studied are rather homogenous in their cultural, morphological, and physiological properties, and their isoenzyme and rDNA profiles (Varga et al. 1995). There are only minor differences in color intensity, cell sizes, starch fermentation and in the assimilation of those carbon compounds that are weakly utilized. However, significant differences in RAPD patterns and electrophoretic karyotypes were found among strains (Nagy et al. 1994, Adrio et al. 1995).

92. *Bensingtonia* Ingold emend. Nakase & Boekhout

T. Boekhout and T. Nakase

Diagnosis of the genus

Cells are ellipsoidal, ovoidal or elongate. Budding is mostly polar, with buds sessile or on short denticles, enteroblastic, and with percurrent or sympodial proliferation. Ballistoconidia are bilaterally symmetrical, straight or curved, apiculate, ellipsoidal, ovoidal, amygdaliform, falcate, allantoid or reniform. Colonies are whitish, cream, pale pink, brownish-yellow (ochre), brownish or grayish-red. True mycelia and/or pseudomycelia may be present. Septal pores are simple. Clamp connections are absent.

Fermentation is absent. D-Glucuronate and nitrate may be assimilated; *myo*-inositol is not assimilated. Diazonium blue B and urease reactions are positive. Xylose is absent from whole-cell hydrolyzates. The major ubiquinone is Q-9.

Type species

Bensingtonia ciliata Ingold

Species accepted

1. *Bensingtonia ciliata* Ingold (1986)

Systematic discussion of the species

92.1. *Bensingtonia ciliata* Ingold (1986)

Growth on 5% malt extract agar: After 5 days at 17°C, the cells are ovoidal to ellipsoidal, (8.5–10.0) × (5.0–7.0) μm , and single. Budding is polar, with the buds sessile or on short denticles and with sympodial or percurrent proliferation (Fig. 367). Cells sometimes germinate with unbranched or irregularly branched hyphae, 2.0–3.5 μm wide, in which septa and retraction septa occur. Colonies are butyrous, smooth, glabrous or somewhat pruinose, shiny or dull, whitish to pale pinkish-cream, with the margin entire.

Growth on the surface of assimilation media (glucose): Absent, but a sediment is formed.

Dalmou plate culture on morphology agar: After 7 days at 17°C, no mycelium or pseudomycelium is formed. Aerobic growth is whitish-cream, shiny, butyrous, smooth, with the center slightly raised, and the margin entire.

Formation of ballistoconidia: Ballistoconidia are formed terminally at hyphae or hyphal branchlets on malt extract agar or on V8 juice agar. They are ovoidal or ellipsoidal to amygdaliform, (6.0–10.0) × (2.5–4.2) μm (Fig. 367).

Fermentation: absent.

Assimilation (17°C):

Co-Q: 9, CBS 7514 (Boekhout 1987).

Mol% G+C: 45.0, CBS 7514 (T_m : Boekhout 1991a).

Origin of the strains studied: CBS 7514 (IMI 291091), *Auricularia auricula-judae* var. *lacteae* Quél., C.T. Ingold, Great Britain, and a morphological mutant derived from this strain (Ingold 1988).

Type strain: IMI 291091.

Fig. 367. *B. ciliata*, CBS 7514. Yeast cells and ballistoconidia on malt extract agar. Bar = 5 μm .

Comments: According to Ingold (1986) the ballistoconidia of this strain measure (12.0–15.0) × (5.0–6.0) μm on 0.2% malt extract agar. Based on our measurements ((6.0–10.0) × (2.5–4.2) μm) on 5% malt extract agar and V8 juice agar, one has to consider a large variability in the size of the ballistoconidia, depending on the media used. Contrary to the report of Nakase and Boekhout (1988), we found *B. ciliata* nitrate positive.

92.2. *Bensingtonia ingoldii* Nakase & M. Itoh (Nakase et al. 1989a)

Growth on 5% malt extract agar: After 5 days at 17°C, the cells are ovoidal, ellipsoidal, fusoidal to subglobose, (6.0–10.0) × (3.5–6.0) μm , single or in short chains. Budding is polar, with the buds sessile or on short denticles and with sympodial proliferation (Fig. 368). Colonies are butyrous, smooth, dull, grayish-cream, with the margin entire.

Growth on the surface of assimilation media (glucose): Absent, but a sediment is formed.

Dalmou plate on morphology agar: After 7 days at 17°C, no mycelium or pseudomycelium is formed. Aerobic growth is yellowish-cream, dull to somewhat shiny, butyrous, smooth with the center somewhat raised, and the margin entire.

Fig. 368. *B. ingoldii*, CBS 7424. Yeast cells and ballistoconidia on malt extract agar. Bar = 5 μ m.

Formation of ballistoconidia: Ballistoconidia are formed on sterigmata of up to ca. 10 μ m long on malt extract, V8 juice, corn meal, and yeast–malt extract agars. They are reniform, and 6.0–9.0 \times 2.0–4.2 μ m (Fig. 368). Ballistoconidia sometimes form many sterigmata, giving the cells a star-like appearance.

Fermentation: absent.

Assimilation (17°C):

Glucose	+	<i>N</i> -Acetyl-D-glucosamine	n
Galactose	–	Methanol	–
L-Sorbose	–	Ethanol	+
Sucrose	+	Glycerol	+

Co-Q: 9, JCM 7445 (Nakase et al. 1989a).

Mol% G+C: 55.7, JCM 7445 (HPLC: Nakase et al. 1989a).

Origin of the strain studied: CBS 7424 (JCM 7445), leaf of *Knightsia excelsa*, J. Sugiyama, New Zealand.

Type strain: JCM 7445.

Comments: *Bensingtonia ingoldii* is physiologically similar to *B. intermedia*. *B. ingoldii* differs from the latter species by the presence of sympodially branched denticles or sterigmata, a somewhat lower mol% G+C content (Nakase et al. 1989a), and assimilation of L-arabinose, lactose, melibiose, meso-erythritol, and nitrate.

92.3. *Bensingtonia intermedia* (Nakase & M. Suzuki) Nakase & Boekhout (1988)

Synonyms:

Bullera intermedia Nakase & M. Suzuki (1986b)

Sporobolomyces intermedius (Nakase & M. Suzuki) Nakase & M. Suzuki (1987c)

Sporobolomyces weijmanii Nakase & M. Suzuki (1987c)

Growth on 5% malt extract agar: After 5 days at 17°C, the cells are ovoidal, fusoidal or cylindrical, straight or slightly curved, (9–30) \times (2.5–7.0) μ m, and frequently in branched short chains. Budding is polar, with the buds showing sessile and sympodial proliferation. Colonies are butyrous, smooth, dull, cream, with the margin entire.

Growth on the surface of assimilation media (glucose): A ring, islets, and a sediment are formed.

Dalmat plate culture on morphology agar: After 7 days at 17°C, a pseudomycelium is formed (Fig. 369); cells may be septate. Aerobic growth is creamish-white, shiny, butyrous, flat, smooth or lightly reticulate, with the margin entire.

Formation of ballistoconidia: Ballistoconidia are formed on morphology, malt extract, corn meal, and potato dextrose agars. They are amygdaliform, ellipsoidal to reniform, and curved, (6.0–11.0) \times (2.0–5.0) μ m (Fig. 369).

Fermentation: absent.

Assimilation (17°C):

Glucose	+	<i>N</i> -Acetyl-D-glucosamine	n
Galactose	–	Methanol	–
L-Sorbose	+	Ethanol	+
Sucrose	v	Glycerol	+

Fig. 369. *B. intermedia*, CBS 7281. Pseudomycelium and ballistoconidia on morphology agar. Bar = 5 μ m.

Additional assimilation tests and other growth characteristics:

2-Keto-D-gluconate	+	Nitrite	-
50% Glucose	-	Growth at 25°C	+
Starch formation	-	Growth at 30°C	-
Urease	+		

Co-Q: 9, JCM 5291, JCM 5651 (Nakase and Suzuki 1986b, 1987c)

Mol% G+C: 57.8–60.0, JCM 5291, JCM 5651 (T_m : Nakase and Suzuki 1986b, 1987c).

Origin of the strains studied: CBS 7226 (JCM 5291), dead leaf of rice (*Oryza sativa*), T. Nakase, Japan; CBS 7281 and 7241 (both JCM 5651), ex dead leaf *Miscanthus sinensis*, T. Nakase, Japan.

Type strain: JCM 5291.

Comments: Yamada and Nakagawa (1988) regarded *B. intermedia* and *Sporobolomyces weijmanii* conspecific based on the electrophoretic comparison of seven enzymes. However, several nutritional differences exist between the type strains of *B. intermedia* and *S. weijmanii*, e.g., assimilation of D-xylose, sucrose, maltose, melezitose and ribitol. The cell wall is layered and electron dense (Boekhout et al. 1992b).

92.4. *Bensingtonia miscanthi* (Nakase & M. Suzuki) Nakase & Boekhout (1988)

Synonym:

Sporobolomyces miscanthi Nakase & M. Suzuki (1987c)

Growth on 5% malt extract agar: After 5 days at 17°C, the cells are ellipsoidal, fusoidal to cylindrical, straight or somewhat curved, (7.0–14.0) × (2.0–4.0) μm, and single. Budding is polar or lateral, with the buds sessile or on short denticles and with sympodial proliferation. Colonies are butyrous, smooth, shiny, pale grayish-cream, with the margin entire or somewhat eroded.

Growth on the surface of assimilation media (glucose): A ring and a sediment are formed.

Dalmau plate culture on morphology agar: After 7 days at 17°C, no pseudomycelium or mycelium is formed. Aerobic growth is pale pinkish-cream, dull, butyrous, with a slightly irregular surface, flat or slightly raised, and with the margin entire or somewhat crenulate.

Formation of ballistoconidia: Ballistoconidia are abundantly formed on potato dextrose, corn meal, malt extract, and morphology agars. They are reniform, allantoicidal, or ellipsoidal. On corn meal agar they measure (9.0–17.0) × (4.3–5.5) μm, and on the lid of the petri dish (5.0–8.5) × (4.0–5.2) μm (Fig. 370).

Fermentation: absent.

Fig. 370. *B. miscanthi*, CBS 7282. Ballistoconidia on corn meal agar. Bar = 5 μm.

Assimilation (17°C):

Glucose	+	<i>N</i> -Acetyl-D-glucosamine	n
Galactose	-	Methanol	-
L-Sorbose	1	Ethanol	-
Sucrose	+	Glycerol	+
Maltose	-	Erythritol	-
Cellobiose	+	Ribitol	+
Trehalose	+	Galactitol	-
Lactose	1	D-Mannitol	+
Melibiose	-	D-Glucitol	+
Raffinose	1	α-Methyl-D-glucoside	-
Melezitose	-	Salicin	-
Inulin	-	D-Gluconate	-
Soluble starch	-	DL-Lactate	w
D-Xylose	1	Succinate	+
L-Arabinose	-	Citrate	+
D-Arabinose	-	Inositol	-
D-Ribose	-	Hexadecane	n
L-Rhamnose	-	Nitrate	+
D-Glucosamine	-	Vitamin-free	-

Additional assimilation tests and other growth characteristics:

2-Keto-D-gluconate	-	Nitrite	+
50% Glucose	-	Growth at 25°C	+
Starch formation	-	Growth at 30°C	-
Urease	+		

Co-Q: 9, JCM 5733, NB-151 (Nakase and Suzuki 1987c).

Mol% G+C: 47.2–47.5, two strains, JCM 5733, NB-151 (T_m : Nakase and Suzuki 1987c).

Origin of the strain studied: CBS 7282 (JCM 5733), dead leaves of *Miscanthus sinensis*, T. Nakase, Japan.

Type strain: JCM 5733.

Comments: Cell shape varies considerably depending on the substrate of growth. On potato dextrose agar and on morphology agar, *Sterigmatomyces*-like sterigmata are formed. Ballistoconidia frequently germinate with short acropetal chains of budding cells.

92.5. *Bensingtonia naganoensis* (Nakase & M. Suzuki) Nakase & Boekhout (1988)

Synonym:

Sporobolomyces naganoensis Nakase & M. Suzuki (1987a)

Growth on 5% malt extract agar: After 5 days at 17°C, the cells are fusoidal to ellipsoidal, (8.0–10.0) × (2.3–4.3) μm, and single. Budding is polar, rarely lateral, with the buds sessile or on short denticles and with

percurrent or sympodial proliferation. Colonies are rather dry, smooth, dull, pale grayish-cream, with the margin entire.

Growth on the surface of assimilation media (glucose): A ring and a sediment are formed.

Dalmu plate on morphology agar: No pseudomycelium or mycelium is formed. Aerobic growth is cream, dull, butyrous, nearly flat, with the surface weakly transversely ridged, and the margin entire.

Formation of ballistoconidia: Ballistoconidia are abundantly formed on morphology, corn meal and malt extract agars. They are amygdaliform, ellipsoidal to allantoid, $(6.0\text{--}10.0)\times(3.0\text{--}4.2)\mu\text{m}$ (Fig. 371).

Fig. 371. *B. naganoensis*, CBS 7286. Ballistoconidia on malt extract agar. Bar = 5 μm .

Fermentation: absent.

Assimilation (17°C):

Glucose	+	<i>N</i> -Acetyl-D-glucosamine	n
Galactose	-	Methanol	-
L-Sorbose	-	Ethanol	-
Sucrose	+	Glycerol	+
Maltose	+	Erythritol	-
Cellobiose	+	Ribitol	+
Trehalose	-	Galactitol	-

Additional assimilation tests and other growth characteristics:

2-Keto-D-gluconate	-	Nitrite	+
50% Glucose	-	Growth at 25°C	+
Starch formation	-	Growth at 30°C	-
Urease	+		

Co-Q: 9, JCM 5978 (Nakase and Suzuki 1987a).

Mol% G + C: 55.8, JCM 5978 (T_m : Nakase and Suzuki 1987a).

Origin of the strain studied: CBS 7286 (JCM 5978), dead leaf of *Sasa* sp., T. Nakase, Japan.

Type strain: JCM 5978.

Comments: *Bensingtonia naganoensis* can be differentiated from both *B. miscanthi* and *B. subrosea*, by its inability to assimilate trehalose, lactose and its ability to grow on melibiose and melezitose. On malt extract agar, long lysed sterigmata are sometimes present.

92.6. *Bensingtonia phyllada* (van der Walt & Y. Yamada) van der Walt, Nakagawa & Y. Yamada ex Boekhout (1991a)

Synonyms:

Sporobolomyces phylladus (as *S. phyllades*) van der Walt & Y. Yamada (van der Walt et al. 1989a)

Bensingtonia phylladus (van der Walt & Y. Yamada) Y. Yamada, Nakagawa & van der Walt (1988c) nom. inval.

Growth on 5% malt extract agar: After 5 days at 17°C, the cells are ellipsoidal, broadly ellipsoidal, ovoidal or subglobose, $(8.0\text{--}13.0)\times(5.0\text{--}8.0)\mu\text{m}$, and single. Budding is polar or lateral, with the buds sessile or on short denticles. Cells may develop 1.5–3.5 μm wide branched hyphae, in which retraction septa occur, and with the cytoplasm retracted in certain cells. Colonies are butyrous, smooth, dull or somewhat shiny, whitish-cream, and with the margin somewhat eroded because of submerged marginal hyphal growth.

Growth on the surface of assimilation media (glucose): A ring and a sediment are formed.

Dalmu plate culture on morphology agar: After 7 days at 17°C, short hyphae with retraction septa may develop. Aerobic growth is whitish to pinkish-cream, somewhat shiny or dull, butyrous, nearly flat, smooth or somewhat transversely reticulate, with the margin entire or somewhat crenulate.

Formation of ballistoconidia: Ballistoconidia are formed on morphology, malt extract and corn meal agars. They are ellipsoidal, amygdaliform, allantoid to falcate, $(9.0\text{--}14.0)\times(4.0\text{--}7.0)\mu\text{m}$ (on the surface of malt extract agar ballistoconidia measure $(14.0\text{--}21.0)\times(5.0\text{--}7.0)\mu\text{m}$) (Fig. 372).

Fermentation: absent.

Fig. 372. *B. phyllada*, CBS 7169. Ballistoconidia on malt extract agar. Bar = 5 μm .

Assimilation (17°C):

Glucose	+	<i>N</i> -Acetyl-D-glucosamine	n
Galactose	-	Methanol	-

Co-Q: 9, CBS 7169 (van der Walt et al. 1989a).

Mol% G+C: 50.4, CBS 7169 (T_m : van der Walt et al. 1989a).

Origin of the strain studies: CBS 7169, leaves of *Sclerocarya caffra*, J.P. van der Walt, South Africa.

Type strain: CBS 7169.

Comments: The ultrastructure of the cell walls is electron dense and layered, and septa are simple diaphragma-like and attenuating towards the pore (Boekhout et al. 1992b). The observed pore structure suggests a close phylogenetic relationship with the genera *Sporobolomyces* and *Sporidiobolus*. Budding of yeast cells occurs percurrently (Boekhout, unpublished results).

92.7. *Bensingtonia subrosea* (Nakase & M. Suzuki) Nakase & Boekhout (1988)**Synonym:**

Sporobolomyces subroseus Nakase and M. Suzuki (1987c)

Growth on 5% malt extract agar: After 5 days at 17°C, the cells are ellipsoidal to cylindrical, (7.0–14.0) × (4.0–7.0) μ m, and single. Budding is mostly polar, and occasionally lateral, with the buds sessile or on short denticles and with percurrent proliferation. Colonies are butyrous, smooth, shiny, grayish-cream, with the margin entire.

Growth on the surface of assimilation media (glucose): Absent, but a sediment may be formed.

Dalmau plate culture on morphology agar: After 7 days at 17°C, no pseudomycelium or mycelium is formed. Aerobic growth is pale pinkish-cream, shiny, butyrous, smooth, flat or slightly raised, and with the margin entire.

Fig. 373. *B. subrosea*, CBS 7283. Ballistoconidia on corn meal agar. Bar = 5 μ m.

Formation of ballistoconidia: Ballistoconidia were observed on corn meal agar. They are ellipsoidal, and sometimes somewhat pointed toward the apex, (7.0–13.0) × (3.8–5.0) μ m (Fig. 373).

Fermentation: absent.

Assimilation (17°C):

Glucose	+	<i>N</i> -Acetyl-D-glucosamine	n
Galactose	-	Methanol	-
L-Sorbose	l	Ethanol	l
Sucrose	+	Glycerol	+

Co-Q: 9, JCM 5735 (Nakase and Suzuki 1987c).

Mol% G+C: 46.5, JCM 5735 (T_m : Nakase and Suzuki 1987c).

Origin of the strain studied: CBS 7283 (JCM 5735), dead leaf of *Miscanthus sinensis*, T. Nakase, Japan.

Type strain: JCM 5735.

Comments: *Bensingtonia subrosea* is similar to *B. miscanthi* in morphology, nutritional physiology and mol% G+C. Due to a low similarity value of about 19% in the electrophoretic patterns of 10 enzymes in both species, Nakase and Suzuki (1987c) described them as separate species. Physiologically, *B. subrosea* can be differentiated from *B. miscanthi* by assimilation of maltose, soluble starch and the inability to assimilate nitrate and nitrite.

92.8. *Bensingtonia yamatoana* (Nakase, M. Suzuki & M. Itoh) Nakase & Boekhout (1988)

Synonym:

Sporobolomyces yamatoanus Nakase, M. Suzuki & M. Itoh (1987b)

Growth on 5% malt extract agar: After 5 days at 17°C, the cells are cylindrical, ellipsoidal or subglobose, straight or somewhat curved, (9.0–15.0)×(2.0–4.0) μm. Septate hyphae are present, in which retraction septa are formed. Conidiogenesis is polar, with the buds sessile or on terminal sterigma-like outgrowths and with percurrent proliferation. Blastoconidia are formed on hyphae. Colonies are rather tough or butyrous, dry, flat or with the center raised, smooth or somewhat irregular, dull, pale yellowish-brown, and the margin may be entire or eroded.

Growth on the surface of assimilation media (glucose): Absent, but a sediment is formed.

Dalmu plate culture on morphology agar: After 7 days at 17°C, a septate mycelium is formed. Cylindrical, oblong or ellipsoidal blastoconidia are formed laterally and terminally on hyphae or sterigma-like outgrowths. Aerobic growth is variable, yellowish-cream, yellowish, or yellowish-brown, dull, tough, dry, or butyrous, with the surface nearly smooth, or irregular, low pustulate, transversely wrinkled to reticulate, with the margin crenulate, entire or eroded.

Formation of ballistoconidia: Ballistoconidia are formed laterally or terminally on hyphae on corn meal agar. They are reniform, falcate or allantoid, (9.0–20.0)×(3.0–6.0) μm (Fig. 374).

Fermentation: absent.

Assimilation (17°C):

Glucose	+	<i>N</i> -Acetyl-D-glucosamine	n
Galactose	–	Methanol	–
L-Sorbose	–	Ethanol	+
Sucrose	+	Glycerol	+

Co-Q: 9 (Nakase et al. 1987b).

Mol% G + C: 53.3–54.1, 5 strains, JCM 2896, JCM 5652, JCM 5975, JCM 6857, JCM 6858 (T_m : Nakase et al. 1987b).

Fig. 374. *B. yamatoana*, CBS 7244. Ballistoconidia on corn meal agar. Bar = 5 μm.

Origin of the strains studied: CBS 7242 (JCM 5977), dead leaf of *Sasa* sp., T. Nakase, Japan; CBS 7243 (JCM 2896), CBS 7244 (JCM 5652), both from dead leaf of *Miscanthus sinensis*, T. Nakase, Japan; CBS 7245 (JCM 5975), dead leaf of *Sasa* sp., T. Nakase, Japan.

Type strain: JCM 2896 (CBS 7243).

Comments: *Bensingtonia yamatoana* can be readily distinguished from all other *Bensingtonia* species because of the following characteristics: assimilation of 2-keto-D-gluconate, abundant formation of hyphae and rather dark yellow (ochre) colonies, and large ballistoconidia. Under TEM, septa of CBS 7243 have a central narrow pore. The cell walls are electron dense and layered (Boekhout et al. 1992b).

92.9. *Bensingtonia yuccicola* (Nakase & M. Suzuki) Nakase & Boekhout (1988)

Synonym:

Sporobolomyces yuccicola Nakase & M. Suzuki (1988)

Growth on 5% malt extract agar: After 5 days at 17°C, the cells are ellipsoidal, (7.0–11.0)×(3.5–6.5) μm, and single. Budding is polar or nearly polar, with the buds sessile or on short denticles and with percurrent proliferation. Colonies are butyrous, smooth, shiny, grayish-cream, with the margin entire.

Growth on the surface of assimilation media (glucose): Absent, but a sediment is formed.

Dalmu plate on morphology agar: After 7 days at 17°C, yeast cells can have short hyphal outgrowths, but there is no formation of extensive pseudohyphae or true hyphae. Aerobic growth is pale yellowish-cream, dull or shiny, butyrous, flat, with a smooth surface, flat, and with the margin entire, straight or somewhat crenulate.

Formation of ballistoconidia: No ballistoconidia were seen in strain CBS 7331. According to Nakase and Suzuki (1988) ballistoconidia, formed on corn meal agar, are apiculate or short ellipsoidal (broadly ellipsoidal) or ellipsoidal, (7.0–11.0)×(2.5–6.0) μm.

Fermentation: absent.

Assimilation (17°C):

Glucose	+	<i>N</i> -Acetyl-D-glucosamine	n

Co-Q: 9, CBS 7331 (Nakase and Suzuki 1988).

Mol% G + C: 45.8–45.9, JCM 6251 (T_m : Nakase and Suzuki 1988).

Origin of the strain studied: CBS 7331 (JCM 6251), leaf of *Yucca* species, R.J. Bandoni, Canada.

Type strain: JCM 6251.

Comments on the genus

Ingold (1986) described *B. ciliata* as the only species of the genus *Bensingtonia*. Because whole-cell hydrolyzates lacked xylose and the coenzyme Q system comprised 9 isoprenologs (Boekhout 1987, 1991a), Nakase and Boekhout (1988) recombined several *Sporobolomyces* species of the 'intermedius' group into *Bensingtonia*. Conidiogenesis of the genus in its current circumscription is variable. Most species show polar conidiogenesis with percurrent or sympodial proliferation. Some species, e.g., *B. ingoldii*, *B. miscanthi* and *B. subrosea*, form elongated denticles similar to that described in *Ballistosporymyces* (Nakase et al. 1989b). Morphologically, species of *Bensingtonia* cannot be differentiated from many of the recently described unpigmented species of *Sporobolomyces* (see key to species with bilaterally symmetrical ballistoconidia, ch. 76).

93. *Bullera* Derx

T. Boekhout and T. Nakase

Diagnosis of the genus

Cells are ellipsoidal, subglobose, or cylindroidal. Budding is mostly polar, and the buds are sessile or on short denticles, enteroblastic, and with percurrent or sympodial proliferation. Ballistoconidia are either rotationally or bilaterally symmetrical. If rotationally symmetrical, ballistoconidia are globose to subglobose, ellipsoidal, sometimes somewhat angular, transversely reniform, flabelliform, or turbinate, and if bilaterally symmetrical, ballistospores are reniform, allantoid or lunate. Colonies are whitish, yellowish, brownish, orange or reddish, smooth, reticulate or venose, mucoid, butyrous or rather dry. Hyphae or pseudohyphae may be present. Clamp connections are absent, but present in the dikaryophase.

Fermentation is absent. Diazonium blue B and urease reactions are positive. Xylose is present in whole-cell hydrolyzates. The major ubiquinone is Q-10.

Type species

Bullera alba (Hanna) Derx

Species accepted

1. *Bullera alba* (Hanna) Derx (1948): see *Bulleromyces albus*, p. 641
2. *Bullera armeniaca* Buhagiar (1983)
3. *Bullera crocea* Buhagiar (1983)
4. *Bullera dendrophila* van der Walt & D.B. Scott (1970)
5. *Bullera globispora* Johri & Bandoni (1984)
6. *Bullera megalospora* Nakase & M. Suzuki (1986)
7. *Bullera miyagiana* Nakase, M. Itoh, Takematsu & Bandoni (1990)
8. *Bullera oryzae* Nakase & M. Suzuki (1985)
9. *Bullera pyricola* Stadelmann (1975)
10. *Bullera pseudoalba* Nakase & M. Suzuki (1986)
11. *Bullera punicea* (Komagata & Nakase) Nakase & M. Suzuki (1986)
12. *Bullera sinensis* Li (1982)
13. *Bullera variabilis* Nakase & M. Suzuki (1987)

^a Abbreviations: Gal, galactose; Lac, lactose; Mel, melibiose; Raf, raffinose; Mlz, melezitose; Inu, inulin; Xyl, D-xylose; Rha, L-rhamnose; - Glu, D-glucosamine; Ery, erythritol; Met, α-methyl-D-glucoside; Lat, DL-lactate; Cit, citrate; Ino, inositol; Nit, nitrate.

^b Abbreviations: Ball., ballistospores, rotationally symmetrical (R) or bilaterally symmetrical (B); Or., orange color of colony; Pi., pink color of colony.

Systematic discussion of the species

93.1. *Bullera alba* (Hanna) Derx (1948)

See *Bulleromyces albus*, p. 641.

93.2. *Bullera armeniaca* Buhagiar (Buhagiar et al. 1983)

Growth on 5% malt extract agar: After 7 days at 17°C, cells are ellipsoidal, (5.0-10.0)×(2.0-4.0) μm, and single. Budding is polar and buds are sessile or on short denticles with percurrent or sympodial proliferation. Growth is butyrous, flat, with the center somewhat raised, shiny, pinkish-orange or orange, and with the margin entire or slightly eroded.

Growth on the surface of assimilation media (glucose): A thin film and a sediment are formed.

Dalmau plate culture on morphology agar: After 7 days at 17°C, a pseudomycelium occurs with cells measuring (10-110)×(3.0-4.5) μm. Aerobic growth is orange to brownish-orange, butyrous, flat, with the center somewhat raised, and with the margin entire, straight or somewhat crenulate.

Formation of ballistoconidia: Ballistoconidia, formed on corn meal, yeast-malt extract and malt extract agars, are subglobose to turbinate and measure (4.0-7.5)×(4.0-8.0) μm (Fig. 375).

Fermentation: absent.

Assimilation (at 17°C):

Glucose	+	N-Acetyl-D-glucosamine	n
Galactose	+	Methanol	-
L-Sorbose	-	Ethanol	-
Sucrose	+	Glycerol	+
Maltose	+	Erythritol	-

Urease	+	Growth at 37°C	-

Co-Q: 10 (Nakase 1987).

Mol% G+C: 54.3-56.6, two strains, CBS 7018, 7091 (T_m : Boekhout 1991a), 55.5 (HPLC: Nakase, unpublished results).

Fig. 375. *B. armeniaca*, CBS 7018. Ballistoconidia on corn meal agar. Bar = 5 μ m.

Origin of the strains studied: CBS 7018, CBS 7091, cabbage, R.W.M. Buhagiar, Great Britain; CBS 7091.1, pale mutant of CBS 7091.

Type strain: CBS 7091.

Comments: Besides the typical orange colored strains, pale mutants do occur. From morphological and physiological points of view, *B. armeniaca* comes close to *B. crocea* Buhagiar (Buhagiar et al. 1983). *Bullera armeniaca* lacks the ability to assimilate melibiose and α -methyl-D-glucoside, and salicin is only weakly assimilated. *Bullera crocea* does not assimilate inositol at all, whereas assimilation of this compound is delayed by *B. armeniaca*. The reported difference in mol% G+C of 2.5 could not be confirmed by the present author using the T_m -method. However, when analyzed by HPLC, *B. crocea* has a lower mol% G+C of 51.6. These two taxa are also kept separate, because of low similarity of electrophoretic enzyme patterns (T. Nakase, personal communication).

93.3. *Bullera crocea* Buhagiar (Buhagiar et al. 1983)

Synonym:

Bullera aurantiaca Johri & Bandoni (1984)

Growth on 5% malt extract agar: After 7 days at 17°C, cells are ellipsoidal to subglobose, (6.0–11.0) × (4.0–7.0) μ m, and single. Short hyphae may occur. Budding is polar and buds are sessile or on short denticles with percurrent or sympodial proliferation. Scars may be visible. Growth is soft, butyrous to rather dry, with the center slightly raised, smooth or reticulately ridged, shiny or dull, salmon-orange, orange, and with the margin entire, straight or strongly lobate.

Growth on the surface of assimilation media: A thin film and a sediment are formed.

Dalmau plate culture on morphology agar: After 7 days at 17°C, well-developed hyphae may be formed, with cells measuring (15–100) × (3.0–4.5) μ m. Aerobic growth is orange to brownish-orange, soft to dry, flat, warty or ridged, with margin entire, straight or lobate.

Formation of ballistoconidia: Ballistoconidia, formed on morphology and corn meal agars, are subglobose to turbinate, and measure (4.0–8.0) × (4.0–9.0) μ m (Fig. 376).

Fermentation: absent.

Fig. 376. *B. crocea*, CBS 6714. Ballistoconidia on corn meal agar. Bar = 5 μ m.

2-Keto-D-gluconate	+	Nitrite	+
50% Glucose	–	Growth at 25°C	+
Starch formation	+	Growth at 30°C	–
Urease	+		

Co-Q: 10 (Nakase 1987).

Mol% G+C: 54.9–56.6, two strains, CBS 6714, 6980 (T_m : Boekhout 1991a), 51.6 (HPLC: Nakase, unpublished results).

Origin of the strains studied: CBS 6714, strawberries, R.W.M. Buhagiar, Great Britain; CBS 6714.1, pale mutant of CBS 6714; CBS 6980, type of *B. aurantiaca* Johri & Bandoni, stems of *Urtica*, R.J. Bandoni, Canada.

Type strain: CBS 6714.

Comments: Pale mutants occur besides the orange colored strains. CBS 6980 extensively forms hyphae on corn meal agar, on which short chains of blastoconidia are formed apically and laterally. Under TEM, cell walls of CBS 6714 are layered and electron dense. No pore structure has been observed (Boekhout, unpublished results).

93.4. *Bullera dendrophila* van der Walt & D.B. Scott (1970)

Synonym:

Aessosporon dendrophilum van der Walt (1973)

Growth on 5% malt extract agar: After 7 days at 17°C, cells are ellipsoidal to somewhat cylindroidal, (7.0–13.0) × (4.5–11.5) μ m, and single. Budding is polar and buds are sessile or on short denticles. Growth is mucoid, with the center somewhat raised, smooth, glossy, cream to pale grayish-brown, and with the margin entire.

Fig. 377. *B. dendrophila*, CBS 6460. Ballistoconidia on corn meal agar. Bar = 5 μm .

Growth on the surface of assimilation media (glucose): A thin film, ring, and a sediment are formed.

Dalmou plate culture on morphology agar: After 7 days at 17°C, no mycelium or pseudomycelium is formed. Cells are ellipsoidal, cylindrical to somewhat dumb-bell-shaped, or ovoidal. Aerobic growth is cream, butyrous, shiny, flat or somewhat raised, smooth or with faint transverse striations, with the margin entire, straight or somewhat crenulate.

Formation of ballistoconidia: Ballistoconidium formation is poor. Best results were obtained on corn meal agar at 17°C. Ballistoconidia are ellipsoidal to subglobose, and measure (4.5–9.0) × (5.5–10.5) μm (van der Walt and Scott 1970). On the surface of the agar plate, ballistoconidia measure (8.5–11.0) × (9.5–13.0) μm (Fig. 377).

Fermentation: absent.

Assimilation (at 17°C):

Glucose	+	<i>N</i> -Acetyl-D-glucosamine	n
Galactose	+	Methanol	–
L-Sorbose	–	Ethanol	+

Starch formation	+	Growth at 30°C	v
Urease	+	Growth at 37°C	–

Co-Q: 10 (Nakase 1987).

Mol% G + C: 38.8–40.4, two strains, CBS 6459, CBS 6074 (T_m : Boekhout 1991a), 38.4 (HPLC: Nakase, unpublished results).

Origin of the strains studied: CBS 6074, frass of larvae of *Buprestidae* in subcortical galleries of

Dichrostachys cinerea, J.P. van der Walt, South Africa; CBS 6459 and CBS 6460, as *Aessosporon dendrophilum*, supposed diplophase of *B. dendrophila*, J.P. van der Walt, South Africa.

Type strain: CBS 6074.

Comments: Selected isolates of CBS 6074 have been interpreted as the perfect state of *Bullera dendrophila*, viz. *Aessosporon dendrophilum* van der Walt (van der Walt 1973), due to the presence of germinating chlamydospores on corn meal agar or potato glucose agar. However, it has not been proven that alternation of stages in the life cycle occurs in these cells, nor that ploidy differences are present. Therefore, we regard *A. dendrophilum* synonymous with *B. dendrophila*.

93.5. Bullera globispora Johri & Bandoni (1984)

Growth on 5% malt extract agar: After 7 days at 17°C, cells are ovoidal, ellipsoidal, cylindrical or subglobose, (7.0–14.0) × (3.0–8.0) μm , and single. Septate hyphae are sometimes present. Budding is polar, with sympodial or percurrent proliferation, and collarette-like scars are visible. Growth is mucoid, flat or somewhat raised, smooth, glossy, pale grayish-brown, and with the margin entire.

Growth on the surface of assimilation media (glucose): A ring, a thin film and a sediment are formed.

Dalmou plate culture on morphology agar: After 7 days at 17°C, poorly developed pseudohyphae are formed. Cells are ellipsoidal or cylindrical, and may be septate. Aerobic growth is pale yellowish-brown, butyrous to mucoid, shiny, flat or somewhat raised, with the surface smooth, or locally somewhat venose or reticulate. The margin is entire, straight or somewhat lobate.

Formation of ballistoconidia: Ballistoconidia, formed on morphology, malt extract, potato extract and corn meal agars, are subglobose, turbinate or transversely reniform, and measure (4.0–10.0) × (6.0–13.5) μm (Fig. 378).

Fermentation: absent.

Fig. 378. *B. globispora*, CBS 6981. Ballistoconidia on morphology agar. Bar = 5 μm .

Assimilation (at 17°C):

Glucose	+	<i>N</i> -Acetyl-D-glucosamine	n
Galactose	+	Methanol	-
L-Sorbose	-	Ethanol	-
Sucrose	+	Glycerol	+
Maltose	+	Erythritol	-
Cellobiose	+	Ribitol	+
Trehalose	+	Galactitol	+
Lactose	-	D-Mannitol	+
Melibiose	-	D-Glucitol	+
Raffinose	+	α -Methyl-D-glucoside	-
Melezitose	-	Salicin	v
Inulin	-	D-Gluconate	+
Soluble starch	v	DL-Lactate	+
D-Xylose	+	Succinate	+

Additional assimilation tests and other growth characteristics:

2-Keto-D-gluconate	+	Nitrite	+
50% Glucose	-	Growth at 25°C	+
Starch formation	+	Growth at 30°C	v
Urease	+	Growth at 37°C	-

Co-Q: 10 (Nakase 1987).

Mol% G + C: 52.9, one strain, CBS 6981 (T_m : Boekhout 1991a), 49.6 (HPLC: Nakase, unpublished results).

Origin of the strains studied: CBS 6981 (UBC 8079), UBC 70-8084, dead wood, B.N. Johri and R.J. Bandoni, Canada.

Type strain: UBC 8079 (CBS 6981).

Comments: According to Johri and Bandoni (1984), *B. globispora* has subglobose ballistoconidia. This feature was considered to be an important characteristic by these authors. However, in the two strains studied here, the ballistoconidia were generally broader than long. In this aspect they agree with the ballistoconidia of *B. armeniaca*, *B. pseudoalba* and *B. sinensis*. Moreover, the ballistoconidia we observed were considerably larger (viz. 4.0–10.0×6.0–12.5 μ m) if compared with the data presented by Johri and Bandoni (i.e., 3.5–6.0×3.5–6.5 μ m). Several differences were observed in the carbon assimilation pattern if compared with the data of Johri and Bandoni (i.e.), viz. no assimilation of L-sorbose, α -methyl-D-glucoside, melezitose, inulin, erythritol and assimilation of citrate. Physiologically, *B. globispora* is close to *B. armeniaca*, but it differs from that species by its inability to assimilate D-glucosamine and melezitose.

93.6. *Bullera megalospora* Nakase & M. Suzuki (1986c)**Synonym:**

Udeniomyces megalosporus (Nakase & M. Suzuki) Nakase & Takematsu (1992)

Growth on 5% malt extract agar: After 7 days at 17°C, cells are ellipsoidal, (12–26)×(4.0–8.5) μ m, and single. Budding is polar and buds are sessile, with percurrent proliferation and visible collarettes. Growth is

butyrous, flat and somewhat raised in the center, smooth, shiny, whitish-cream, and with the margin entire, straight or somewhat undulate.

Growth on the surface of assimilation media (glucose): A thin film, islets, and a sediment are formed.

Dalmau plate culture on morphology agar: After 7 days at 17°C, part of the cells form short hyphal outgrowths, which may be branched. Cells are ellipsoidal, and somewhat fusiform or limoniform. Aerobic growth is cream or pale pinkish-cream, shiny, flat or with the center somewhat raised, with the margin entire or slightly eroded, and straight or somewhat crenulate.

Formation of ballistoconidia: Ballistoconidia, formed on morphology, malt extract, yeast–malt extract and corn meal agars, are bilaterally symmetrical, lunate, allantoid or ellipsoidal, and measure (11.0–18.0)×(5.0–14.0) μ m (Fig. 379).

Fermentation: absent.

Assimilation (at 17°C):

Glucose	+	<i>N</i> -Acetyl-D-glucosamine	n
Galactose	w	Methanol	-
L-Sorbose	w	Ethanol	+
Sucrose	+	Glycerol	+

Co-Q: 10 (Nakase and Suzuki 1986c).

Mol% G + C: 48.8–50.9, three strains, JCM 5269, NO-59, NO-102 (T_m : Nakase and Suzuki 1986c).

Fig. 379. *B. megalospora*, CBS 7236. Ballistoconidia on corn meal agar. Bar = 5 μ m.

Origin of the strains studied: CBS 7236 (JCM 5269), CBS 7339 (JCM 5272), CBS 7355 (JCM 5271), CBS 7356 (JCM 5273), all four from dead leaves of rice (*Oryza sativa*), T. Nakase, Japan; CBS 7340 (JCM 5711), CBS 7359 (JCM 5712), both from dead leaves of *Miscanthus sinensis*, T. Nakase, Japan; CBS 7363 (JCM 5870), *Sasa* species, T. Nakase, Japan.

Type strain: JCM 5269 (CBS 7236).

Comments: *Bullera megalospora* can physiologically be differentiated from *B. punicea* by its inability to assimilate inositol. The other *Bullera* species with bilaterally symmetrical ballistospores, *B. pyricola*, differs by the ability to assimilate melibiose, lactose, galactitol and inositol.

93.7. *Bullera miyagiana* Nakase, M. Itoh, Takematsu & Bandoni (1990a)

Growth on 5% malt extract agar: After 7 days at 17°C, cells are ellipsoidal, limoniform to subglobose, (7.0–10.0) × (5.5–6.0) μm, and single. Budding is polar, on denticles or short stalks, with percurrent proliferation. Short hyphae may be present, up to ca. 180 μm long and 3.0–4.0 μm wide. Growth is butyrous, flat to slightly raised, somewhat venose, dull, pale yellowish, and with the margin entire, straight or slightly crenulate.

Growth on the surface of assimilation media: A ring and a sediment are formed.

Dalmu plate culture on morphology agar: After 7 days at 17°C, neither hyphae nor pseudohyphae are formed. Cells are ellipsoidal to subglobose. Aerobic growth is pale yellowish, dull, flat to slightly raised, with the margin entire, straight or somewhat crenulate. Hyphae are formed on malt extract agar and corn meal agar.

Formation of ballistoconidia: Ballistoconidia, formed on malt extract agar, are rotationally symmetrical, subglobose to flabelliform, and measure (5.5–10.5) × (5.0–11.0) μm (Fig. 380).

Fermentation: absent.

Assimilation (at 17°C):

Glucose	+	<i>N</i> -Acetyl-D-glucosamine	n
Galactose	+	Methanol	–
L-Sorbose	–	Ethanol	+
Sucrose	+	Glycerol	–

Fig. 380. *B. miyagiana*, CBS 7526. Ballistoconidia on malt extract agar. Bar = 5 μm.

Additional assimilation tests and other growth characteristics:

2-Keto-D-gluconate	+	Nitrite	+
50% Glucose	–	Growth at 25°C	+
Starch formation	+	Growth at 30°C	+
Urease	+	Growth at 37°C	–

Co-Q: 10 (Nakase et al. 1990a).

Mol% G+C: 61.4, JCM 7536 (T_m : Nakase et al. 1990a), 58.9, JCM 7536 (HPLC: Nakase et al. 1990a).

Origin of the strain studied: CBS 7526 (JCM 7536), *Abies firma*, R.J. Bandoni, Japan.

Type strain: JCM 7536.

Comments: *Bullera miyagiana* is close to *B. oryzae*, and differs by growth with ethanol, and lack of growth with D-glucosamine, galactitol and nitrate. Ballistoconidia of *B. miyagiana* germinate by sympodial proliferation (Fig. 380) (Boekhout 1991a).

93.8. *Bullera oryzae* Nakase & M. Suzuki (1985c)

Growth on 5% malt extract agar: After 7 days at 17°C, cells are ellipsoidal to subglobose, (5.0–10.0) × (3.0–6.0) μm, and single. Budding is polar and buds are sessile or on short denticles. Growth is butyrous, flat, smooth, shiny, pale grayish-brown, and with entire margins.

Growth on the surface of assimilation media (glucose): A ring, islets, a film, and a sediment are formed.

Dalmu plate culture on morphology agar: After 7 days at 17°C, no pseudohyphae or true hyphae are formed, but cells may form short hyphal-like outgrowths. Cells are ellipsoidal to subglobose and frequently somewhat thick-walled with the outer cell wall layer peeling off. Aerobic growth is pale yellow or brownish-yellow, with the margin slightly discolorous, dull, somewhat raised, flat or weak venose. The margin is entire, straight, lobate or crenulate.

Formation of ballistoconidia: Ballistoconidia, formed on corn meal agar, are globose to subglobose, and measure (4.5–8.0) × (4.0–6.5) μm (Fig. 381). Occasionally, huge globose to subglobose ballistoconidia were observed on corn meal agar, measuring (10.0–13.0) × (8.0–10.0) μm (Fig. 381).

Fermentation: absent.

Fig. 381. *B. oryzae*, CBS 7194 (top) and CBS 7342 (bottom). Ballistoconidia on corn meal agar. Bar = 5 μ m.

Assimilation (at 17°C):

Glucose	+	<i>N</i> -Acetyl-D-glucosamine	n
Galactose	+	Methanol	-
L-Sorbose	-	Ethanol	-
Sucrose	+	Glycerol	-
Maltose	+	Erythritol	+
Cellobiose	+	Ribitol	l
Trehalose	+	Galactitol	+
Lactose	+	D-Mannitol	+
Melibiose	+	D-Glucitol	+

Additional assimilation tests and other growth characteristics:

2-Keto-D-gluconate	+	Nitrite	+
50% Glucose	-	Growth at 25°C	+
Starch formation	+	Growth at 30°C	+
Urease	+	Growth at 37°C	-

Co-Q: 10 (Nakase and Suzuki 1985c).

Mol% G+C: 62.7, JCM 5281 (T_m : Nakase and Suzuki 1985c), 59.7 (HPLC: Nakase, unpublished results).

Origin of the strains studied: CBS 7194 (JCM 5281), dead leaf of rice (*Oryza sativa*), T. Nakase, Japan; CBS 7341 (JCM 5718), CBS 7360 (JCM 5719), CBS 7361 (JCM 5728), all three from dead leaves of *Miscanthus sinensis*, T. Nakase, Japan; CBS 7342 (JCM 5987), leaf of *Sasa* species, T. Nakase, Japan.

Type strain: JCM 5281 (CBS 7194).

Comments: *Bullera oryzae* belongs to the group of species similar to *B. alba*, and can be readily identified

because of assimilation of nitrite. *Bullera oryzae* differs from both *B. sinensis* and *B. pseudoalba* by forming ballistoconidia that are more globose to subglobose. Moreover, *B. sinensis* can be separated by the assimilation of L-sorbose and its inability to use lactose. *Bullera pseudoalba* differs by growth on glycerol (Boekhout 1991a) and its inability to assimilate erythritol. Mol% G+C of *Bullera alba* differs by 8.3% from *B. oryzae*.

93.9. *Bullera pyricola* Stadelmann (1975)

Synonyms:

Udeniomyces pyricola (as *U. piricola*) (Stadelmann) Nakase & Takematsu (1992)

Bullera grandispora Derox (1930) nomen dubium sensu B.N. Johri & Bandoni (1984)

Growth on 5% malt extract agar: After 7 days at 17°C, cells are ellipsoidal, ovoidal, cylindrical, sometimes somewhat constricted in the middle, and with the apices rounded or truncate, (9.0–35.0) \times (5.0–12.0) μ m, single or in short chains. Budding is polar with percurrent or sympodial proliferation, and with distinct annellations. Sometimes buds grow out as short hyphae. Growth is butyrous or mucoid, flat or somewhat raised, smooth, shiny, grayish-cream to pale yellowish-brown, and with the margin entire, straight or somewhat crenulate.

Growth on the surface of assimilation media (glucose): A ring and a sediment are formed.

Dalmu plate culture on morphology agar: After 7 days at 17°C, poorly developed pseudohyphae are formed. Cells are ellipsoidal, ovoidal or cylindrical, and are sometimes rather thick-walled. Aerobic growth is pale yellowish-brown, pinkish-brown, butyrous or mucoid, flat, or somewhat raised, and smooth or somewhat reticulate in the center. The margin is entire, straight, lobate or crenulate.

Formation of ballistoconidia: Ballistoconidia, formed on morphology and corn meal agars, are bilaterally symmetrical, ovoidal, ellipsoidal or allantoid, and measure (8.0–16.0) \times (4.0–9.0) μ m (Fig. 382).

Fermentation: absent.

Fig. 382. *B. pyricola*, CBS 6784. Ballistoconidia on corn meal agar. Bar = 5 μ m.

Assimilation (at 17°C):

Glucose	+	<i>N</i> -Acetyl-D-glucosamine	n

Urease	+		

Co-Q: 10 (Nakase and Suzuki 1986d).

Mol% G+C: 50.2–53.5, three strains, CBS 6754, CBS 6784, CBS 6982 (T_m : Boekhout 1991a); 50.8–51.7, JCM 2958, and one other strain (T_m : Nakase and Suzuki 1986c).

Origin of the strains studied: CBS 6754, from leaf of pear tree, F. Stadelmann, Switzerland; CBS 6784, from leaf of pear tree infected by *Operophthora brumata*, F. Stadelmann, Switzerland; CBS 6785, from leaf of pear tree infected by *Venturia pirina*, F. Stadelmann, Switzerland; CBS 6982, from rotten wood, originally identified as *B. grandispora* Derx, B.N. Johri and R.J. Bandoni, Canada.

Type strain: CBS 6754.

Comments: *Bullera grandispora* sensu Johri & Derx is considered conspecific with *B. pyricola*, because of about 85% DNA–DNA homology (Boekhout and Poot, unpublished results). The cell walls of CBS 6982 were found to be layered, electron-dense, and surrounded by a fibrous capsule (Boekhout, unpublished results).

93.10. Bullera pseudoalba Nakase & M. Suzuki (1986a)

Growth on 5% malt extract agar: After 7 days at 17°C, cells are ellipsoidal, (4.0–7.0) × (2.0–4.0) μ m, and single. Budding is polar and buds are sessile or on short denticles. Growth is mucoid or butyrous, flat or slightly raised, smooth, shiny, brownish-yellow, and with the margin entire.

Growth on the surface of assimilation media (glucose): A ring and a sediment are formed.

Dalmou plate culture on morphology agar: After 7 days at 17°C, septate hyphae occur. Cells are ellipsoidal.

Fig. 383. *B. pseudoalba*, CBS 7227. Ballistoconidia on corn meal agar. Bar = 5 μ m.

Aerobic growth is pale yellowish to pinkish yellow-brown, butyrous, shiny, flat, smooth or weakly transversely furrowed, and with the margin entire or somewhat eroded, straight or somewhat crenulate.

Formation of ballistoconidia: Ballistoconidia, formed on morphology and corn meal agars, are subglobose, and measure (5.0–10.0) × (3.5–8.0) μ m (Fig. 383).

Fermentation: absent.

Assimilation (at 17°C):

Glucose	+	<i>N</i> -Acetyl-D-glucosamine	n
Galactose	+	Methanol	-
L-Sorbose	-	Ethanol	+
Sucrose	+	Glycerol	+
Maltose	+	Erythritol	-

2-Keto-D-gluconate	+	Nitrite	-
50% Glucose	-	Growth at 25°C	+
Starch formation	-	Growth at 30°C	+
Urease	+	Growth at 37°C	-

Co-Q: 10 (Nakase and Suzuki 1986a).

Mol% G+C: 52.6–53.7, two strains, JCM 5290, NB-104 (T_m : Nakase and Suzuki 1986a).

Origin of the strains studied: CBS 7227 (JCM 5281), dead leaf of rice (*Oryza sativa*), T. Nakase, Japan; CBS 7343 (JCM 5721), CBS 7344 (JCM 5722) CBS 7362 (JCM 5723), all three from dead leaves of *Miscanthus sinensis*, T. Nakase, Japan.

Type strain: JCM 5281.

Comments: *Bullera pseudoalba* is similar to *B. alba* in morphological, physiological and biochemical aspects. *Bullera pseudoalba* differs from *B. alba*, as well as from *B. oryzae* and *B. sinensis* by the assimilation of glycol (Boekhout 1991a), the formation of blastoconidia at the apex of hyphae on corn meal agar (Boekhout 1991a), more yellowish-brown colonies, and differences

in electrophoretic enzyme patterns (Nakase and Suzuki 1986a).

93.11. *Bullera punicea* (Komagata & Nakase) Nakase & M. Suzuki (1986c)

Synonyms:

Candida punicea Komagata & Nakase (1965)

Sporobolomyces puniceus (Komagata & Nakase) Ahearn & Yarrow apud Yarrow (1972)

Udeniomyces punicea (Komagata & Nakase) Nakase & Takematsu (1992)

Growth on 5% malt extract agar: After 7 days at 17°C, cells are ellipsoidal to cylindroidal, rarely subglobose, (10.0–17.0)×(5.5–8.5) μm, and single. Budding is polar, rarely lateral, and buds are sessile, with percurrent proliferation and scars. Cells may form hyphae of up to ca. 75 μm long and 4.0–7.0 μm wide. Growth is butyrous, somewhat raised, smooth, dull, pale pinkish-cream, and with the margin entire.

Growth on the surface of assimilation media (glucose): A weak ring and a sediment are formed.

Dalmu plate culture on morphology agar: After 7 days at 17°C, no true mycelium or pseudomycelium is formed, but short hyphal cells may be present. Cells are ellipsoidal, ogival or limoniform. Aerobic growth is cream, butyrous, shiny, flat or somewhat raised, with the margin smooth and entire.

Formation of ballistoconidia: Ballistoconidia, formed on corn meal agar, are bilaterally symmetrical, allantoid, clavate or ellipsoidal, (10.0–14.0)×(5.5–7.0) μm (Fig. 384).

Fermentation: absent.

Assimilation (at 17°C):

Glucose	+	<i>N</i> -Acetyl-D-glucosamine	n

Co-Q: 10 (Nakase and Suzuki 1986d).

Mol% G + C: 53.9–54.4 (T_m : Nakase 1989), 53.3 (HPLC, Nakase unpublished results).

Origin of the strain studied: CBS 5689 (JCM 1535), frozen food, K. Komagata and T. Nakase, Japan.

Type strain: CBS 5689.

Comments: In the original diagnosis of *Candida punicea* (= *Bullera punicea*), a type was not designated. However, only one strain was listed by the original authors (Komagata and Nakase 1965). This strain, CBS 5689, was recently designated the neotype (Boekhout 1991a). Carotenoid composition, cell wall composition, and physiological characteristics were considered as indicative for affiliation of this strain with *Bullera* by Fiasson (1972), Weijman and Rodrigues de Miranda (1983) and Stadelmann (1975), respectively.

93.12. *Bullera sinensis* Li (1982)

Synonyms:

Bullera alba (Hanna) Derox var. *lactis* Li (1982)

Bullera deroxii Nakase & M. Suzuki (1986a)

Growth on 5% malt extract agar: After 7 days at 17°C, cells are ellipsoidal, (4.5–10.0)×(3.0–5.0) μm, and single. Budding is polar, and with buds sessile or on short denticles and with percurrent or sympodial proliferation. Growth is mucoid, glossy, pale yellowish-brown, with the margin entire.

Growth on the surface of assimilation media (glucose): A thin film, islets and a sediment are formed.

Dalmu plate on morphology agar: Poorly developed pseudohyphae are formed in some strains. Cells are ellipsoidal. Aerobic growth is yellowish to pinkish-cream, mucoid, glossy, flat or with the center somewhat raised, smooth or weakly transversely striated. The margin is entire, straight or crenulate.

Formation of ballistoconidia: Ballistoconidia, formed on corn meal, potato extract and morphology agars, are flabelliform, somewhat turbinate or globose to subglobose, and measure (3.0–7.0)×(3.0–7.0) μm (Fig. 385).

Fig. 385. *B. sinensis*, CBS 7225. Ballistoconidia on corn meal agar. Bar = 5 μm .

Fermentation: absent.

Assimilation (at 17°C):

Glucose	+	<i>N</i> -Acetyl-D-glucosamine	n

Urease	+	Growth at 37°C	-

Co-Q: 10 (Nakase and Suzuki 1986d).

Mol% G + C: 54.5–56.8, JCM 5280 (T_m : Nakase and Suzuki 1986a), CBS 7237, CBS 7238 (T_m : Nakase et al. 1990c), 54.3–54.9 (HPLC: Nakase et al. 1990c).

Origin of the strains studied: CBS 7225 (JCM 5280), CBS 7345 (JCM 5734), CBS 7358 (JCM 5279), all three from dead leaves of rice (*Oryza sativa*), T. Nakase, Japan; CBS 7346 (JCM 5874), dead leaf of *Miscanthus sinensis*, T. Nakase, Japan; CBS 7237, from *Coccinella*, M. Li, China; CBS 7238, from leaf of wheat (*Triticum* sp.), M. Li, China.

Type strain: CBS 7238.

Comments: *Bullera sinensis* is similar to *B. alba* and can be differentiated from the latter species by lack of growth on lactose and inulin, and by the ballistoconidia which are generally somewhat broader than long. Moreover, the colony on morphology agar is slightly more pinkish. Ballistoconidia were not observed in the type strains of *B. sinensis* and *B. alba* var. *lactis*. Because of similarities in the nutritional physiology (Boekhout 1991a) and electrophoretic enzyme patterns (Nakase et al. 1990c), *B. dextrii* and *B. alba* var. *lactis* are considered synonyms of *B. sinensis*.

93.13. *Bullera variabilis* Nakase & M. Suzuki (1987d)

Growth on 5% malt extract agar: After 7 days at 17°C, cells are ellipsoidal, fusiform, straight or somewhat curved, (5.0–13.5) × (3.0–5.0) μm , and single. Budding is polar or lateral, and buds are sessile or on denticles, which may be sympodially branched. Hyphal outgrowths are sometimes present. Growth is butyrous, flat or somewhat raised, smooth, shiny, pale yellowish-brown to pinkish yellow-brown, and with the margin entire, straight or somewhat undulating.

Growth on the surface of assimilation media (glucose): A ring, islets, a thin film, and a sediment are formed.

Dalmeida plate culture on morphology agar: After 7 days at 17°C, irregularly branched pseudohyphae may be present, made up of cells measuring (15–110) × (3.0–5.5) μm . Cells have variable shapes including fusiform, ellipsoidal, allantoid or subglobose. Aerobic growth is yellowish-cream, butyrous, dull or shiny, flat or somewhat raised, smooth or weakly transversely wrinkled. The margin is smooth, straight or somewhat crenulate.

Formation of ballistoconidia: Ballistoconidia, formed on corn meal agar and potato dextrose agar, are flabelliform, transversely reniform, or somewhat turbinate, frequently somewhat angular, and measure (3.5–8.0) × (4.5–9.0) μm (Fig. 386).

Fermentation: absent.

Assimilation (at 17°C):

Co-Q: 10 (Nakase and Suzuki 1987d).

Mol% G + C: 55.9–56.9, three strains, JCM 5275, NO-43, NO-11 (T_m : Nakase and Suzuki 1987d).

Fig. 386. *B. variabilis*, CBS 7354. Ballistoconidia on corn meal agar. Bar = 5 μm .

Origin of the strains studied: CBS 7354 (JCM 3914), dead base of bamboo culm, R.J. Bandoni, Canada; CBS 7347 (JCM 5275), dead leaf of rice (*Oryza sativa*), T. Nakase, Japan; CBS 7364 (JCM 5984), dead leaf of *Sasa* sp., T. Nakase, Japan; CBS 7365 (JCM 7265), CBS 7366 (JCM 7266), CBS 7367 (JCM 5661), all three from dead leaves of *Miscanthus sinensis*, T. Nakase, Japan.

Complementary mating types: CBS 7347 and CBS 7367.

Type strain: JCM 5275.

Comments: *Bullera variabilis* can be readily recognized by its somewhat angular ballistoconidia. Mating and dikaryon formation were observed to occur between CBS 7357 and CBS 7367 on corn meal agar. Dikaryotic hyphae are regularly septate, with clamp connections at the septa, and with cells measuring $(40\text{--}120) \times (2.0\text{--}3.0) \mu\text{m}$. Cylindrical-lageniform and subglobose dikaryotic cells, measuring $(7.0\text{--}27.0) \times (4.0\text{--}6.5) \mu\text{m}$, are formed laterally and terminally on the hyphae or hyphal branchlets. However, no basidia were observed. Septal pores are dolipores with parenthesomes made up of U-shaped vesicles (Boekhout et al. 1991a, Boekhout 1991a).

Comments on the genus

Derx (1930) defined *Bullera* by the rotational symmetry of the ballistoconidia. However, in the present circumscription, the genus also contains species with bilaterally

symmetrical ballistoconidia. These species, viz. *B. megalospora*, *B. pyricola* and *B. punicea*, alternately placed in the genus *Udeniomyces* by Nakase and Takematsu (1992), are additionally characterized by the formation of annellidic scars (Boekhout 1991a). Color of the colonies, also used to differentiate *Bullera* and *Sporobolomyces*, is not a good discriminative character. *Bullera armeniaca* and *B. crocea* have orange colored colonies. Moreover, *B. alba* (= *Bulleromyces albus*) was found to contain β -carotenoids, γ -carotenoids and torulene (Fiasson 1972). Presence of xylose in whole-cell hydrolyzates is a reliable character to differentiate *Bullera* from *Sporobolomyces* (Weijman and Rodrigues de Miranda 1983, Suzuki and Nakase 1988a). Recently, it became clear that the septal pore of the dikaryophase of *Bullera* is a dolipore, with a parenthesome made up of U-shaped vesicles (Boekhout et al. 1991a). Additional characters were found in the metabolism of D-glucuronic acid (Golubev 1989b), sensitivity to killer toxins (Golubev and Kuznetsova 1989, Golubev 1990a) and nucleotide sequences of 5S rRNA (Gottschalk and Blanz 1985). The life cycle is usually heterothallic, and comprises mating of compatible yeast strains, and formation of dikaryotic hyphae and basidia in which karyogamy and meiosis occur. In addition, self-sporulating strains occur (Boekhout et al. 1991a). The presumed homothallic life cycle of *B. dendrophila* (van der Walt 1973) is not accepted, as there is no experimental evidence for a sexual cycle.

Editors' note

Based on nucleotide sequence analysis of 18S rDNA (Suh and Nakase 1995) and partial sequences of 26S rDNA (G. Scorzetti and J.W. Fell, unpublished), *Udeniomyces* is related to *Cystofilobasidium* and *Mrakia* and well separated from *Bullera*. Consequently, the separate designation of *Udeniomyces* appears correct, but the information was received too late for inclusion in this edition.

94. *Cryptococcus* Vuillemin

J.W. Fell and A. Statzell-Tallman

Diagnosis of the genus

Cells are spheroidal, ovoidal or elongate. Reproduction by multilateral or polar budding; pseudo- or true hyphae may develop. Ascospores, ballistospores and ballistoconidia are not formed. Colony color on solid media may be white or cream, and some strains produce red, yellow or brown pigments. All species utilize D-glucuronate and most species synthesize starch; those species that do not synthesize starch utilize inositol, a combination that distinguishes those species from *Rhodotorula* spp. (Table 74). Fermentative ability is lacking. Xylose is present in cell hydrolyzates. Diazonium blue B and urease reactions are positive. Coenzymes Q-9 and Q-10 are present. Some species are anamorphic states of *Filobasidium*, *Filobasidiella*, *Cystofilobasidium*, and other teleomorphic genera in the Tremellales and Filobasidiales.

Systematic discussion of the species

94.1. *Cryptococcus aerius* (Saito) Nannizzi (Pollacci & Nannizzi 1927)

Synonyms:

Torula aerea Saito (1922)

Torulopsis aerea (Saito) Lodder (1934)

Paratorulopsis aerea (Saito) Novák & Zsolt (1961)

Cryptococcus albidus (Saito) C.E. Skinner var. *aerius* (Saito) Phaff & Fell (1970)

Growth in malt extract: After 3 days at 20°C, the cells are globose to ovoidal, (3.4–9.4) × (4.0–10.1) μm and may be single, in pairs and often in small clusters or in short chains. Usually a small amount of sediment is formed. After one month a moderate ring, no film or a few moist islands and a moderate to heavy sediment are present.

Growth on malt agar: After one month at 20°C, the streak culture is cream-colored to slightly yellowish or buff, mostly smooth, highly glossy, soft, with the margin entire or sometimes rough and wrinkled with an irregular margin.

Slide culture on potato agar: Pseudomycelium is absent.

Fermentation: absent.

Assimilation:

Glucose	+	<i>N</i> -Acetyl-D-glucosamine	–
Galactose	+	Methanol	–
L-Sorbose	s	Ethanol	s

Saccharate	+	Urease	+
D-Glucuronate	+	Growth at 30°C	+
50% (w/w) glucose–yeast extract agar	–	Growth at 37°C	–
10% NaCl/5% glucose	–		

Co-Q: 10 (Yamada and Kondo 1972a).

Mol% G + C: 55.5 (T_m : Nakase and Komagata 1968b); 54.3 (T_m : Sugita et al. 1992).

Cell hydrolyzates: Not determined.

Origin of the strain studied: Air in Tokyo (1).

Type strain: CBS 155, isolated by Saito from the air.

Comments: *Cryptococcus aerius* has been considered a variety of *C. albidus* (Rodrigues de Miranda 1984d),

however, LSU rDNA nucleotide sequence analysis in our laboratory (unpublished) demonstrated that the two taxa are phylogenetically distinct and separate species. The two species can be separated by abilities to produce starch and grow in vitamin-free media.

94.2. *Cryptococcus albidosimilis* Vishniac & Kurtzman (1992)

Growth in 1% glucose–yeast extract–peptone water: The cells are ovoid, encapsulated and functionally monopolar. The organisms slowly produce a scanty annulus and a little sediment.

Growth on 1% glucose–yeast extract–peptone agar: The colony is mucoid and shining white. The average size of the cells is 6.6 × 4.9 μm. Neither mycelium nor pseudomycelium is formed.

Fermentation: absent.

Assimilation:

Creatine	–	Growth at 37°C	–

Co-Q: Not determined.

Mol% G + C: 55 (BD: Vishniac and Kurtzman 1992).

Cell hydrolyzates: Not determined.

Origin of the strain studied: Soil in Antarctica (Vishniac and Kurtzman 1992).

Type strain: CBS 7711, isolated from soil from Linnaeus Terrace, Wright Valley, South Victoria Land, Antarctica (Vishniac strain MYSW A823-2Y761/70).

Comments: This species came belatedly to our attention, therefore the above information is from the original

description (Vishniac and Kurtzman 1992). According to this description, *C. albidosimilis* is indistinguishable from *C. albidus*. The authors described this strain as a new species based on a low (18%) DNA reassociation between the type strain of *C. albidosimilis* and *C. albidus*. Based on mol% G+C contents (50–55%), *C. albidus* consists of a complex of species that is possibly reflected in the list of synonyms of *C. albidus*. The relationship of *C. albidosimilis* to these synonyms must be determined. Analysis of LSU rDNA nucleotide sequences in our laboratory (unpublished) does, however, confirm that the type strains of *C. albidosimilis* and *C. albidus* represent separate species, consistent with the reported low rDNA relatedness.

94.3. *Cryptococcus albidus* (Saito) C.E. Skinner (1947b)

Synonyms:

- Torula albida* Saito (1922)
Torulopsis albida (Saito) Lodder (1934)
Torulopsis albida (Saito) Lodder var. *japonica* Lodder (1934)
Torula gelatinosa Saito (1922)
Rhodotorula gelatinosa (Saito) Hasegawa, Banno & Yamauchi (1960)
Torulopsis rotundata Redaelli (1925)
Torulopsis liquefaciens Saito & Oda (1934)
Torulopsis nadaensis Saito & Oda (1934)
Torulopsis diffuens Zach (Wolfram and Zach 1934b)
Cryptococcus diffuens (Zach) Lodder & Kreger-van Rij (1952)
Rhodotorula diffuens (Zach) Hasegawa, Banno & Yamauchi (1960)
Cryptococcus albidus (Saito) C.E. Skinner var. *diffuens* (Zach) Phaff & Fell (1970)
Cryptococcus diffuens Zach var. *urugaiensis* Artagaveytia-Allende & Aciole de Queiroz (1970)
Torulopsis acris var. *granulosa* Marcilla & Feduchy (Lodder 1970) nom. dub.
Torula alpina (Grüss) Lodder (1934) nom. nud.
Rhodotorula alpina (Grüss) Krasil'nikov (1954b) nom. nud.
Hansenula amylofaciens Dietrichson (1954) nom. nud.
Cryptococcus mucorugosus Benham (1955) nom. nud.
Cryptococcus neoformans (Sanfelice) Vuillemin var. *innocuous* Benham (1955) nom. nud.
Torulopsis dattila (Kluyver) Lodder var. *armeniaca* Sarukhanyan (1957)
Torulopsis dattila (Kluyver) Lodder var. *armeniensis* Sarukhanyan (1957)
Torulopsis pseudoaeria Zsolt (1958)
Paratorulopsis pseudoaeria (Zsolt) Novák & Zsolt (1961)
Cryptococcus terricolus Pedersen (1958)
Cryptococcus genitalis Castellani (1963) nom. nud.
Naganishia globosa S. Goto (1963)
Cryptococcus albidus (Saito) C.E. Skinner var. *ovalis* Sugiyama & Goto (1967)
Torulopsis ptarmiganii Hedrick nom. nud.? (Barnett et al. 1990)

Growth in malt extract: After 3 days at 25°C, the cells are globose to ovoidal and single, in pairs and often in small clusters or short chains; elongate cells may be present. Some strains have small cells, e.g., (3.0–6.1) × (3.5–6.2) µm, other strains have larger cells, e.g., (3.5–8.8) × (5.5–10.2) µm to 14 µm long. Usually a small amount of sediment is formed. After one month a moderate ring, no film or a few moist islands and a moderate to heavy sediment are present.

Growth on malt agar: After one month at 25°C, the streak culture is cream-colored to slightly yellowish or tan, mostly smooth, highly glossy, soft and slimy with the margin entire or sometimes rough and wrinkled with an irregular margin.

Slide culture on potato agar: Pseudomycelium is absent.

Fermentation: absent.

10% NaCl/5% glucose	–	Growth at 37°C	v

Co-Q: 10 (Yamada and Kondo 1972a).

Mol% G+C: 53.7, *C. albidus*, type strain, CBS 142 (T_m : Nakase and Komagata 1971c); 55 (BD: Storck et al. 1969); 54.1–55.1, *C. diffuens*, type strain, CBS 160; 50.5, *Naganishia globosa*, type strain, CBS 5106 (T_m : Nakase and Komagata 1971c).

Cell hydrolyzates: Xylose, mannose low, hexitol (probably mannitol) (Weijman and Rodrigues de Miranda 1988).

Origin of the strains studied: Air (4), bumble bee (1), skin of dog (1), sputum, lung and bronchial secretion (7), patients with various diseases (4), nails (3), skin (1), sake moto (2), wine (2), dew-retted flax (2), leaves (2), soil (1), blue cheese (*Naganishia globosa*) (1), goat dung (1), washed bottle in brewery (1), purification tank for polluted water (1), unknown (4), a strain labeled *Torulopsis dattila* var. *armeniensis* of unknown origin.

Type strain: CBS 142, isolated by Saito from the air.

Comments: As indicated by the variability in mol% G+C, *C. albidus* consists of a complex of species. This variability is also reflected in the large number of synonyms. Sugita et al. (1992) reported that the variety *diffuens* is a separate species based on limited DNA relatedness (41%) with *C. albidus*. This observation has been confirmed by LSU rDNA nucleotide sequence analysis in

our laboratory. Similarly, we find that *C. terricolus* is a separate species. These unpublished data were obtained after the completion of this manuscript.

94.4. *Cryptococcus amyloletus* (van der Walt, D.B. Scott & van der Klift) Golubev (1981)

Synonym:

Candida amyloletus van der Walt, D.B. Scott & van der Klift (1972)

Growth in 1% glucose–yeast extract–peptone water: After 3 days at 25°C, the cells are spheroidal, ovoidal or ellipsoidal, (3.4–6.7)×(3.4–7.4) µm. After one month there is a sediment, a ring and a few islets.

Growth on 1% glucose–yeast extract–peptone agar: After one month at 25°C, the streak culture is white to cream-colored, pasty, dull and smooth. The margin is entire to undulating.

Dalmu plate culture on corn meal agar: The pseudomycelium consists of ramified chains of ovoidal to elongate cells, bearing clusters of short, ovoidal blastoconidia in verticillate positions.

Fermentation: absent.

Assimilation:

Glucose	+	<i>N</i> -Acetyl-D-glucosamine	+
Galactose	+	Methanol	–

50% (w/w) glucose–yeast extract agar	+	Growth at 37°C	–
10% NaCl/5% glucose	w		

Co-Q: Not determined.

Mol% G+C: 55.1, type strain (T_m : Meyer et al. 1984).

Cell hydrolyzates: Xylose, mannose low, hexitol (probably mannitol) (Weijman and Rodrigues de Miranda 1988).

Origin of the strains studied: Frass from tunnels of the beetle *Enneadesmus forficulus* Fairm. in timber of *Dombeya rotundifolia* (Hochst.) Harv. near Grobersdal in the Transvaal, South Africa (1); frass from the tunnels of *Sinoxylon ruficorne* Fahr. infesting *Dichrostachys*

cinerea L. (Wright & Arn.) near Grobersdal in the Transvaal (1) (van der Walt 1972).

Type strain: CBS 6039, from frass of the tunnels of *Enneadesmus forficulus*.

Comments: Nucleotide sequence analysis of a region of the LSU rDNA indicates that *C. amyloletus* is related to *Tsuchiyaea wingfieldii* (Fell et al. 1995).

94.5. *Cryptococcus antarcticus* Vishniac & Kurtzman (1992)

Growth in 1% glucose–yeast extract–peptone water: A scanty annulus and a little sediment are produced. The cells are ovoid, possess a scanty capsule and are functionally monopolar, budding repeatedly from the site of the primary bud scar.

Growth on 1% glucose–yeast extract–peptone agar: The colony is slightly mucoid and shining white to cream. The cells measure 4.0–7.5 µm. Neither mycelium nor pseudomycelium is formed.

Fermentation: absent.

Assimilation:

Co-Q: Not determined.

Mol% G+C: 55 (T_m : Vishniac and Kurtzman 1992).

Cell hydrolyzates: Not determined.

Origin of the strain studied: Soil in Antarctica (Vishniac and Kurtzman 1992).

Type strain: CBS 7687, isolated from soil from University Valley, South Victoria Land, Antarctica (Vishniac strain MYSW A812-20bY693/64).

Comments: Because this species came belatedly to our attention, the above descriptive information is from the original description (Vishniac and Kurtzman 1992). According to that description, *C. antarcticus* is phenotypically indistinguishable from *C. albidus* and the species distinction is based on a low (14%) DNA reassociation between the type strains of *C. antarcticus* and *C. albidus*. Analysis of LSU rDNA nucleotide sequences in our laboratory (unpublished) confirms that *C. albidus* and *C. antarcticus* are separate species and that *C. antarcticus* is closely related to *C. bhutanensis*.

**94.6. *Cryptococcus aquaticus* (Jones & Slooff)
Rodrigues de Miranda & Weijman (Weijman
et al. 1988)**

Synonyms:

Candida aquatica Jones & Slooff (1966)

Vanrija aquatica (Jones & Slooff) R.T. Moore (1980)

Growth in glucose–yeast extract–peptone water: After 3 days at 19°C, the cells are ovoidal or elongate, (2.7–5.4)×(8.0–13.4)µm. Budding is mono- or bipolar; multiple buds, which form on separate sites at the poles, remain attached to the parent cells. Groups of cells thus formed have a star-like arrangement. After one month a thin ring and a heavy sediment are present.

Growth on glucose–yeast extract–peptone agar: After one month at 19°C, the streak culture is yellowish cream-colored, semi-dull, soft, and slightly wrinkled.

Dalmau plate culture on corn meal agar: The pseudomycelium consists of branched short chains of ovoidal or elongate cells. The elongate cells may be flask-, dumbbell- or club-shaped, lageniform or display other unusual shapes. (Fig. 387).

Fermentation:

Glucose	w	Maltose	v
Galactose	–	Lactose	–
Sucrose	v	Raffinose	v

Fig. 387. *C. aquaticus*, CBS 6758. Cells grown on corn meal agar at 19°C for 2 weeks. Bar = 10µm.

Assimilation:

10% NaCl/5% glucose	–	Growth at 30°C	–
Starch formation	+		

Co-Q: Not determined.

Mol% G+C: 58.4, type strain (BD: Meyer et al. 1984).

Cell hydrolyzates: Fucose, xylose, mannose low (Weijman and Rodrigues de Miranda 1988)

Origin of the strain studied: Scum on a freshwater mountain lake in Malham Tarn, Yorkshire, England, Oct. 1962 (Jones and Slooff 1966).

Type strain: CBS 5443 (Jones and Slooff strain P.181).

Comments: Jones and Slooff (1966) found this species in “large quantities” in water scums in Oct. 1962 and March 1963 in one area, Malham Tarn. They did not find the fungus in scums collected in other parts of Great Britain. They speculated the presence or absence of the yeast was dependent on the types and levels of organic material in the water. Based on morphological and physiological criteria, Jones and Slooff (1966) noted the possible relationship of *C. aquaticus* to species currently included in the genus *Mrakia*. This observation is in agreement with results of nucleotide sequence alignment comparisons of a region the LSU rDNA (Fell et al. 1995).

**94.7. *Cryptococcus ater* (Castellani ex Cooke) Phaff
& Fell (Lodder 1970)**

Synonyms:

Cryptococcus ater Castellani (1960) nom. nud.

Cryptococcus laurentii (Kufferath) C.E. Skinner var. *magnus* Lodder & Kreger-van Rij forma *ater* Castellani ex Cooke (1966)

Growth in 5% malt extract: After 3 days at 25°C, the cells are ovoidal to globose, (3.7–6.9)×(4.0–8.0)µm, rarely to 9µm long; single or in pairs, a few short chains

of three and four cells. A thin ring and a little sediment are present. After one month there is a moderate ring and a thick sediment.

Growth on 5% malt agar: After one month, the streak culture is cream to buff to blackish-brown, smooth, glossy, slimy (running to the bottom of the tube). The dark color infuses into the agar.

Dalmau culture on corn meal agar: Pseudomycelium is absent.

Fermentation: absent.

Assimilation:

Co-Q: 10 (Roeymans and Zijlstra, cited by Guého et al. 1993).

Mol% G+C: 48.6 (PC: Golubev and Vagabova 1977).

Cell hydrolyzates: Xylose, mannose dominate (Weijman and Rodrigues de Miranda 1988).

Origin of the strains studied: Ulcers on leg of a patient (3).

Type strain: CBS 4685, the original strain of Castellani (1960) isolated from multiple ulcers on the leg of a young man.

Comments: Based on molecular sequence analyses, *C. ater* may be closely related to *Filobasidium elegans* (Guého et al. 1993) and *C. magnus* (Yamada et al. 1990a). Sequence analyses in our laboratory confirm close relationships of *C. ater*, *C. magnus*, *F. elegans* and *F. floriforme*.

94.8. *Cryptococcus bhutanensis* S. Goto & Sugiyama (1970)

Growth in 5% malt extract: After 3 days at 25°C, the cells are ovoidal to spheroidal, measuring (4.0–6.7×4.7–8) μ m and may be single or budding. After one month a sediment is present.

Growth on 5% malt agar: After one month at 25°C, the streak culture is cream to buff-colored, smooth, slightly glistening and the edges are entire.

Dalmau plate culture on corn meal agar: Both true and pseudomycelium are absent.

Fermentation: absent.

Co-Q: Not determined.

Mol% G+C: 53.4 (T_m : Nakase and Komagata 1971c); 54.2 (BD: Baharaean et al. 1982).

Cell hydrolyzates: Xylose, mannose dominate (Weijman and Rodrigues de Miranda 1988).

Origin of the strain studied: Soil sample from Laya, Bhutan, collected May 1967 (Goto and Sugiyama 1970).

Type strain: CBS 6294 (Goto and Sugiyama strain H-3-9-3, designated as type no. TI-0029).

Comments: *C. bhutanensis*, based on unpublished nucleotide sequence data in our laboratory, is related to *C. antarcticus*.

94.9. *Cryptococcus consortionis* Vishniac (1985a)

Growth in 5% malt extract: After 3 days at 19°C, the cells are ovoidal to spherical, (3.4–6.0)×(4.0–6.7) μ m, single or in pairs. Budding is polar. After one month there is little sediment but neither a ring, nor a pellicle are present.

Growth on 5% malt extract agar: After one month at 19°C, the streak colony is cream-colored, flat and semi-glistening.

Dalmau plate culture on corn meal agar: After one week at 19°C, pseudomycelium is not formed.

Fermentation: absent.

Co-Q: 10 (Yamada and Kondo 1972a).**Mol% G+C:** 59.8–60.3, 2 strains (T_m : Nakase and Komagata 1971c); 54.2, type strain (T_m : von Arx and Weijman 1979).**Cell hydrolyzates:** Xylose, mannose low, hexitol (probably mannitol) (Weijman and Rodrigues de Miranda 1988).**Origin of the strain studied:** Human sputum.**Type strain:** CBS 570, isolated in 1932 in the Netherlands from sputum of a patient with tuberculosis (Diddens and Lodder 1942).

Comments: Other strains have been isolated from human sputum (1), human feces (1), human urine (2), tissue culture medium (1), uterus of a cow (1) and uncertain origin (3). Nakase and Komagata (1971c) reported the species from frozen food. Nucleotide sequence analysis of the LSU rRNA indicates that *C. curvatus* is related to the genus *Trichosporon* (Guého et al. 1993).

94.11. *Cryptococcus dimennae* Fell & Phaff (1967)

Growth in 5% malt extract: After 3 days at 25°C, the cells are ovoidal, occasionally spheroidal, (3.3–6.8) × (6.0–11.4) μm and may be single or in pairs. No ring or pellicle and very little sediment form. After one month there is a thin ring, a thin, smooth pellicle and a moderate amount of sediment.

Growth on 5% malt agar: After one month at 25°C, the streak culture is tan to pinkish-cream-colored; the surface is smooth and glossy, the texture soft and the margin entire.

Dalmou culture on corn meal agar: Pseudomycelium is absent.

Fermentation: absent.

Co-Q: 9 (Roeymans and Zijlstra, cited by Guého et al. 1993).

Mol% G + C: 53.1 (T_m : Nakase and Komagata 1971c).

Cell hydrolyzates: Xylose, mannose low (Weijman and Rodrigues de Miranda 1988).

Origin of the strains studied: Isolated by M.E. di Menna in 1960 from leaves of pasture plants at Hanks Bay, New Zealand (2).

Type strain: CBS 5770 (di Menna strain number 60 BGF 10).

Comments: M.E. di Menna (personal communication) reported the isolation of two strains of this species from pasture plants, but she was unable to isolate additional strains from the same habitat during repeated samplings over a 3–4 year period.

94.12. *Cryptococcus feraegula* Saëz & Rodrigues de Miranda (1988)

Growth in 5% malt extract: After 3 days at 25°C, the cells are ovoidal to spherical, measuring (3–7) × (5–8) μm, and they may be budding or single. After one month a thin ring and a slight sediment are present.

Growth on 5% malt agar: After one month at 25°C, the streak culture is orange, smooth, glistening, slightly raised and the margin is entire.

Dalmou plate culture on corn meal agar: After 7 days at 19°C, short pseudohyphae are formed.

Fermentation: absent.

Co-Q: Not determined.

Mol% G + C: Not determined.

Cell hydrolyzates: Not determined.

Origin of the strains studied: CBS 7201, from the mouth of a rhea (*Rhea americana*) that was born in captivity and died in Oct. 1978 in the Zoological Park Museum, Paris, France (Saëz and Rodrigues de Miranda 1988).

Type strain: CBS 7202 (Saëz and Rodrigues de Miranda No A3539 (B)) from a male baboon (*Papio papio*) that died in Nov. 1976 in the Zoological Park of Paris (Saëz and Rodrigues de Miranda 1988).

Comments: In addition to the strains listed above, Saëz and Rodrigues de Miranda (1988) isolated a strain from a female aye-aye (*Daubentonia madagascariensis*) in the same zoo in April 1986. Sequence analysis in our laboratory indicates that *C. feraegula* is related to *Cystofilobasidium*.

94.13. *Cryptococcus flavus* (Saito) Phaff & Fell (1970)

Synonyms:

Torula flava Saito (1922)

Chromotorula flava (Saito) F.C. Harrison (1928)

Rhodotorula flava (Saito) Lodder (1934)

Rhodotorula tokyoensis Kobayoshi ex Hasegawa var. *flava* (Saito) Hasegawa (1958)

Growth in 5% malt extract: After 3 days at 25°C, the cells are ovoidal or irregular; single or in pairs, (3.2–5.2)×(5.0–8.8) µm. A thin ring and a little sediment begin to form. After one month a moderate yellowish ring and sediment are present.

Growth on 5% malt agar: After one month at 20°C, the streak culture is light brown-yellow, semiglossy and nearly smooth with a butyrous texture and entire margins.

Dalmu plate culture on corn meal agar: No pseudomycelium is present, although a few chains of cells may be formed.

Fermentation: absent.

Assimilation:

50% (w/w) glucose–yeast extract agar	–	Growth at 30°C	–
10% NaCl/5% glucose	–		

Co-Q: 10 (Vishniac 1985b).

Mol% G+C: Not determined.

Cell hydrolyzates: Not determined.

Origin of the strain studied: A single strain was isolated from an Antarctic rock bearing a cryptoendolithic lichen (Vishniac strain MYSW A801-133Y100).

Type strain: CBS 7160.

Comments: We found that the production of urease was weak rather than negative as reported in the original description. Analysis of the nucleotide sequence of the LSU rRNA (Fell et al. 1992) confirmed that *C. friedmannii* and *C. vishniacii* are separate species.

94.15. *Cryptococcus fuscescens* Golubev (1984)

Growth in 5% malt extract: After 3 days at 25°C, the cells are spheroidal, measuring (5.4–7.4)×(5.4–8.0) µm, and they occur singly and in pairs. After one month a sediment is present.

Growth on 5% malt extract agar: After one month at 25°C, the streak culture is buff, flat, semi-glistening, butyrous and the margin is entire.

Dalmou plate culture on corn meal agar: After one month at 25°C, no pseudomycelium is present.

Fermentation: absent.

10% NaCl/5% glucose	–		

Co-Q: Not determined.

Mol% G+C: 52.4 (PC: Golubev 1984).

Cell hydrolyzates: Glucose and glucosamine predominant (Golubev 1984).

Monosaccharide composition of extracellular polysaccharides: Glucose, mannose, xylose, galactose and glucuronic acid (Golubev 1984).

Origin of the strain studied: Isolated by Bab'eva in 1962 from saline Takyr soil from the valley of the river Axai, Murgabski region, East Pamir, USSR.

Type strain: CBS 7189 (Golubev type MGU 674; Acad. Sci. USSR strain BKM Y-2600).

Comments: Golubev (1984) reported in the original description that *C. fuscescens* is related to *C. terreus*, based on the brown pigmentation on old malt agar cultures, positive assimilation of D-ribose, and the inability to assimilate α -methyl-D-glucoside, sucrose and raffinose. These characteristics distinguish these two species from the other nitrate-positive cryptococcoid species. This close relationship was also observed in the nucleotide sequence analysis of the LSU rRNA of each species (Fell et al. 1992). *C. fuscescens* differs from *C. terreus* by the inability to assimilate L-sorbose, lactose, L-rhamnose, D-glucosamine, D-glucitol and the inability to grow in vitamin-free medium.

94.16. *Cryptococcus gastricus* Reiersöl & di Menna (1958)

Growth in 5% malt extract: After 3 days at 20°C,

the cells are mainly globose, but also short-ovoidal, (3.3–10.0) × (4.0–10.0) μ m; single, in pairs or in short chains. After one month at 20°C, there is a moderate ring and a small amount of sediment.

Growth on 5% malt agar: After one month at 20°C, the streak culture is pale, cream or yellow to tan-colored. The surface is smooth and glossy, the texture slightly mucoid. The growth is flat to low convex with an irregular to entire margin.

Dalmou plate culture on corn meal agar: Pseudomycelium absent; a few chains of cells may be formed under the coverslip.

Fermentation: absent.

Assimilation:

50% (w/w) glucose–yeast extract agar	–	Growth at 20°C	+
10% NaCl/5% glucose	–	Growth at 30°C	–

Co-Q: Not determined.

Mol% G+C: 51.0, strain CBS 1927; 65.5, strain CBS 2288 (BD: Storck et al. 1969).

Cell hydrolyzates: Xylose, mannose low (Weijman and Rodrigues de Miranda 1988).

Origin of the strains studied: Soil in New Zealand (1) received from di Menna; washings of the stomach of a tuberculosis patient in Norway (1).

Type strain: CBS 2288 (Reiersöl and di Menna strain V39) from stomach lavage of a tuberculosis patient in Norway.

Comments: Because Reiersöl and di Menna (1958) did not designate a type strain, Phaff and Fell (1970) designated CBS 1927 as the type culture; that strain was isolated by di Menna from soil. This designation has been followed by subsequent authors (Rodrigues de Miranda 1984d, Barnett et al. 1990) and it is listed as the type culture in the CBS and ATCC catalogues. However, the

Reiersöl and di Menna (1958) description is based on strain V39 and the statement is made "In this genus V39, according to its assimilation pattern, represents a new species". The only mention of soil isolates is: "the same species was earlier isolated in New Zealand by one of the authors (di Menna) from a soil near Dunedin. She recovered a total of six strains of the species". It is clear that the authors intended V39 to be the type strain of *C. gastricus*. The reported strain differences in mol% G+C values suggest that the species may be genetically heterogenous and represent more than one species. In contrast to those results, our nucleotide sequence analyses (unpublished) indicate that the two strains are identical. In light of any potential differences, the name *C. gastricus* should be retained for strain V39 (CBS 2288).

94.17. *Cryptococcus gilvescens* Chernov & Bab'eva (1988)

Growth in 5% malt extract: Not determined.

Growth on 5% malt agar: Not determined.

Dalmau plate culture on corn meal agar: Not determined.

Fermentation: absent.

Co-Q: 9 (Chernov and Bab'eva 1988).

Mol% G+C: Not determined.

Cell hydrolyzates: Not determined.

Origin of the strain studied: Humus from tundra, western Taimyr near Dikson, Russia.

Type strain: CBS 7525.

Comments: This species was brought to our attention after the completion of this manuscript. The data above were provided by D. Yarrow, Centraalbureau voor Schimmelcultures.

94.18. *Cryptococcus heveanensis* (Groenewege) Baptist & Kurtzman (1976)

Synonyms:

Torula heveanensis Groenewege (1921b)

Candida heveanensis (Groenewege) Diddens & Lodder (1942)

Torulopsis heveanensis (Groenewege) Mager & Aschner (1947)

Cryptococcus laurentii (Kufferath) C.E. Skinner var. *magnus* Lodder & Kreger-van Rij (1952)

Cryptococcus magnus (Lodder & Kreger-van Rij) Baptist & Kurtzman var. *heveanensis* (Groenewege) Golubev (1981)

Growth in 5% malt extract: After 3 days at 25°C, the cells are ovoidal to elongate, and single, in pairs or in short chains of three or four cells, (2.0–4.5) × (3.0–7.0) μ m. A small ring and some sediment are present. After one month a moderate thick ring and a heavy sediment are formed.

Growth on 5% malt agar: After one month the streak culture is smooth, glossy, cream-colored with a tan line in the middle; it is mucoid and the growth runs to the bottom of the slant. The margin is entire.

Dalmau plate culture on corn meal agar: Short chains of cells form.

Fermentation: absent.

Assimilation:

Glucose	+	<i>N</i> -Acetyl-D-glucosamine	-

Additional assimilation tests and other growth characteristics:

2-Keto-D-gluconate	n	Starch formation	+
5-Keto-D-gluconate	n	Urease	+
Saccharate	+	Gelatin liquefaction	–
D-Glucuronate	+	Thiamine-free	–
50% (w/w) glucose–	–	Growth at 30°C	+
yeast extract agar		Growth at 37°C	–
10% NaCl/5% glucose	w		

Co-Q: Not determined.

Mol% G+C: 49.0 (BD: Storck et al. 1969); 52.0 (BD: Baptist and Kurtzman 1976).

Cell hydrolyzates: Xylose, mannose low, hexitol (probably mannitol) (Weijman and Rodrigues de Miranda 1988).

Origin of the strain studied: Rubber (1).

Type strain: CBS 569, isolated by Groenewege (1921b) from rubber stored in a moist room.

Comments: This species was originally described in the genus *Torula* by Groenewege (1921b). Subsequently, based on the presence of primitive pseudomycelium Diddens and Lodder (1942) transferred the species to the genus *Candida*. Mager and Aschner (1947) found that the species produced “starch” and then transferred the species to *Torulopsis*. Lodder and Kreger-van Rij (1952) considered the species as a synonym of *C. laurentii* var. *laurentii*. Phaff and Fell (1970) transferred the species to synonymy with *C. laurentii* var. *magnus*. Baptist and Kurtzman (1976) established *Cryptococcus heveanensis* based on differences in mol% G+C (*C. laurentii* var. *laurentii*, 59.7; *C. laurentii* var. *magnus*, 54.1; *C. heveanensis*, 52.0) and by differences in electrophoretic enzyme patterns. Nucleotide sequence analysis in our laboratory (unpublished) confirmed that these three species are distinct. *C. heveanensis* can be separated from *C. laurentii* var. *laurentii* by the inability to assimilate melibiose and from *C. magnus* by the ability of *C. heveanensis* to assimilate L-rhamnose, erythritol and ribitol.

94.19. *Cryptococcus huempii* (Ramírez & González) Roelijmans, van Eijk & Yarrow (1989)

Synonyms:

Candida huempii Ramírez & González (1984j)

Candida huempii Ramírez & González emend. Ramírez (1988)

Growth in 5% malt extract: After 3 days at 19°C, the cells are ovoidal to elongate, (2.7–6.7) × (8.0–16.1) μm, single or in pairs. After one month a slight sediment and ring are present.

Growth on 5% malt extract agar: After one month at 19°C, the streak culture is semi-glistening, cream-colored, butyrous and flat and the margin is entire.

Dalmeu plate culture on corn meal agar: After one month at 19°C, primitive pseudomycelium is present.

Fermentation: absent.

suaveolens (Krzemecki) Burns (1933)]

Sporobolomyces albidus Ramírez Gómez (1957)

Nadsonia slovaká Kocková-Kratochvílová & Svobodová-Poláková (1959)

Growth in 5% malt extract: After 3 days at 25°C, the cells are variable in form and size. They may be short-ovoidal, drop-like, lemon-shaped, long-ovoidal to cylindrical and measure (2.5–4.7) × (4.7–21.4) μm. After one month, a pellicle and sediment are present.

Growth on 5% malt extract agar: After one month

at 25°C, the streak culture is yellow, glistening to dull, smooth to densely rugoid.

Dalmay plate culture on corn meal agar: Pseudomycelium and true mycelium are abundantly formed. Hyphae and pseudohyphae are often wavy in appearance. Branching is characteristically at narrow angles resulting in branches that are almost parallel to the main axes, as seen through the bottom of the plate. The ovoidal blastoconidia may form laterally on small terminal hyphal projections. (Fig. 389).

Fermentation: absent.

Co-Q: 9 (type strain); 9 (Yamada and Kondo 1972a).

Mol% G + C: 58.8–63.2, 3 strains (T_m : Nakase and Komagata 1971f).

Cell hydrolyzates: Glucose, mannose, xylose, galactose, glucuronic acid (von Arx and Weijman 1979).

Fig. 389. *C. humicolus*, CBS 571. Cells grown on potato-dextrose agar at 25°C for 2 weeks. Bar = 10 μ m.

Origin of the strain studied: Soil (1).

Type strain: CBS 571, isolated in Switzerland by Daszewska (1912) from heath soil.

Comments: In contrast to previous editions of “The Yeasts”, *Apiotrichum porosum* is no longer considered a synonym of *C. humicolus*. The decision is based on LSU rRNA nucleotide sequence analyses (Fell et al. 1992) and the lack of yeastlike morphology of *A. porosum*. The hyphae lack blastospores and the colony has a fuzzy appearance due to the presence of tufts of aerial hyphae. Molecular sequence analysis of the LSU rRNA suggests that *C. humicola* is related to members of the genus *Trichosporon* (Guého et al. 1993).

Strains reported from other sources include: culture contaminant (1); mushrooms (2); decaying toadstools (2); skin (2); water (1). Nakase and Komagata (1971f) reported isolating strains from strawberries and moss.

94.21. *Cryptococcus hungaricus* (Zsolt) Phaff & Fell (1970)

Synonym:

Dioszegia hungarica Zsolt (1957)

Growth in 5% malt extract: After 3 days at 17°C, the cells are globose to ovoidal, (4.0–5.4) × (6.0–8.7) μ m, and are single, in pairs or in small clusters; budding is multilateral and occasionally a bud is connected to the parent cell by a very short neck. A slight ring and a little sediment may be present. After one month there is a moderate brownish-red ring or islets and some sediment.

Growth on 5% malt agar: After one month at 20°C, the streak culture is reddish to slightly orange, semi-glossy, smooth, pasty with an entire margin.

Dalmay plate culture on corn meal agar: Pseudomycelium is absent.

Fermentation: absent.

Co-Q: Not determined.

Mol% G+C: 54.4 (T_m : Nakase and Komagata 1971c).

Cell hydrolyzates: Xylose, mannose low (Weijman and Rodrigues de Miranda 1988).

Origin of the strain studied: Medlar fruit (*Mespilus* sp.), isolated by G. Protii in Italy in 1953 (CBS 1926).

Type strain: CBS 1926.

Comments: Strains were also isolated from trachea rinsings of a patient by G.A. de Vries in the Netherlands, 1955 (CBS 2289); a strain of unknown origin (CBS 4234) contributed by G. Ricci (Rome, Italy); air in the Netherlands by A. Kikstra (CBS 6086) and dog's skin in the Netherlands by E.A.R.F. Baudet (CBS 922). After the completion of this manuscript, nucleotide sequence analysis in our laboratory (unpublished) indicates that *C. kuetzingii* is closely related to *C. albidus*.

94.23. *Cryptococcus laurentii* (Kufferath) C.E. Skinner (1950)**Synonyms:**

Torula laurentii Kufferath (1920)

Torulopsis laurentii (Kufferath) Lodder (1934)

Torula aurea Saito (1922)

Chromotorula aurea (Saito) F.C. Harrison (1928)

Rhodotorula aurea (Saito) Lodder (1934)

Torula flavescens Saito (1922)

Torulopsis flavescens (Saito) Lodder (1934)

Cryptococcus flavescens (Saito) C.E. Skinner (1947b)

Cryptococcus laurentii (Kufferath) C.E. Skinner var. *flavescens* (Saito)

Lodder & Kreger-van Rij (1952)

Rhodotorula laurentii (Kufferath) Hasegawa, Banno & Yamauchi (1960)

Torulopsis carnescens Verona & Luchetti (1936)

Rhodotorula peneaus Phaff, Mrak & Williams (1952)

Rhodotorula nitens Mackenzie & Auret (1963)

Growth in 5% malt extract: After 3 days at 25°C, the cells are spheroidal to ovoidal to elongate and are single, in pairs or in short chains of three or four cells. Cell sizes are (2.0–5.5) × (3.0–7.0) µm; some strains may have elongate cells which measure 8.5 × 13 µm. A thin ring, a moderate sediment and sometimes islets are present. After one month a moderate to thick slimy ring and a heavy sediment are present; a pellicle or islets may form.

Growth on 5% malt agar: After one month at 20°C, the streak culture is cream-colored, yellowish, pinkish, orange or tan colored. The surface is smooth and glossy, sometimes pasty (not mucoid); in most strains the texture is slimy so that the growth runs to the bottom of the slant. The margin is entire to lobate.

Dalmou plate culture on corn meal agar: Pseudomycelium is absent or rudimentary.

Fermentation: absent.

Mol% G+C: 51.2–59.0 (T_m : Nakase and Komagata 1971c); 58 (BD: Storck et al. 1969); 59.7 (BD: Baptist and Kurtzman 1976).

Cell hydrolyzates: Xylose, mannose low (Weijman and Rodrigues de Miranda 1988).

Origin of the strains studied: Palm wine isolated by Kufferath (1920) from "malafou" or palm wine from the Congo; wheat and corn isolated by Kurtzman (1973).

Type strain: CBS 139.

Comments: Strains were also isolated from other sources: Italian muscatel wine (1), bottle in brewery (1), slime flux of oak (1), tumor (1), bronchial tube of patient (1), leaves of tropical plants (4), insect frass in *Acacia karroo* (1), sea water (1), air (3), deep frozen beans (1), shrimp (1), soil (3) and beech-forest soil, Denmark (7).

Strains of opposite mating types from wheat and corn (CBS 6473, CBS 6474: MT- α and CBS 6475, CBS 6476: MT- α) were isolated and described by Kurtzman (1973). After conjugation, the zygote formed true mycelium with chlamydospore-like structures that lacked clamp connections. The complete life cycle was not determined. *C. laurentii*, as noted by strain differences in mol% G+C, is genetically heterogenous. This heterogeneity was confirmed by Guého et al. (1993) who reported differences in nucleotide sequence analysis of the mating strains and the type strain of *C. laurentii*.

94.24. *Cryptococcus luteolus* (Saito) C.E. Skinner (1950)

Synonyms:

Torula luteola Saito (1922)

Chromotorula luteola (Saito) F.C. Harrison (1928)

Torulopsis luteola (Saito) Lodder (1934)

Rhodotorula luteola (Saito) Hasegawa, Banno & Yamauchi (1960)

Growth in 5% malt extract: After 3 days at 25°C, the cells are ovoidal to elongate, (3.1–6.0) × (5.5–9.0) μ m, and are single, in pairs or short chains; a ring begins to form and a light sediment is present. After one month a moderate amount of sediment and a ring are present. A thin film may also form.

Growth on 5% malt agar: After one month at 20°C, the streak culture is cream-colored to yellowish or tan to gray-brown. The surface is smooth and glossy, the texture slimy so that the growth runs to the bottom of the slant. The margin is entire.

Slide culture on potato agar: Pseudomycelium is absent or chains of cells are formed.

Fermentation: absent.

Co-Q: 10 (Yamada and Kondo 1973).

Mol% G+C: 59.5 (T_m : Nakase and Komagata 1971c).

Cell hydrolyzates: Xylose, mannose low, hexitol (probably mannitol) (Weijman and Rodrigues de Miranda 1988).

Origin of the strains studied: Air in Tokyo by K. Saito (1); foliage of tropical plants (2); coastal waters of the Bahamas by J. Fell (12); acidic sludge in the Netherlands by A.M. Jansen (1).

Type strain: CBS 943, from the air in Tokyo in 1922.

94.25. *Cryptococcus macerans* (Frederiksen) Phaff & Fell (1970)

Synonyms:

Rhodotorula macerans Frederiksen (1956)

Rhodotorula lini Wieringa (1956)

Cryptococcus hungaricus (Zsolt) Phaff & Fell var. *gallicus* Saëz (1973b)

Growth in 5% malt extract: After 3 days at 25°C, the cells are ovoidal or long-ovoidal, single or in pairs, (3.0–4.5) × (5.0–15.0) μm. A thin ring and some sediment are present. After one month a moderate to heavy, slimy reddish ring and a heavy sediment are formed; islets may develop.

Growth on 5% malt agar: After one month at 20°C, the streak culture is bright coral-red to pink-peach, surface nearly smooth with some rugose or sectored areas, and glossy with entire margins. The texture is pasty.

Dalmou plate culture on corn meal agar: Pseudomycelium absent or rudimentary.

Fermentation: absent.

Co-Q: 8 (Guého et al. 1993, Yamada and Kondo 1973).

Mol% G + C: 61.2 (PC: Golubev and Vagabova 1977).

Cell hydrolyzates: Xylose, mannose low (Weijman and Rodrigues de Miranda 1988).

Origin of the strains studied: Dew-retted flax, Denmark (3); pharynx of deer, *Axis axis* (2); flowers, Canada (2); spring water in California, USA (1), slime flux of elm (*Ulmus carpiniifolia*) in California, USA.

Type strain: CBS 2206, isolated by Frederiksen (1956) from field-retted flax straw in Denmark. This species formed the major proportion of the red yeasts on this substrate, particularly during the winter months.

Comments: Mating types were reported by Rodrigues de Miranda (1984d); CBS 2206 and CBS 6532 are of one type (*a*), CBS 2425 and CBS 2426 of the opposite

type (*α*). Rodrigues de Miranda did not describe a complete life cycle for this species; mating studies in our laboratory were unsuccessful. According to nucleotide sequence analysis (Guého et al. 1993), this species may be related to *Cystofilobasidium*; this relationship is also suggested by the presence of Co-Q 8, which is found in *Cystofilobasidium*.

94.26. *Cryptococcus magnus* (Lodder & Kreger-van Rij) Baptist & Kurtzman (1976)

Synonym:

Cryptococcus laurentii (Kufferath) C.E. Skinner var. *magnus* Lodder & Kreger-van Rij (1952)

Growth in 5% malt extract: After 3 days at 25°C, the cells are ovoidal to elongate, (3.5–15.0) × (4.5–45.0) μm, single, in pairs or in short chains of up to six cells. A ring begins to form and a little sediment is present. After one month a moderate ring and a fair amount of sediment are formed.

Growth on 5% malt agar: After one month at 19°C, the streak culture is cream-colored to tan. The surface is smooth, highly glossy and the texture slimy, so that the growth runs to the bottom of the slant. The margin is entire.

Slide culture on potato agar: Pseudomycelium is absent.

Fermentation: absent.

Assimilation:

5-Keto-D-gluconate	n	Urease	+
Saccharate	+	Gelatin liquefaction	–
D-Glucuronate	+	Growth at 30°C	+
50% (w/w) glucose-yeast extract agar	–	Growth at 37°C	–
10% NaCl/5% glucose	–		

Co-Q: 10 (Yamada and Kondo 1973).

Mol% G + C: 49.0 (BD: Storck et al. 1969); 54.1 (BD: Baptist and Kurtzman 1976).

Cell hydrolyzates: Xylose, mannose low, hexitol (probably mannitol) (Weijman and Rodrigues de Miranda 1988).

Origin of the strain studied: Atmosphere in the Netherlands.

Type strain: CBS 140, isolated by Sobels in 1943 from the atmosphere.

Comments: *C. laurentii* var. *magnus* was described by Lodder and Kreger-van Rij (1952) as distinct from *C. laurentii* var. *laurentii* on the basis of differences in cell morphology: the cells of var. *magnus* were found to be larger than those of var. *laurentii*, although Phaff and Fell (1970) could not separate them on this characteristic nor did we see the elongated cells. Baptist and Kurtzman (1976) raised the taxon to the rank of species based on differences in G+C content and comparative enzyme patterns. *C. magnus* can be separated from *C. laurentii* based on the inability of *C. magnus* to grow on melibiose and ribitol. Based on nucleotide sequence analysis (Yamada et al. 1990a), *C. magnus* may be related to *C. ater*, an observation that we have confirmed in our laboratory (unpublished).

94.27. *Cryptococcus marinus* (van Uden & Zobell) Golubev (1981)

Synonym:

Candida marina van Uden & Zobell (1962)

Growth in glucose–yeast extract–peptone water: After 3 days at 25°C, the cells are ovoidal to elongate, (2.7–6) × (5.4–12) µm, and may be single, in pairs or in chains. After one month, a dull pellicle and heavy sediment are present.

Growth on glucose–yeast extract–peptone agar: After one month at 25°C, the streak culture is cream to brownish-yellow, dull, soft, smooth.

Dalmeu plate culture on corn meal agar: The pseudomycelium may be primitive or consist of long wavy pseudohyphae bearing, globose and ovoidal, often curved cells that are often terminal or sometimes lateral on short pedicels (Fig. 390).

Fermentation: absent.

Fig. 390. *C. marinus*, CBS 5235. Cells grown on corn meal agar at 25°C for 2 weeks. Bar = 5 µm.

Assimilation:

Co-Q: 10 (Yamada and Kondo 1972a).

Mol% G+C: 64.0 (T_m : Stenderup et al. 1972); 61.2 (T_m : Nakase and Komagata 1971c).

Cell hydrolyzates: Xylose, mannose low, hexitol (probably mannitol) (Weijman and Rodrigues de Miranda 1988).

Origin of the strain studied: Seawater over coral and algal growth at the Great Barrier Reef, Torres Strait, Australia during July and August, 1960 (van Uden and Zobell 1962).

Type strain: CBS 5235.

Comments: Van Uden and Zobell (1962) did not indicate a type culture; van Uden and Buckley (1970) designated the strain listed above.

94.28. *Cryptococcus neoformans* (Sanfelice) Vuillemin (1901)

See *Filobasidiella neoformans* p. 656

94.29. *Cryptococcus podzolicus* (Bab'eva & Reshetova) Golubev (1981)

Synonym:

Candida podzolica Bab'eva & Reshetova (1975)

Growth in 5% malt extract: After 3 days at 25°C, the cells are polymorphic, including obpyriform, ovoidal, spheroidal to elongate, measuring (3.4–4.7) × (5.4–8.7) µm. They occur singly, in pairs and may bear lateral or polar elongate appendages. A light sediment is present. After one month a heavy sediment and a ring are present (Fig. 391).

Fig. 391. *C. podzolicus*, CBS 6819. Cells grown on glucose-yeast extract water at 25°C for one week. Bar = 10 μm.

Growth on 5% malt extract agar: After one month at 25°C, the streak colony is white to cream or tan-colored, the surface is very rugoid, and the margin is fringed with true and pseudomycelium.

Dalmu plate culture on corn meal agar: True and pseudomycelium are present; buds are produced on short or elongate conidiophores.

Fermentation: absent.

Assimilation:

50% (w/w) glucose-yeast extract agar	-	Growth at 25°C	+
10% NaCl/5% glucose	-	Growth at 30°C	-

Co-Q: Not determined.

Mol% G+C: 62.8 (Bab'eva and Reshetova 1975).

Extracellular polysaccharides: Glucose, galactose, mannose and xylose (Bab'eva and Reshetova 1975).

Origin of the strain studied: From a sod-podzolic soil in a birch forest (Chashnikov, Solnechnogorsk district, Moscow Province, Russia).

Type strain: CBS 6819 (Bab'eva and Reshetova strain BKM Y-1982).

Comments: Bab'eva and Reshetova (1975) sampled the main soil and climatic zones of the European part of the Soviet Union, the Siberian North and the mountainous regions of the Pamirs, the Tien Shan, the Caucasus, the Crimea and the Altai (Lake Teletskoe region). They reported finding this species in podzolic and sod-podzolic soils in the taiga zone but not in the tundra. They also found it in bog and meadow (flood plain) soils of the same zone and farther south in the gray forest soils, as well as in red earth (Georgia) and brown forest soils in a pine forest in the Lake Teletskoe region. *C. podzolicus* was not found in black earth, nor chestnut soils, nor mountain soils of the Pamirs, the Tien Shan and the Crimea. They found the species in the soils and not on plants, from studies throughout the year. Sampaio and Fonseca (1995) reported several strains of *C. laurentii*, also isolated from soil, which are physiologically related to *C. podzolicus*.

We were unable to confirm the following assimilation test results from the original description: assimilation of sorbitol and salicin, negative, as well as starch production; assimilation of ribitol, positive and slow.

94.30. *Cryptococcus skinneri* Phaff & do Carmo-Sousa (1962)

Growth in 5% malt extract: After 3 days at 25°C, the cells are ovoidal to globose, (3.4–6.7) × (4.0–7.4) μm, single or in pairs. A light sediment is present after one month.

Growth on 5% malt agar: After one month at 25°C, the streak culture is white to cream-colored, smooth, glossy, slightly mucoid, raised and the margin is entire.

Dalmu plate culture on corn meal agar: Pseudomycelium is absent.

Fermentation: absent.

Co-Q: Not determined.

Mol% G+C: 53.0 (BD: Storck et al. 1969).

Cell hydrolyzates: Xylose, mannose low (Weijman and Rodrigues de Miranda 1988).

Origin of the strain studied: Insect frass underneath the bark of a young dying specimen of the Pacific coast hemlock (*Tsuga heterophylla*) located on the bank of the Siletz River in NW Oregon (Phaff and do Carmo-Sousa 1962).

Type strain: CBS 5029 (Phaff and do Carmo-Sousa strain UCD FST60-82).

Comments: Strains were also isolated from slime fluxes of willow (*Salix*) and aspen (*Populus*) spp. in Alaska, Yukon Territory and British Columbia.

94.31. *Cryptococcus terreus* di Menna (1954b)**Synonyms:**

Cryptococcus himalayensis S. Goto & Sugiyama (1970)

Cryptococcus elinovii Golubev & Tauson (1979)

Growth in 5% malt extract: After 3 days at 25°C, the cells are mainly globose or short-ovoidal, single, in pairs or short chains, (3.5–6.5) × (4.0–8.0) µm. A light ring and a small amount of sediment may be present. After one month at 25°C, a moderate ring and a moderate to heavy sediment are formed. At 19°C in 2% glucose-peptone-yeast extract-water, a few cells were seen to bud on short stalks (Fig. 392).

Growth on 5% malt agar: After one month at 19°C, the streak culture is brownish cream-colored or yellowish-tan. The surface is smooth, glossy, and the texture is in some strains soft but not mucoid, in other strains the growth

is so mucoid that it runs to the bottom of the slant. The margin is entire.

Dalmat plate culture on corn meal agar: Pseudomycelium absent.

Fermentation: absent.

Assimilation:

5-Keto-D-gluconate	+	Urease	+
Saccharate	+	Gelatin liquefaction	-
D-Glucuronate	+	Growth at 30°C	+
50% (w/w) glucose-yeast extract agar	-	Growth at 37°C	-
10% NaCl/5% glucose	w		

Co-Q: 10 (Yamada and Kondo 1973).

Mol% G+C: 59.5, *C. terreus* strain, CBS 1895 (BD: Storck et al. 1969); 54.7 (T_m : Vancanneyt et al. 1994); 57–58, *C. elinovii* strains (paper chromatography: Golubev and Tauson 1979); 55.4, 55.7 (paper chromatography: Golubev and Vagabova 1977, Golubev and Tauson 1979); 58.0, *C. himalayensis* strain (T_m : Baharaeen et al. 1982).

Cell hydrolyzates: Xylose, mannose low (Weijman and Rodrigues de Miranda 1988).

Origin of the strains studied: Soil in New Zealand by di Menna (18); type strain of *C. himalayensis*, CBS 6293, from soil sample from Chawa Gassar, Bhutan, May 1967, by H. Kanai; type strain of *C. elinovii*, CBS 7051, from soil on a high mountain in U.S.S.R. by Golubev.

Type strain: CBS 1895, isolated from soil in New Zealand, obtained from di Menna.

Comments: *Cryptococcus himalayensis* was described by Goto and Sugiyama (1970) as a separate species, because of the ability to assimilate sucrose, raffinose, and melezitose and the inability to assimilate maltose. Repeated tests by Rodrigues de Miranda (1984d) proved the opposite and this species fits the standard description for *Cryptococcus terreus*. A synonymous relationship between *C. elinovii* and *C. himalayensis* is evident when nuclear sequences are compared (Fell et al. 1992). The nuclear sequence alignment results also show a close relationship of *C. fuscescens* to *C. terreus*.

Fig. 392. *C. terreus*, CBS 1895. Cells with buds on short stalks grown in glucose-yeast extract water for one week at 19°C. Bar = 10 µm.

Strains were also isolated from desert soil in Chile by di Menna (3); soil in Belgian forest by L. Hennebert; soil in New York by S. Gochenaer, 1974; soil in northern California by Phaff (1); and from gut contents of trout caught in northern California by Spencer and Phaff (2).

94.32. *Cryptococcus uniguttulatus* (Zach) Phaff & Fell (1970)

See *Filobasidium uniguttulatum* p. 667

94.33. *Cryptococcus vishniacii* Vishniac & Hempfling (1979)

Synonyms:

Cryptococcus asgardensis Vishniac & Baharaeen (1982)

Cryptococcus baldrensis Vishniac & Baharaeen (1982)

Cryptococcus hempflingii Vishniac & Baharaeen (1982)

Co-Q: 9 (Vishniac and Baharaeen 1982).

Mol% G + C: 53.48–56.09 (T_m : Baharaeen and Vishniac 1982, Vishniac 1985a).

Cell hydrolyzates: Not determined.

Origin of the strains studied: Soils of the Dry Valleys, South Victoria Land, Antarctica, collected in 1973 by W.V. Vishniac and Z. Bowen: type strain of *C. asgardensis*, CBS 8141 (MYSW 302Y310); type strain of *C. baldrensis*, CBS 8142 (SW 302Y259); type strain of *C. hempflingii*, CBS 8143 (MYSW 306Y212); type strain of *C. lupi*, CBS 8100 (MYSW 202Y252); type strain of *C. tyrolensis*, CBS 8144 (MYSW 303Y336); type strain of *C. wrightensis*, CBS 8145 (MYSW 303Y206); type strain of *C. vishniacii* var. *asocialis*, CBS 8146 (MYSW 302Y312); type strain of *C. vishniacii* var. *vladimirii*, CBS 6810 (MYSW 302Y265); type strain of *C. vishniacii* var. *wolfii*, CBS 6812 (MYSW 303Y216).

Type strain: CBS 7110 (MYSW 304Y268), soil isolate (sandstone, sand) from Mt. Baldr, South Victoria Land, Antarctica.

Comments: According to the original description, optimal growth except for the type strain is 10°C, and 20°C for the other strains. We recommend 5°C for short term storage and cryopreservation for long term storage. The basis for the species listed in synonymy with *C. vishniacii* is similarity in nucleotide sequences (Fell et al. 1992, Guého et al. 1993) and results of standard taxonomic tests.

94.34. *Cryptococcus yarrowii* A. Fonseca & van Uden (1991)

Growth in 5% malt extract: After 3 days at 25°C, the cells are elongate cylindrical to fusiform, (1.1–2.7) × (3.2–7.4) μm, and reproduce predominantly by polar budding. They may be single, in pairs or in short chains. A slight sediment is formed. After one month, both a ring and sediment are present.

Growth on 5% malt agar: After one month at 25°C, the colony is white to cream-colored, slightly raised, semi-glistening, butyrous, and the margin is entire.

Dalmat plate culture on corn meal agar: Rudimentary pseudomycelium is present.

Fermentation: absent.

Co-Q: 10 (Fonseca and van Uden 1991).

Mol% G+C: 60.3 (T_m : Fonseca and van Uden 1991).

Cell hydrolyzates: Mannose, glucose, mannitol, rhamnose, galactose, xylose, inositol and arabitol.

Origin of the strain studied: From a decaying mushroom collected in a woods, Lisbon, Portugal, 1988.

Type strain: CBS 7417 (Fonseca and van Uden strain IGC 4525).

Comments: Sequence analysis of a partial region of the LSU rDNA in our laboratory indicates that *C. yarrowii* is a member of the genus *Rhodotorula* and that the cell wall analysis should be re-evaluated.

Comments on the genus

The generic name *Cryptococcus* was introduced by Kützing (1833) for an organism observed from dried scrapings collected from a window sill. Kützing's description was "Globuli museosi hyalini non colorati, in stratum determinatum mucosum facile secedens sine oidine aggregati". The organism was placed among the algae and a description of the only species, *C. mollis* Kützing, was not presented. In 1901, Vuillemin introduced the concept that *Cryptococcus* should be characterized by pathogenic yeasts and he transferred *Saccharomyces*

neoformans Sanfelice 1895 to *Cryptococcus*. The history of the genus and the confusion caused by the two definitions of *Cryptococcus* can be found in Benham (1935), Lodder (1938), Skinner (1950) and Rodrigues de Miranda and Batenburg-van der Vegte (1981). In the meantime, nomenclature of the pathogen *Cryptococcus neoformans* was widely accepted by the medical community. Stability of that nomenclature was in question as taxonomic separations of *Torulopsis*, *Candida*, *Cryptococcus* and *Rhodotorula* came under scrutiny and von Arx and Weijman (1979) recommended the transfer of *C. neoformans* to *Apiotrichum*. In order to conserve the genus and retain stability of the binomial nomenclature of *C. neoformans*, the genus *Cryptococcus* Vuillemin was conserved with the type species *C. neoformans* (Fell et al. 1989, Greuter et al. 1994).

The first edition of "The Yeasts" (Lodder and Kreger-van Rij 1952) defined *Cryptococcus* as: cells surrounded by a capsule, formation of starch-like compounds, absence of pseudomycelium, inability to ferment and the lack of carotenoid pigments. Five species were accepted in the genus. The only change in the generic description through the 3rd edition of "The Yeasts" was the capacity of *Cryptococcus* species to assimilate inositol. *Cryptococcus* grew to 19 species. The major informative step, by this time, was the relationship of some species to the teleomorphic genera *Filobasidium* and *Filobasidiella*. The greatest pressure on *Cryptococcus* taxonomy was the retention of the ascomycetous species in *Candida* and the separation of basidiomycetous *Candida* species based on the composition of cell hydrolyzates (Weijman and Rodrigues de Miranda 1983). Species with xylose were incorporated into *Cryptococcus* and those species that lacked xylose were relegated to *Rhodotorula*. As a result, *Cryptococcus* expanded to 34 species.

The genus, as currently defined, is polyphyletic with tenuous boundaries based on a combination of abilities to utilize inositol and D-glucuronate and to synthesize starch (Table 74). This polyphyletic nature will have to be examined by a combination of molecular and classical systematics, particularly in consort with other members of the Filobasidiaceae and Tremellaceae. The goal should be a classification based on phylogenetic relationships and not the separation into several genera based on one or more artificial taxonomic characters. The latter type of taxonomy merely adds names and confusion to the literature and consequently hinders the ability to undertake the practical application of taxonomy viz., species identifications.

Separation of the 34 species assigned to *Cryptococcus* requires 2 morphological observations and 21 physiological tests, generally more time and effort than one wishes to devote to a routine identification. Therefore, we split all the species represented in Tables 74 and 75 into four groups (Tables 76–79) based on starch synthesis and assimilation of inositol, D-glucuronate and nitrate. Using these compounds as an initial screen, followed by testing the compounds in the appropriate Tables 76–79, it

is possible to reduce the number of tests required for a routine identification.

An alternative to classical taxonomy is the use of molecular identifications from nucleotide sequence analyses. Through use of species-specific oligonucleotide sequences as a primer in a polymerase chain reaction, a species can be rapidly identified. A primer for *C. neoformans* has been described (Fell 1995, Haynes et al.

1995) and primers for all species should be available in the near future.

A study of the molecular systematics of the genus is currently underway in our laboratory; some of the results are included under the comments of the individual species, which indicate relationships between certain species. We anticipate that, with the completion of this study, some changes within the genus will have to be made.

95. *Fellomyces* Y. Yamada & Banno

I. Banno and Y. Yamada

Diagnosis of the genus

Cells are spherical to ellipsoidal and produce one or more stalks, each giving rise to a single conidium. The conidium is freed without forceful ejection at the distal end of the stalk (Table 80). The stalks get longer than 4.0 µm. True mycelia may or may not be produced. Ballistoconidia are not formed.

Glucose is not fermented. Nitrate is not assimilated. Diazonium blue B color reaction is positive. Xylose is present in the cells. The coenzyme Q-10 system is present. D-Glucuronate and *myo*-inositol are assimilated.

Table 80

Salient characteristics differentiating the anamorphic stalked conidium-forming yeast genera *Fellomyces*, *Kurtzmanomyces*, *Sterigmatomyces* and *Tsuchiyaea*

Genus	Reproduction	CoQ system	Xylose in cells
<i>Fellomyces</i>	Conidium separated at distal end of long stalk	Q-10	+
<i>Kurtzmanomyces</i>	Conidium separated at distal end of long stalk, branching and elongating to form additional conidia	Q-10	-
<i>Sterigmatomyces</i>	Conidium disjointed in mid-region of short stalk	Q-9	-
<i>Tsuchiyaea</i>	Enteroblastic bud and conidium disjointed in mid-region of stalk	Q-9	+

Type species

Fellomyces polyborus (D.B. Scott & van der Walt) Y. Yamada & Banno

Species accepted

1. *Fellomyces fuzhouensis* (Yue) Y. Yamada & Banno (1988)
2. *Fellomyces horovitziae* Spaaij, Weber & Oberwinkler (1991)
3. *Fellomyces penicillatus* (Rodrigues de Miranda) Y. Yamada & Banno (1984)
4. *Fellomyces polyborus* (D.B. Scott & van der Walt) Y. Yamada & Banno (1984)

Key to species

See Table 81.

1. a Soluble starch and α-methyl-D-glucoside assimilated → 2
b Soluble starch and α-methyl-D-glucoside not assimilated → 3
- 2(1). a True mycelium present *F. penicillatus*: p. 770
b True mycelium absent *F. polyborus*: p. 771
- 3(1). a True mycelium present *F. fuzhouensis*: p. 769
b True mycelium absent *F. horovitziae*: p. 769

Table 81

Key characters of species in the genus *Fellomyces*

Species	Assimilation		True mycelium	Mol% G + C
	Soluble starch	α-Methyl-D-glucoside		
<i>Fellomyces fuzhouensis</i>	-	-	+	55.2, 54.0
<i>F. horovitziae</i>	-	-	-	54.2
<i>F. penicillatus</i>	+	w	+	48.9
<i>F. polyborus</i>	+	s	-	49.6

Systematic discussion of the species

95.1. *Fellomyces fuzhouensis* (Yue) Y. Yamada & Banno (Yamada et al. 1988a)

Synonyms:

Sterigmatomyces fuzhouensis Yue (1982)

Sterigmatomyces tursiopsis Kurtzman, Smiley, Johnson & Hoffman (Fell et al. 1984a) nom. nud.

Growth in malt extract: After 3 days at 25–30°C, the cells are spheroidal, (2.4–6) µm, ovoidal, (2.37–5.5) × (2.8–6.2) µm, or sometimes irregularly shaped. Conidia are produced on stalks measuring 4–15 µm (Fig. 393). The number of stalks is 1–8 or more. The stalks may be sympodially formed. The conidia may produce additional stalks, and conidia may form in branched chains of cells. The conidia are separated at the distal end of the stalks from parent cells. The conidium is pear-shaped or bottle-shaped. True mycelium may be produced. A ring, powdery pellicle and sediment are present.

Growth on malt agar: After 3 days at 25°C, the streak culture is cream-colored, pasty, with a dry, dull and wrinkled surface. The margin is crenulate. True mycelium and filamentous elongation of the cells occur. A variant frequently occurs, producing a smooth, glistening colony with an entire margin. The conidia may be produced on short stalks that give the appearance of budding cells.

Dalmau plate culture on corn meal agar: True mycelium (<2 µm wide) is branched with lateral and terminal stalks, rarely septate. Terminal conidia may develop from numerous stalks, resembling a penicillate head. Single or clustered blastoconidia may be produced on the hyphae.

Fermentation: absent.

Assimilation:

Co-Q: 10 (Yamada and Banno 1984a).

Mol% G+C: 54.0 (HPLC), type strain IFO 10374; 55.2 (T_m), CBS 6133.

Xylose in cells: Present.

Origin of the species: IFO 10374 (CBS 8243; NRRL Y-12916; 1519C) flower of mango, J.-Z. Yue, China; IFO 10205 (CBS 6133; NRRL Y-7956), type strain of *Sterigmatomyces tursiopsis* nom. nud., bottlenosed dolphin (*Tursiops truncatus*), D.G. Ahearn, USA.

Type strain: CBS 8243 (IFO 10374).

95.2. *Fellomyces horovitziae* Spaaij, Weber & Oberwinkler (1991)

Growth in 5% malt extract: After 5 days at 25°C, the cells are globose to ovoidal, (3.0–8.0) × (2.0–6.0) µm, reproduce by enteroblastic budding or by forming conidia on stalks. A sediment, ring, pellicle and islets are formed. After 4 weeks at 25°C, a sediment, ring and a creeping pellicle are present.

Growth on 5% malt extract agar: After 5 days at 25°C, the cells are globose, ellipsoidal to ovoidal, occasionally asymmetric, (2.5 × 6.0) × (2.0–6.0) µm. They occur singly or in pairs connected by stalks. They reproduce by enteroblastic budding or by forming conidia on stalks. The conidium detaches by disjunction at a septum in the distal region of the stalks. The mature conidia are clavate with a truncate base. They measure (2.0–4.0) × (1.5–2.5) µm. Parent cells are as a rule lipid-rich, forming 1–8 stalks. The size of the stalks is variable. The streak culture is mucoid, creamish-white with an entire margin. The culture surface is glistening with dull areas, caused by the formation of conidia on stalks.

Dalmau plate culture on corn meal agar: Neither hyphae nor pseudohyphae are formed.

Fermentation: absent.

Co-Q: 10 (Spaaij et al. 1991).

Mol% G+C: 54.2 (T_m : Spaaij et al. 1991).

Xylose in cells: Present (Spaaij et al. 1991).

Origin of the strain studied: Fruit-body of *Xenasmattella* sp. collected in May 1981, at Hagelloch (Hornkopf) near Tübingen, Germany.

Type strain: CBS 7515 (Spaaij's strain FS-H-0043).

Comments: This species was not part of the original manuscript as received from Banno and Yamada; consequently the description was included in this chapter by the editors. The description presented above was extracted from Spaaij et al. (1991). Data supplied by CBS differed as follows: soluble starch, +; L-arabinose, +; L-rhamnose, +; ribitol, s; α -methyl-D-glucoside, s; inositol, s; arbutin D, -; growth at 25°C, -. CBS reported a second strain, CBS 7727, from rotting wood, Uppsala Stadsskogen, Sweden, that was isolated in May 1985 by O. Constantinescu.

Spaaij et al. (1991) distinguished *Fellomyces horovitziae* from *F. fuzhouensis*, *F. penicillatus* and *F. polyborus* by physiological differences in the utilization of L-rhamnose, erythritol, ribitol, mannitol, galactitol, *myo*-inositol and D-gluconate. An additional diagnostic character is the formation of true hyphae by *F. penicillatus* and *F. fuzhouensis* in contrast to an absence of hyphae or pseudohyphae in *F. horovitziae*.

95.3. *Fellomyces penicillatus* (Rodrigues de Miranda) Y. Yamada & Banno (1984a)

Synonym:

Sterigmatomyces penicillatus Rodrigues de Miranda (1975)

Growth in malt extract: After 3 days at 24°C, the cells, (1–6)×(2–11) μ m, have a variety of shapes that may be spheroidal, ovoidal, obpyriform and apiculate and propagate by formation of blastic cells (conidia) at the top of stalks (Fig. 394). When attached to short hyphal strands, the cells are ventricose. The conidiogenous stalks (1–6 per cell) range in size from 0.5×(0.7–9) μ m. After 30 days the majority of the cells are (1–7)×(2–8) μ m with as many as 17 stalks per cell. The stalks range in size from 0.5×(0.7–35) μ m. Conidium separation is at the distal position where an adjacent septum is formed.

Growth on malt agar: After 3 days at 24°C, the cell sizes are similar to those in malt extract and the stalks (1–15 or more per cell) are simple or branched, with a length of 40 μ m or greater. The streak culture is dull, white to pale luteus, pasty, soft, and rugose with an irregularly crenulate border. Variation of colonies is frequently found which are smooth, glistening, soft, mucoid, raised, pale luteus to cream-colored with a border that is entire. The cells in these colonies are spheroidal to ovoidal, (2–3)×(3–4) μ m. Stalks are few in the smooth colony type, thus the cells have the appearance of typical budding yeast cells.

Dalmau plate culture on corn meal agar: Rugose colonies develop branched true mycelium (<2 μ m wide); cross walls are rare, stalks are lateral, short to elongated, with terminal conidia. The latter may develop numerous stalks with conidia to give the appearance of a penicillate head. Hyphae may also develop in the smooth colonies, however, the majority of the cells are similar to those on malt agar.

Fermentation: absent.

Fig. 394. *F. penicillatus*, IFO 10119. After 72 hours at 25°C in malt extract. Bar = 10 μ m.

Assimilation:

50% Glucose	-		

Co-Q: 10 (Yamada and Banno 1984a).

Mol% G + C: 48.9 (T_m), type strain (CBS 5492).

Xylose in cells: Present.

Origin of the strains studied: IFO 10119 (CBS 5492), contaminant on agar plate, G. Kraepelin, Germany; CBS 7046, birch tree, I.P. Bab'eva, U.S.S.R.; CBS 7152, woodland soil, J.P. van der Walt, South Africa.

Type strain: CBS 5492 (IFO 10119).

Comments: *Sterigmatomyces penicillatus* was considered to be a later, facultative synonym of *S. polyborus* by Jong and King (1977a), since the type strains of the two species were morphologically and physiologically similar. In contrast, Kurtzman (in Fell et al. 1984a) and Kurtzman (1990a) confirmed by DNA reassociation that *S. penicillatus* and *S. polyborus* are distinct. Yamada et al. (1986a,b) reported that the two species are separable at the specific level by electrophoretic patterns of seven enzymes. In this monograph, therefore, the authors regard *F. penicillatus* as a separate species on the basis of the low homology of DNA reassociation and of the different electrophoretic enzyme patterns from *F. polyborus*. The latter is distinguished morphologically from the former by absence of true mycelium.

95.4. *Fellomyces polyborus* (D.B. Scott & van der Walt) Y. Yamada & Banno (1984a)

Synonym:

Sterigmatomyces polyborus D.B. Scott & van der Walt (1970b)

Growth in malt extract: After 3 days at 24°C, the cells are spheroidal to ovoidal, (1.3–4.0) × (2.5–5.5) μ m. The cells may be single or reproduce by the formation of single conidia on stalks that range in size from 0.5 × (0.7–10) μ m (Fig. 395). After one month there may be as many as

15 stalks per cell. Newly formed cells generally separate at the distal end of stalks. Islets, a light ring and sediment are present.

Growth on malt agar: After 3 days at 24°C, the streak culture is restricted, dull, creamy-white, powdery, and rugose with irregularly crenulate margins. The cells are similar to those in malt extract. Variants are present that form colonies which are glistening, raised, smooth and pale luteus. The margin is entire. The encapsulated cells bear few short (<0.5 μ m in length) stalks. The cells appear similar to budding cells of the genus *Cryptococcus*.

Dalman plate culture on corn meal agar: Non-septate, hypha-like elongation of the cells occurs. Neither pseudomycelium nor true mycelium is present.

Fermentation: absent.

Type strain: CBS 6072 (IFO 10120).

Comments on the genus

Yeasts of the genus propagate mainly by conidiogenesis. A conidiogenous cell develops slender projections, on which a conidium is vegetatively produced. The conidia are never forcibly discharged. Fell (1966) and Fell et al. (1984a) called the projection bearing the conidium, "sterigma". The term "sterigma" should be strictly used for the ballistospore-bearing projection according to Snell

and Dick (1957). Here, the term "stalk" is used for the projection. Nakase et al. (1989b) applied the term "non-ballistosporous conidium" to a conidium produced on the stalk. However, "non-ballistosporous conidium" does not specify this type of conidium as all blastoconidia are implied by this term. In this monograph, consequently the term "stalked conidium" is used for the conidium produced on a stalk and disjointed at the mid-region or at the distal position of the stalk according to van der Walt et al. (1987d) and Nakase et al. (1991b).

The stalked conidium-forming yeast genera *Fellomyces*, *Kurtzmanomyces*, *Sterigmatomyces* and *Tsuchiyaea* are phylogenetically separate from each other at the generic level on the basis of the comparison of the partial sequences of 18S and 26S (or 25S) ribosomal RNAs (Yamada et al. 1989b, Guého et al. 1990). The genus *Sterigmatosporidium* appears not to be a perfect state of the genus *Fellomyces*, although the two genera share the following characteristics: the formation of conidia which are freed by an end-break in the stalks, coenzyme Q-10 and presence of xylose in the cells (Kraepelin and Schulze 1982, Fell et al. 1984a, Yamada et al. 1986a, 1988a).

96. *Hyalodendron Diddens*

G.S. de Hoog and M.Th. Smith

Diagnosis of the genus

Colonies are dry, farinose to velvety, and white to cream-colored. Budding cells and pseudomycelium are absent or rare. Hyphae are hyaline, coherent or locally disarticulating. Conidia arise in short chains and are ellipsoidal to cylindroidal with truncate ends.

Sugars are not fermented. Nitrate is not assimilated. *myo*-Inositol is assimilated. Urease reaction is positive. Diazonium blue B reaction is positive. Dolipores are present. Coenzyme Q-9 system is present. Xylose is present in cell walls.

Type species

Hyalodendron lignicola Diddens

Species accepted

1. *Hyalodendron lignicola* Diddens (1934)

Systematic discussion of the species

96.1. *Hyalodendron lignicola* Diddens (1934)

Synonyms:

Hyalodendron lignicola Diddens var. *undulatum* Diddens (1934)

Hyalodendron lignicola Diddens var. *simplex* Diddens (1934)

Growth on potato carrot agar: After 10 days at 20–22°C, colonies are dry, flat, farinose, white, and vaguely zonate. True hyphae are thin-walled, often flexuose, 1.5–2.5 µm wide, and profusely branched at acute angles. Conidia arise in lateral or terminal, mostly unbranched chains comprising up to 10 conidia; conidia are ellipsoidal with truncate ends or cylindroidal with slightly swollen median parts and measure (1.5–3.0) × (5–15) µm (Fig. 396). Pale olivaceous, firm-walled inflated cells up to 30 µm in diameter are occasionally present in old cultures.

Fermentation: absent.

Type strain: CBS 219.34.

Comments on the genus

The species sporulates well on nutritionally poor media. The rather coherent chains of conidia with truncate ends are characteristic.

The single species in this genus has long been regarded as a hyphomycete since it forms dry colonies with true

hyphae and mostly lacks budding cells. However, Martínez (1979) demonstrated a basidiomycetous nature on the basis of cell wall ultrastructure. The dolipore structure is identical to that known in the genus *Trichosporon* (Guého et al. 1992b). From partial 26S rRNA sequences, the species was found among other *Trichosporon* species (Guého et al. 1993). Also, the lack of fermentation and assimilation of many carbon compounds, indicates a close affinity to *Trichosporon*. The cell walls contain xylose (Weijman 1979a) which further indicates a tremellaceous relationship.

No teleomorph is known. De Hoog (1979a) described the occurrence of large, chlamydospore-like cells, of which the karyology has not yet been elucidated.

97. *Itersonilia* Derx

T. Boekhout

Diagnosis of the genus

Mycelium is hyaline, septate, and dikaryotic, or more rarely monokaryotic. Clamp connections are present in dikaryophase, but incomplete clamps occur in hyphal monokaryophase. Septa have dolipores without parenthesomes. Inflated cells ("sporogenous cells") are globose, subglobose, pyriform or ovoidal, and single or in clusters, terminal or intercalary, and thin to somewhat thick-walled. Ballistoconidia are bilaterally symmetrical, lunate or, more rarely, subpyriform, and formed either by germination of inflated cells or as secondary ballistoconidia. Germinating ballistoconidia give rise to appressoria. Chlamydospores are sometimes present. Monokaryophase is mostly yeastlike.

Sugars are not fermented. Diazonium blue B and urease reactions are positive. Xylose is present in whole-cell hydrolyzates. The major ubiquinone is Q-9.

Type species

Itersonilia perplexans Derx

Species accepted

1. *Itersonilia perplexans* Derx (1948)

Systematic discussion of the species

97.1. *Itersonilia perplexans* Derx (1948)

Synonyms:

Itersonilia pyriformans Nyland (1949)

Itersonilia pastinacae Channon (1963)

Description of the hyphal phase on yeast-peptone-glucose agar:

After 5 days at 20°C, colonies are flat or somewhat raised, dull, cream, arachnoid to velutinous, with aerial fascicles, and with the margin entire or eroded. Hyphae are regularly branched, with cells of (50–120) × (2.0–7.0) μm. Inflated cells ("sporogenous cells") are intercalary or terminal on hyphae or hyphal branchlets, single or in clusters (10.0–18.0) × (8.0–15.0) μm, and germinating with hyphae or sterigmata (Fig. 397A). Ballistoconidia are bilaterally symmetrical, lunate to subpyriform (10.0–22.0) × (6.0–14.0) μm, and germinate with secondary ballistoconidia or appressoria. Appressoria are stalked or not, ellipsoid, circular or elongate in outline, and usually with dichotomously lobed margin (Fig. 397B). Chlamydospores are sometimes present and are subglobose (13.0–20.0) × (10.0–14.0) μm.

Growth of yeast phase on 5% malt extract agar:

After 7 days at 17°C, the cells are ellipsoidal, allantoid, cylindrical or fusiform (9.0–40) × (3.0–11.0) μm, and single (Fig. 398A). Budding is usually polar, sometimes lateral, sessile or on short denticles, and with sympodial or percurrent proliferation. Occasionally, cells grow with short hyphae or revert to monokaryotic hyphae with incomplete clamp connections and may have inflated cells and chlamydospores. Colonies are butyrous or rather dry, smooth, transversely ridged or reticulate, shiny or dull, pale yellowish-brown, and with the margin entire, straight or crenulate.

Growth on the surface of assimilation media (glucose):

Absent, but a sediment is formed.

Dalmau plate culture on corn meal agar:

After

7 days at 17°C, pseudohyphae may be present (Fig. 398B). Yeast phases sometimes revert to monokaryotic hyphae, which form incomplete clamp connections, inflated cells, ballistoconidia and chlamydospores. Aerobic growth is cream to pale yellowish-brown, dull or shiny, butyrous or rather dry, flat or slightly raised, smooth, transversely ridged or reticulate, with the margin entire, straight or crenulate. The colonies of reverted monokaryotic hyphal strains are whitish to cream, velutinous to hirsute, and morphologically indistinguishable from those of the dikaryotic phase.

Formation of ballistoconidia: Ballistoconidia are formed abundantly by both the di- and monokaryotic hyphal phases, are bilaterally symmetrical, lunate, ovoidal or subpyriform, and measure (10.0–22.0) × (6.0–13.5) μm.

Fig. 397. *I. perplexans*, CBS 363.85. (A) Dikaryotic hyphae with inflated cells. (B) Appressoria. Bar = 5 μm.

Fig. 398. *I. perplexans*, CBS 363.85. (A), (B) Yeast cells on MEA and morphological agar, respectively. (C) Ballistospores of the dikaryophase (MEA). Bar = 5 μ m.

Bilaterally symmetrical ballistoconidia are occasionally formed by yeast cells (Fig. 398).

Fermentation: absent.

Co-Q: 9, CBS 144.68, 286.50, 197.53, 356.64 (Yamada and Konda 1984).

Mol% G+C: 60.1–63.9, eleven strains (T_m : Boekhout et al. 1991b).

Origin of the strains studied: CBS 197.53Y, yeast phase isolated from CBS 197.53, parsnip (*Pastinaca sativa*), G. Sowell, U.S.A; CBS 144.68Y, yeast phase isolated from CBS 144.68, air, A. Kikstra, Netherlands; CBS 363.85, wood of beech (*Fagus sylvatica*), C.T. Ingold,

Great Britain, and CBS 363.85Y, yeast phase isolated from CBS 363.85; PD 85/1013Y, yeast phase isolated from PD 85/1013, curly kale (*Brassica oleracea*), W. Loerakker, Netherlands.

Complementary mating types: Four *A* and two *B* factors have been identified and were arbitrarily assigned as follows: A_1B_1 (CBS 363.85Y, CBS 144.68Y, PD 85/1013Y), A_1B_2 (CBS 197.53Y and PD 87/693Y), A_2B_2 (isolate “Boekhout”Y), A_3B_2 (PD 85/1007Y) and A_4B_2 (CBS 286.50Y) (Boekhout 1991b).

Type strain: CBS 363.85 (neotype, designated by Boekhout et al. 1991b).

Comments on the genus

Itersonilia perplexans is characterized by the presence of hyphae with clamp connections, inflated cells (“sporegenous cells”), and ballistoconidia. No teliospores occur. The species inhabits the phyllosphere, and dikaryotic strains of *Itersonilia* are reported to be pathogenic to parsnip (*Pastinaca sativa*) and chrysanthemums (*Chrysanthemum* sp.) (Channon 1956, 1963, Gandy 1966, Boekhout 1991b, Boekhout et al. 1991b). Isolates from parsnip were described as *I. pastinacae* (Channon 1963). However, “interspecific” matings, rather high DNA similarities and an intergrading morphology were observed (Boekhout 1991b, Boekhout et al. 1991b).

In mating experiments yeast strains were mixed thoroughly on Flegel’s conjugation medium (Flegel 1976), which was slightly modified as suggested by van der Walt (see Boekhout 1991b). Two or three streaks of the mixed strains were made on the agar surface. All mating experiments were performed at 17°C.

Yeast phases may be formed under different environmental conditions, e.g., high humidity or submerged growth. Yeast cells of *I. perplexans* have never been isolated from nature. Nitrate-assimilating and non-assimilating yeast strains were observed (Boekhout 1991b). *Itersonilia* seems to have a tetrapolar mating system, and the life cycle comprises dikaryotic hyphal phases, and monokaryotic yeast- and hyphal phases. No karyogamy has been observed (Olive 1952, Boekhout 1991b).

Tremellales affinity is supported by the presence of dolipores without parenthesomes (Kreger-van Rij and Veenhuis 1971a, Boekhout 1991b), the presence of xylose in whole-cell hydrolyzates (Boekhout 1987, Weijman and Golubev 1987), 5S rRNA nucleotide sequences (Gottschalk and Blanz 1985), and sensitivity to killer toxins of *Cryptococcus laurentii* (Golubev 1990a, Golubev and Kuznetsova 1989).

98. *Kockovaella* Nakase, Banno & Y. Yamada

T. Nakase and I. Banno

Diagnosis of the genus

Vegetative cells are spherical, short ovoidal, ovoidal or kidney-shaped, and reproduce by stalked conidia and ballistoconidia or, rarely, by budding cells. Ballistoconidia are globose, napiform, kidney-shaped or ellipsoidal.

Fermentation is absent. Diazonium blue B color test is positive. The major ubiquinone is Q-10. Xylose is present in the cells.

The teleomorph is unknown.

Type species

Kockovaella thailandica Nakase, Banno & Y. Yamada

Species	Assimilation of galactitol	Growth at 31°C	Mol% G + C		Ballistoconidia
			T_m	HPLC	
<i>Kockovaella imperatae</i>	+	–	52.3	49.0	globose, napiform
<i>K. thailandica</i>	–	+	49.5	47.7–48.4	kidney shaped, ellipsoidal

Systematic discussion of the species**98.1. *Kockovaella imperatae* Nakase, Banno & Y. Yamada (Nakase et al. 1991b)**

Growth in YM broth: After 3 days at 25°C, the cells are spherical to ovoidal, (1.5–5.9) × (4.0–10.0) μm. They propagate by conidiation on a sterigma-like stalk, and by budding. The conidia are produced holoblastically on a stalk which develops multilaterally and holoblastically from the parent cell. Occasionally chains or clusters of conidia are formed. Stalks measure 0.3–0.6 μm in width and 4–10 μm in length. Newly formed cells generally separate at the distal position of the stalk. A sediment is formed. After one month at 17°C, a fragile, incomplete pellicle and a sediment are present. There may be as many as 5 stalks on a cell.

Growth on YM agar: After one month at 17°C, the streak culture is grayish-yellow to grayish-orange, delicately wrinkled, dull, soft to butyrous and an entire margin. Stalked conidia and ballistoconidia are produced.

Dalmau plate culture on corn meal agar: Mycelium and pseudomycelium are not formed.

Production of ballistoconidia: Ballistoconidia are produced on corn meal agar and YM agar. They are

globose or napiform, (1.4–4.6) × (2.1–7.4) μm, and produced on sterigmata, which are generally 4.0–5.2 μm in length, but occasionally become much longer than 30 μm. Sterigma may be branched with a terminal ballistoconidium (Fig. 399).

Fermentation: absent.

Fig. 399. *K. imperatae*, CBS 7554. (A) Vegetative reproduction by conidiation on stalks produced by parent cells after 3 days at 24°C on YM agar. (B) Ballistoconidia ejected from a colony on corn meal agar after 5 days at 22°C. Some ballistoconidia produce secondary ballistoconidia. Bars = 10 μm.

Co-Q: 10 (Nakase et al. 1991b).

Mol% G + C: 52.3 (T_m); 49.0 (HPLC).

Xylose in cells: Present.

Origin of the strain studied: CBS 7554 (JCM 7826), a dead leaf of blady-grass (*Imperata cylindrica*), Nakase and Fungsin, Thailand.

Type strain: CBS 7554 (JCM 7826).

Comments: *K. imperatae* resembles *K. thailandica* in biochemical and physiological characteristics but can be separated by ballistoconidia morphology, which is symmetrical in the former and asymmetrical in the latter. DNA-DNA reassociation experiments clearly indicate the presence of two species (Nakase et al. 1991b).

98.2. *Kockovaella thailandica* Nakase, Banno & Y. Yamada (Nakase et al. 1991b)

Growth in YM broth: After 3 days at 25°C, the vegetative cells are spherical to ovoidal, (1.6–4.6) × (2.0–7.7) μ m, single, in pairs, or in clusters, and reproduce by conidiation or rarely by budding. Conidia are produced holoblastically on a sterigma-like stalk. Stalks develop multilaterally and holoblastically from a conidiogenous cell, rarely proliferate sympodially, and measure 4–15 μ m in length and 0.3–0.6 μ m in width. Newly formed cells generally separate at the distal position of stalks. Occasionally chains and clusters of stalked conidia are formed. A sediment is formed. After one month at 17°C, a fragile pellicle and a sediment are present. There may be as many as 12 stalks on a cells.

Growth on YM agar: After one month at 17°C, the streak culture is grayish-orange, smooth, shining, soft to mucoid, and has an entire margin. Stalked conidia and ballistoconidia are formed.

Dalmu plate culture on corn meal agar: Mycelium and pseudomycelium are not formed.

Production of ballistoconidia: Ballistoconidia are produced on corn meal agar and YM agar. They are kidney-shaped or ellipsoidal, (1.3–5.3) × (2.1–9.2) μ m, and formed on sterigma, which proliferate singly or in branches. The sterigmata occasionally become much longer than 30 μ m (Fig. 400).

Fermentation: absent.

(JCM 7825, IF0 10521), dead leaf of rice plant (*Oryza sativa*), Nakase and Fungsin, Thailand.

Type strain: CBS 7552 (JCM 7824).

Comments on the genus

Nakase et al. (1991b) proposed the genus *Kockovaella* based on three strains isolated from leaves of plants in Thailand. This genus is characterized by the formation of three kinds of conidia: stalked conidia, ballistoconidia,

and budding cells (blastoconidia); by the presence of xylose in the whole-cell hydrolyzate, and by ubiquinone Q-10. Partial sequences of 18S ribosomal RNA suggest a close phylogenetic relationship to *Fellomyces* species which produce neither ballistoconidia nor budding cells. The conidial characteristics of *Kockovaella* raise the question of the taxonomic significance of mode of conidiogenesis as a criterion for description of genera or higher taxa, and this issue was discussed by Nakase et al. (1991a).

99. *Kurtzmanomyces* Y. Yamada, M. Itoh, Kawasaki, Banno & Nakase

Y. Yamada and I. Banno

Diagnosis of the genus

Cells are globose, ovoidal to cylindrical. A single conidium is formed at the top of stalks and freed without forceful ejection at the distal end of the stalks. Occasionally stalks branch or elongate and additional conidia are formed. True mycelium is produced. Ballistoconidia are absent.

Glucose is not fermented. Nitrate is assimilated. D-Glucuronate and *myo*-inositol are not assimilated. Diazonium blue B color reaction is positive. Xylose is absent from the cells. Coenzyme Q-10 is present.

Type species

Kurtzmanomyces nectairei (Rodrigues de Miranda) Y. Yamada, M. Itoh, Kawasaki, Banno & Nakase

Species accepted

1. *Kurtzmanomyces nectairei* (Rodrigues de Miranda) Y. Yamada, M. Itoh, Kawasaki, Banno & Nakase (1988)
2. *Kurtzmanomyces tardus* Giménez-Jurado & van Uden (1990)

Key to species

1. a Trehalose assimilated *K. nectairei*: p. 780
- b Trehalose not assimilated *K. tardus*: p. 781

Systematic discussion of the species

99.1. *Kurtzmanomyces nectairei* (Rodrigues de Miranda) Y. Yamada, M. Itoh, Kawasaki, Banno & Nakase (1988a)

Synonyms:

Sterigmatomyces nectairei Rodrigues de Miranda (1975)

Fellomyces nectairei (Rodrigues de Miranda) Y. Yamada & Banno (1984a)

Growth in malt extract: After 3 days at 25°C, the cells are spheroidal to ovoidal, (2–7)×(4–8) µm, with 1–10 short stalks. Conidia develop laterally or terminally on stalks and branching of the stalks occurs (Fig. 401). Conidia separate at the distal end. After one month, stalks are branched and irregularly shaped (0.7–1)×(1–17) µm. A sediment is present.

Growth on malt extract agar: The cells are similar in

size to those in malt extract; colonies are creamy, become salmon-colored by 5 days and orange-colored by one month. The texture is smooth, and the edges are entire.

Dalmau plate culture on corn meal agar: Within one month, short, sparse strands of true mycelium are present.

Fermentation: absent.

Origin of the strain studied: CBS 6405 (IFO 10118), cheese, E.G. Dale, France.

Type strain: CBS 6405.

99.2. *Kurtzmanomyces tardus* Giménez-Jurado & van Uden (Giménez-Jurado et al. 1990)

The species description is from Giménez-Jurado et al. (1990).

Growth in glucose (2%)–yeast extract (0.5%)–peptone (1%) broth: After 3 days at 25°C, the cells are variable both in shape and size, spheroidal, ovoidal, ogival and obovate, measuring (3.0–5.0)×(4.0–8.0) µm. Reproduction occurs by the enteroblastic formation of 1–4 0.5–2.0 µm-long sterigmata per cell. Some of these sterigmata will eventually elongate to hypha-like outgrowths. Conidia separate distally from the parent cell. Mature conidia are ovate to clavate and may give rise to secondary cells. Quite often sterigmata branch to produce two distinct newly divided cells. Mycelial growth is produced sparingly in liquid medium, however, single cells with short and long hyphae are common. Growth is rather slow and after 1 week only a small sediment is formed.

Growth on glucose (2%)–yeast extract (0.5%)–peptone (1%) agar: After 1 week at 25°C, the streak culture is pale-orange to salmon-colored, smooth, soft, glossy, butyrous and the edges are entire. After 8 days or more, colonies are slightly raised, convex and sometimes have an elevated center. True mycelium develops abundantly without clamp connections.

Dalmu plate cultures on corn meal agar: Abundant formation of true mycelium consisting of slender, septate, branching hyphae without blastoconidia. Pseudomycelium is absent.

Fermentation: absent.

Assimilation:

Co-Q: 10 (Giménez-Jurado et al. 1990).

Mol% G+C: 58.2, CBS 7421 (T_m : Giménez-Jurado et al. 1990).

Origin of the strain studied: The only known strain (CBS 7421, IGC 4529) was isolated from contaminated demineralized water in a laboratory, Oeiras, Portugal.

Type strain: CBS 7421.

Comments: This species grows slowly on common laboratory media. Giménez-Jurado et al. (1990) showed only 2.3% nDNA relatedness between the two species of *Kurtzmanomyces*.

Comments on the genus

Yamada and Banno (1984b) emended the genus *Sterigmatomyces* and described the new genus *Fellomyces*. They reserved *Sterigmatomyces* for anamorphic yeasts characterized by coenzyme Q-9 and by conidia borne on sterigmata which disjoint at septa formed in the mid-region of the sterigmata, and *Fellomyces* for anamorphic yeasts with coenzyme Q-10 and conidia which disjoint at distal septa in the sterigmata. Yamada et al. (1988b), based on the presence or absence of xylose in whole cell hydrolyzates, separated the newly created genus *Kurtzmanomyces* (xylose negative) with the single species *K. nectairei* from the genus *Fellomyces* (xylose positive). The validity of this generic rearrangement was confirmed by Yamada et al. (1989b) and Guého et al. (1990) based on rRNA sequence analyses. A second species of *Kurtzmanomyces* was described by Giménez-Jurado et al. (1990). Large subunit rRNA sequence analysis (J.W. Fell, personal communication) suggests the species to be congeneric. However, small subunit rRNA sequence analysis indicates that the two species are divergent (Yamada et al. 1991d).

100. *Malassezia* Baillon

D.G. Ahearn and R.B. Simmons

Diagnosis of the genus

Asexual reproduction is typically by monopolar (phialidic) enteroblastic budding on a broad base. The extruded bud is separated from the parent cell by a septum followed by fission. Elongate hyphal-like cells are rare in culture but true hyphae with clusters of blastospores may be commonly observed in skin scales from hosts (Fig. 402A). The formation and separation of the bud generally leaves a pronounced scar or collar from which later buds emerge (Fig. 402B₁). Multipolar budding has been observed in one species (Fig. 402B₂). The cell wall is multilamellar in nature, and the inner layer of the cell wall as observed with electron microscopy is corrugated with the grooves spiraling from the bud site (Fig. 402C). Chitin is concentrated in the portion of the cell wall forming the collar at the budding site.

Growth may require fatty acid (olive oil) supplementation. Growth occurs in enriched nutrient agars in the presence of 400 ppm cycloheximide. Sugars are not fermented. The urease and diazonium blue B reactions are positive. Coenzyme Q-9 is formed. Xylose is absent in whole-cell hydrolyzates.

Comments on physiological characterization of species of the genus: Because of their requirements for fatty acids (olive oil) and the fact that the fatty acid components of olive oil serve as sole sources of carbon for growth, standard sugar assimilation and fermentation tests are not applied.

Type species

Malassezia furfur (Robin) Baillon

Species accepted

1. *Malassezia furfur* (Robin) Baillon (1889)
2. *Malassezia pachydermatis* (Weidman) Dodge (1935)
3. *Malassezia sympodialis* Simmons & Guého (1990)

Key to species

1. a Lipophilic species, but show growth on enriched organic agars (e.g., Sabouraud's and glucose agars) without addition of oil *M. pachydermatis*: p. 782
b Obligatory lipophilic species; addition of long-chain fatty acids to culture media is required → 2
- 2(1). a Cells occasionally show sympodial budding; insignificant growth with the addition of Tween 80 or oleic acid *M. sympodialis*: p. 783
b Cells budding exclusively percurrently; growth with the addition of Tween 80 *M. furfur*: p. 782

Systematic discussion of the species

100.1. *Malassezia furfur* (Robin) Baillon (1889)

Synonyms:

Microsporium furfur Robin (1853)
Sporotrichum furfur (Robin) Saccardo (1886)
Pityrosporium furfur (Robin) Emmons, Binford & Utz (1970)
Saccharomyces ovalis Bizzozero (1884)
Malassezia ovalis (Bizzozero) Acton & Panja (1927)
Pityrosporium ovale (Bizzozero) Castellani & Chalmers (1913)
Saccharomyces sphaericus Bizzozero (1884) [non *Saccharomyces sphaericus* von Nägeli (1879)]
Pityrosporium malassezii Sabouraud (1904)
Cryptococcus malassezii (Sabouraud) Benedek (1930)
 ?*Pityrosporium orbiculare* Gordon (1951)

Growth on glucose-peptone-yeast extract agar with olive oil: After 3 days at 34°C, the cells are usually slightly ovoidal to ellipsoidal, (1.5–4.5) × (2.0–6.5) μm. Cells of some strains are mostly orbiculate and (2.5–4.5) μm in diameter; a few large cells (8–10 μm) may be observed (Figs. 402A, B₁, B₂, C). The streak culture is cream to yellowish, usually smooth, sometimes lightly wrinkled. The margin is typically entire, occasionally lobate. There is an essential requirement for olive oil or

oleic acid for growth on malt or Sabouraud's agars. Some strains grow slowly with oleic acid. Optimum temperature for growth is near 34°C. Growth occurs at 37°C.

Mol% G+C: 66.0–66.7, four isolates (neotype CBS 1878, 66.7%) (*T_m*: Guého and Meyer 1989).

Origin of strains studied: Human skin scales (6); human blood (4); human ear (4); human lung tissue (1); human urine (1).

Type strain: CBS 7019.

100.2. *Malassezia pachydermatis* (Weidman) Dodge (1935)

Synonyms:

Pityrosporium pachydermatis Weidman (1925)
Pityrosporium canis Gustafson (1955)

Growth on glucose-peptone-yeast extract agar: After 3 days at 34°C, the cells are mostly ellipsoidal, (2.5–5.5) × (3.0–7.0) μm. The streak culture is cream to yellow, glistening to dull, smooth to rough, with an entire or lobate margin. Olive oil is not essential for growth but is

Fig. 402. (A) Clusters of budding yeast cells and hyphal elements of *M. furfur* in human skin. Bar = 100 μm . (B₁) Photomicrograph of *M. furfur* from glucose-peptone-yeast extract agar. Arrow indicates the collarette characteristic of the genus. (B₂) Photomicrograph of *M. sympodialis* showing sympodial budding. Bar = 50 μm . (C) TEM of *M. furfur* showing multilayered cell wall with corrugated inner surface. Bar = 0.1 μm . Inset: oblique section through cell showing spiral nature of the corrugations. (D) TEM of *M. sympodialis* showing characteristic cell wall and sympodial budding with continuity of cytoplasm between parent cell and buds. Bar = 1 μm .

stimulative for some strains. Glucose is assimilated slowly in yeast nitrogen base medium.

Mol% G+C: 55.1–56.1, five isolates; neotype (CBS 1879) 56.1 (T_m : Guého and Meyer 1989).

Origin of strains studied: Human sputum (1); human blood (5); human skin (7); human ear (1); human vagina (1); ear of dog (1).

Type strain: CBS 1879.

Comments: Some strains of this species do not grow, or only grow slowly, in yeast nitrogen base medium without the presence of olive oil. Slooff (1970c) reported that growth occurs with mannitol, glucitol, and occasionally with glycerol, lactic acid, and citric acid when tested with auxanogram plates. The species is most often associated with animals, particularly the ears of canines (Abou-Gabal et al. 1979, Guillot et al. 1995), but is also associated with humans (Simmons and Ahearn 1987).

100.3. *Malassezia sympodialis* Simmons & Guého (1990)

Growth on glucose-peptone-yeast extract agar with oil: After 3 days at 34°C, the cells are usually orbiculate and measure (2.5–7.5) × (2.0–8.0) μm . Asexual reproduction is mainly by monopolar budding, but sympodially budding cells may be observed (Fig. 402D).

The streak culture is cream to yellowish, usually smooth and glistening. The margin is typically entire. Olive oil is essential for growth on enriched media, but no growth occurs when oleic acid is used as the fatty acid supplementation. Optimal growth occurs near 34°C. Growth occurs at 37°C.

Mol% G+C: 62.2 ± 0.2, 13 isolates (Guillot and Guého 1995).

Origin of strains examined: Human skin (1); human ear (1).

Type strain: CBS 7222 is designated as the neotype. From human ear and tinea capitis.

Comments on the genus

The general characteristics of *M. sympodialis* are similar to those described for *Pityrosporum orbiculare* Gordon (1951). In the original description of *P. orbiculare*, Gordon (1951) noted that an essential requirement for fatty acids could not be satisfied by supplementation with oleic acid and that some cells reproduced by multipolar budding. Slooff (1970c) accepted the species in the genus noting its short viability in culture and a more stringent fatty acid requirement than observed for *P. ovale*. She examined only recently isolated material and indicated that multipolar budding did not occur, but that in some circumstances “budding or extrusion of a germ tube has been observed

from the free poles or from another locus on the cell wall.” More recent reports of *P. orbiculare* appear to have relied only on globose cell shape for their identification of the species. Salkin and Gordon (1977) examined fresh isolates of *Pityrosporum* species with changing cell shape and fatty acid requirements and suggested, in agreement with others, that *P. ovale* and *P. orbiculare* were synonymous with *Malassezia furfur*. This synonymy was maintained by Yarrow and Ahearn (1984). The original type material and past isolates designated *P. orbiculare* (on the basis of inability to grow on oleic acid, as well as cell shape) are dead. Other isolates designated as *P. orbiculare* on the basis of globose cell shape have been found to represent *M. furfur* (Guého and Meyer 1989); therefore, *P. orbiculare* is continued as a synonym for *M. furfur*. The differences in mol% G+C between *M. furfur* (66%) and *M. sympodialis* (62%) and their low

DNA relatedness clearly support their separate species status.

Polymerase chain reaction (PCR) fingerprinting studies have further confirmed the separation of *Malassezia* into the three described species accepted here (van Belkum et al. 1994). Guillot and Guého (1995) used ribosomal RNA sequence analysis and nuclear DNA comparisons to study diversity within the genus. The separate nature of *M. sympodialis* and *M. pachydermatis* was substantiated and phylogenetic groupings based on large subunit rRNA diversity indicated strains described as *M. furfur* to represent several species. More recently, Guého et al. (1996) described four new species of *Malassezia* on the basis of molecular divergence and have provided morphological and physiological comparisons that allow laboratory separation of the species using non-molecular criteria (Guillot et al. 1996).

101. *Moniliella* Stolk & Dakin

G.S. de Hoog and M.Th. Smith

Diagnosis of the genus

Colonies are smooth or velvety, grayish to olivaceous-black. Budding cells are ellipsoidal, and formed terminally on true hyphae which disarticulate at a later stage. Pseudomycelium and chlamydo-spores may be present. Cell walls are multilamellar. Septal dolipores are present.

Sugars are fermented. Nitrate is assimilated. Diazonium blue B reaction is positive. Urease is produced. Coenzyme Q-9 is produced. Xylose and fucose are absent from cell walls.

Type species*Moniliella acetoabutens* Stolk & Dakin**Species accepted**

1. *Moniliella acetoabutens* Stolk & Dakin (1966)
2. *Moniliella mellis* (Fabian & Quinet) V. Rao & de Hoog (1975)
3. *Moniliella pollinis* (Hennebert & Verachtert) de Hoog & Guého (1984)
4. *Moniliella suaveolens* (Lindner) von Arx (1972)

Key to species

See Table 83.

1. a Dark brown, thick-walled chlamydo-spores are present *M. acetoabutens*: p. 785
b Chlamydo-spores are absent → 2
- 2(1). a Growth at 37°C *M. pollinis*: p. 787

Systematic discussion of the species**101.1. *Moniliella acetoabutens* Stolk & Dakin (1966)****Growth on 4% malt extract/0.5% yeast extract agar:**

After 10 days at 20–22°C, colonies are 15–19 mm in diameter, evenly felty, vaguely zonate, whitish, brownish-gray at the center, with dirty yellowish to blackish-brown reverse. Hyphae present, 3.5–4.5 µm wide, with intercalary, dark brown, thick-walled chlamydo-spores and with terminal chains of blastoconidia which finally disarticulate into rectangular arthroconidia (Fig. 403). Blastoconidia are (3.5–6.0) × (4.5–9.0) µm, subhyaline.

Fig. 403. *M. acetoabutens*, CBS 169.66. Chains of blasto- and arthroconidia. Various media, 22°C, 10 days. CBS 594.68, liberated conidia. ChA, 22°C, 30 days. CBS 593.68, chlamydospores. ChA, 22°C, 30 days.

Additional assimilation tests and other growth characteristics:

Growth at 37°C +
Co-Q: 9, CBS 169.66.

Mol% G + C: 61.1–61.3, CBS 169.66, CBS 593.68 (T_m : de Hoog and Guého 1984).

Origin of the strains studied: CBS 169.66 (ATCC 18455), from sweet fruit sauce, Dakin, U.K.; from fruit sauce (1); from sweet pickle (1); from acetic acid containing product (2); from synthetic vinegar (1).

Type strain: CBS 169.66.

Comments: The species occurs nearly exclusively in substrates with low pH. It is easily distinguished from other *Moniliella* species by the consistent presence of intercalary chlamydospores in true hyphae, and hyaline or subhyaline conidia. In addition, *M. acetoabutens* does not ferment D-galactose but is able to grow at 37°C.

101.2. *Moniliella mellis* (Fabian & Quinet) V. Rao & de Hoog (1975)

Synonym:

Torula mellis Fabian & Quinet (1928)

Growth on 4% malt extract/0.5% yeast extract agar: After 10 days at 20–22°C, colonies are 10 mm in diameter, cream-colored, gradually darkening to olivaceous-gray, dry, mat, finely velvety, cerebriform, and with a soft texture. Margins are sharp, slightly lobed. Odor is faintly fruity. Hyphae are 2.5–3.5 µm wide, subhyaline,

Fig. 404. *M. mellis*, CBS 350.33. Pseudomycelium with blasto- and arthroconidia. MEYA, 22°C, 5 days.

disarticulating into arthroconidia, and in a later stage locally forming short chains of blastoconidia. Conidia are subhyaline, ellipsoidal to cylindrical, variable in size, mostly about (4–6) × (10–25) µm (Fig. 404). Denticles are absent.

Fermentation:

Glucose	+	Maltose	+
Galactose	+	Lactose	–
Sucrose	–	Raffinose	–

Assimilation:

Glucose	+	<i>N</i> -Acetyl-D-glucosamine	n
Galactose	+	Methanol	n
L-Sorbose	–	Ethanol	n
Sucrose	–	Glycerol	n
Maltose	+	Erythritol	w

D-Glucosamine	n	Vitamin-free	–

Additional assimilation tests and other growth characteristics:

Urease	+	Growth at 37°C	–
Co-Q: 9, CBS 350.33.			

Mol% G + C: 58.7, CBS 350.33 (T_m : de Hoog and Guého 1984).

Origin of the strain studied: CBS 350.33, from honey.

Type strain: CBS 350.33.

Comments: The species was preliminarily listed as a

synonym of *M. suaveolens* by de Hoog (1979a), which was confirmed by de Hoog and Guého (1984) on the basis of a similar mol% G+C of DNA. However, its source of isolation is quite peculiar. Additional differences are found in absence of utilization of sucrose (fermentative and assimilative) and absence of growth without vitamins. *Moniliella suaveolens* is a lipophilic species, whereas *M. mellis* is osmophilic. *Trichosporonoides nigrescens* Hocking & Pitt may be a synonym; see under the description of that species, p. 875.

101.3. *Moniliella pollinis* (Hennebert & Verachtert) de Hoog & Guého (1984)

Synonym:

Moniliella tomentosa (van Beyma) Stolk & Dakin var. *pollinis* Hennebert & Verachtert (Dooms et al. 1971)

Growth on 4% malt extract/0.5% yeast extract agar:

After 10 days at 20–22°C, colonies are 3 mm in diameter, dry, grayish-white, and farinose with strong transverse fissures. The margin is sharp and lobed. Odor is insignificant. Hyphae are about 3 µm wide, hyaline or subhyaline, and disarticulate into arthroconidia; hyphae terminally change into pseudomycelium and produce apical chains of blastoconidia. Conidia are hyaline or subhyaline, ellipsoidal, (3.5–5.0) × (9–15) µm, continuous or with a median septum; short-cylindrical denticles often remain on supporting cells (Fig. 405).

Fermentation:

Glucose	+	Maltose	+
Galactose	w	Lactose	–
Sucrose	+	Raffinose	–

Assimilation:

Glucose	+	<i>N</i> -Acetyl-D-glucosamine	n
Galactose	–	Methanol	n

Additional assimilation tests and other growth characteristics:

Urease + Growth at 37°C +

Co-Q: 9, CBS 461.67.

Mol% G+C: 50.4, CBS 461.67 (T_m : de Hoog and Guého 1984).

Fig. 405. *M. pollinis*, CBS 461.67. Pseudomycelium with blasto- and arthroconidia. PCA, 22°C, 10 days.

Origin of the strain studied: CBS 461.67 (MUCL 11525), from pollen in honey comb, Hajny, U.S.A.

Type strain: CBS 461.67.

Comments: *M. pollinis* was recognized as a separate species by de Hoog and Guého (1984) on the basis of a mol% G+C of DNA which was considerably lower than that of *M. suaveolens*. Presence of growth at 37°C is usable as a key feature. It was the only strain isolated from fresh pollen. The type strain is now degenerative in that the arthroconidial form of propagation is prevalent.

101.4. *Moniliella suaveolens* (Lindner ex Lindner) von Arx (1972)

Synonyms:

Sachsia suaveolens Lindner (1895)
Oospora suaveolens (Lindner) Saccardo & D. Saccardo (1906)
Candida suaveolens (Lindner) Langeron & Guerra (1938)
Geotrichum suaveolens (Lindner) Ciferri (Diddens & Lodder 1942)
Cladosporium suaveolens (Lindner) Delitsch (1943)
Sachsiella suaveolens (Lindner) Ciferri (1955a)
Monilia nigra Burri & Staub (1909)
Torula nigra (Burri & Staub) Saccardo & Trotter (1911)
Moniliella suaveolens (Lindner) von Arx var. *nigra* (Burri & Staub) de Hoog (1979a)
Torula dematia Berkhout (1923)
Monilia cerebriforme van Beyma (1933)
Monilia macrospora van Beyma (1933)
Monilia microspora van Beyma (1933)
Monilia tomentosa van Beyma (1933)
Moniliella tomentosa (van Beyma) Stolk & Dakin (1966)

Growth on 4% malt extract/0.5% yeast extract agar:

After 10 days at 20–22°C, colonies are 4–12 mm in diameter, quite variable, grayish-white, olivaceous-green to olive-black with a light marginal zone and velvety or cerebriform, with butyrous texture. The margin is mostly sharp and lobed. Odor is faintly vinaceous or cheese-like. Hyphae are 1.5–3.5 µm wide, hyaline to pale olivaceous and they disarticulate into arthroconidia; hyphae terminally change into pseudomycelium and produce apical chains of blastoconidia. Conidia are subhyaline to olivaceous-brown, ellipsoidal, (3–6) × (6–19) µm, and finally thick-walled; short-cylindrical denticles often remain on supporting cells (Fig. 406).

Fig. 406. *M. suaveolens*. Various strains on PCA, 22°C. Branched chains of blasto- and arthroconidia, 5 days; liberated conidia in various stages of pigmentation, 1 month.

 Co-Q: 9, CBS 126.42.
 Mol% G+C: 58.1-61.7, 5 strains (T_m : de Hoog and Guého 1984).

Origin of the strains studied: CBS 126.42, from mash syringe, Lindner, Germany; CBS 220.32, type strain of *Monilia cerebriforme*, from tobacco; CBS 221.32, type strain of *Monilia macrospora*, from tobacco; CBS 223.32, type strain of *Monilia microspora*, from tobacco; CBS 224.32, type strain of *Monilia tomentosa*, from tobacco; from milk (1); from margarine and butter (19); from tobacco (1); from cheese (4); from spoiled muffin (1); from human sputum (1).

Type strain: CBS 126.42.

Comments: The species is extremely variable in its morphology (de Hoog 1979a) as well as in its physiology (Martínez et al. 1979). Key features are the olivaceous pigments in nearly all cultures, the relatively large conidia often borne on protruding scars, fermentation of D-glucose, sucrose, maltose and mostly D-galactose, absence of growth with L-sorbose, trehalose and inositol and at 37°C. In addition, the fruity fragrance is remarkable.

Colonies may become hyphal due to long-term maintenance on artificial media. Such cultures mostly show more expanding growth, are velvety rather than butyrous and show less pigmentation. For practical reasons, de Hoog (1979a) maintained a separate variety for such variants, which, however, is taxonomically insignificant. The few strains from pollen and honey, listed by de Hoog (1979a) under *M. suaveolens*, are treated here as separate taxa.

Nearly all strains were isolated from fatty substrates such as cheese, butter, margarine, and bakery products; some came from tobacco. Isolates sometimes proved to be resistant to food preservatives, such as sorbic acid. Two reports have been published of strains that were pathogenic in mammals. The human case (Kocková-Kratochvílová et al. 1987) concerned a mixed superficial infection. McKenzie et al. (1984) reported two cases from cats, but the described strains are atypical for *M. suaveolens*. It may be supposed that the low maximum growth temperature of *M. suaveolens* prevents serious infections.

The species is of basidiomycetous affinity, as demonstrated by lamellar cell walls and dolipore septa (Martínez 1979). Teleomorphs are unknown. Large numbers of mating experiments were unsuccessful (de Hoog, unpublished). On acidic media, some strains show very large, erect, clavate hyphae, terminally provided with variously shaped conidium-like inflations. The karyology of these structures has not yet been determined.

102. *Phaffia* M.W. Miller, Yoneyama & Soneda

M.W. Miller and H.J. Phaff

Diagnosis of the genus

Vegetative cells reproduce by enteroblastic budding, are ellipsoidal and occur singly, in pairs, and occasionally in short chains. Carotenoid pigments are synthesized (mainly astaxanthin and a minor proportion of β -carotene) which give cells *en masse* a red to salmon-red color. True mycelium is absent, but a rudimentary pseudomycelium may be present. Chlamydospores are formed. A pellicle is formed on liquid media.

Fermentative ability is present. Starchlike compounds are formed (synthesis is pH independent). Inositol is not assimilated as sole carbon source. Nitrate is not assimilated. Coenzyme Q-10 is present. Diazonium blue B and urease reactions are positive. Xylose is present in whole-cell hydrolyzates.

Type species

Phaffia rhodozyma M.W. Miller, Yoneyama & Soneda

Species accepted

1. *Phaffia rhodozyma* M.W. Miller, Yoneyama & Soneda (1976)

Systematic discussion of the species

The description of *Phaffia rhodozyma* is given under its teleomorph *Xanthophyllomyces dendrorhous*: p. 718.

Comments on the genus

Phaffia rhodozyma was tentatively described under the name *Rhodozyma montanae* by Phaff et al. (1972). This binomial is a *nomen nudum*, because a Latin description was not provided. Miller et al. (1976b) renamed the yeast *Phaffia rhodozyma*, provided a Latin description and gave a more detailed listing of its physiological and morphological properties. They also compared it with *Rhodomycetes dendrorhous*, a yeast superficially described by Ludwig (1891, 1896). Apparently, Ludwig never isolated this organism in pure culture, and as a consequence, it is not possible to determine whether *P. rhodozyma* and *R. dendrorhous* represent the same species. Because the type strain of *P. rhodozyma* is conspecific with *Xanthophyllomyces dendrorhous* (Golubev 1995), *P. rhodozyma* is regarded as the anamorph of *X. dendrorhous*.

Phaffia appears to have a restricted geographic distribution. Nine strains were isolated in mountainous locations

in a wide area of Japanese islands and a single strain came from Alaska, U.S.A., all from exudates of broad-leaved trees (Miller et al. 1976b). Golubev et al. (1977a) isolated 67 additional strains in Russia from birch fluxes and bark during a seven year survey. One additional strain was obtained from Turpeinen, who isolated it from birch sap in Finland. Although numerous surveys have been published on tree associated yeasts in many parts of the world (reviewed by Phaff and Starmer 1987) no other isolations of *Phaffia rhodozyma* have been reported.

Because of its high astaxanthin content, *Phaffia rhodozyma* has been used as a dietary pigment source to impart the desirable orange-red color to the normally white flesh of pen-reared salmonids and crustaceans (Johnson et al. 1977). Because the pigment of untreated cells is only poorly absorbed by fish, an enzymatic procedure for improving the extractability of astaxanthin was developed by Johnson et al. (1979). To increase astaxanthin yields, An et al. (1989) were able, by mutagenesis, to derive highly pigmented mutant strains of *Phaffia rhodozyma* with greatly increased astaxanthin content.

Systematic discussion of the species

103.1. *Pseudozyma antarctica* (S. Goto, Sugiyama & Iizuka) Boekhout (1995)

Synonyms:

Sporobolomyces antarcticus S. Goto, Sugiyama & Iizuka (1969)
Candida antarctica nom. nud., as *C. antarctica* (S. Goto, Sugiyama & Iizuka) Kurtzman, Smiley, Johnson & Hoffman (Meyer et al. 1984)
Vanrija antarctica (S. Goto, Sugiyama & Iizuka) R.T. Moore (1987a)
Trichosporon oryzae Ito, Iizuka & Sato (1974)

Growth on 5% malt extract agar: After 5 days at 17°C, cells are cylindrical to fusiform, variable in size, (5–35) × (1.5–3.0) µm, with 1–3 oil droplets, and single. Conidiogenesis is polar on short denticles and with sympodial proliferation (Fig. 407). Hyphae are abundant with the cytoplasm retracted in cells, (25–60) × (1.5–2.2) µm, and with sterigmata on which fusiform blastoconidia are formed. Colonies are dimorphic, with the center flat to somewhat raised, glabrous to velvety hirsute, smooth to somewhat irregularly furrowed, dull, pale creamish-white to yellowish-brown. Growth near the margin is zonate, somewhat hairy to velutinous, and with the margin fringed.

Growth on the surface of assimilation media (glucose): A ring, floating flocks and a sediment are formed.

Dalmeijer plate culture on morphology agar: After 5 days at 17°C, extensive hyphae may be formed with the cytoplasm retracted. Yeastlike cells are ellipsoidal, (4.0–10.0) × (2.0–4.0) µm, with polar conidiogenesis and sympodial proliferation. Aerobic growth is whitish to pinkish-cream, dull, with the surface smooth, somewhat pustulate to reticulate, and covered with hyphal fascicles or tiny hairs. The aerial mycelium is made up of ramifying

Fig. 407. *P. antarctica*, CBS 214.83. Hyphae and chains of blastoconidia. Yeast morphology agar, 5 days, 25°C. Bar = 10 µm.

acropetal chains of fusiform blastoconidia being formed on sterigmata.

Fermentation: absent.

Co-Q: 10 (Boekhout et al. 1992b).

Mol% G+C: 61.2–61.6 (BD; Kurtzman 1990a).

Cell wall hydrolyzates: Glucose, mannose low, galactose and glucosamine (Weijman 1979b, Weijman and Rodrigues de Miranda 1988, Boekhout et al. 1992b).

Origin of the strains studied: CBS 214.83, type strain of *Sporobolomyces antarcticus*, from lake sediment, J. Sugiyama, Lake Vanda, Victoria Land, Antarctica; CBS 516.83, type strain of *Trichosporon oryzae*, from unpolished new crop rice, H. Ito, Japan.

Type strain: CBS 214.83.

Comments: The species *Sporobolomyces antarcticus*, *Trichosporon oryzae* and *Sterigmatomyces aphidis* have been considered conspecific because of high DNA–DNA binding values (Kurtzman 1990a). For the first two species this is also supported by nucleotide sequence analysis, as their partial 26S ribosomal DNA sequences were found to be identical (Boekhout et al. 1995a). However, the partial 26S ribosomal DNA sequence of *Sterigmatomyces aphidis* was found to be slightly different, and therefore this species is maintained as separate in this treatment. The basidiomycetous nature of these fungi is supported by positive diazotium blue B and urease reactions. Phylogenetic affinity with the Ustilaginales is supported by morphology (Boekhout 1987), the presence of a narrow pore-like structure between the conidia (Boekhout, unpublished data) and partial 26S rDNA nucleotides (Boekhout et al. 1995a). Arthroconidia as they occur in *Trichosporon* are not formed. It seems likely that hyphal cells in which the cytoplasm retracts may have

been interpreted as arthroconidia (see Ito et al. 1974). *Trichosporon oryzae* was reported to be highly resistant to gamma radiation (Ito et al. 1974). The suggested synonymy of *Trichosporon oryzae* with *Candida edax* (Jong and King 1977b) is not accepted, as this latter species is the anamorph of *Stephanoascus smithiae* (Ascomycetes), p. 402 (Giménez-Jurado et al. 1994).

103.2. *Pseudozyma aphidis* (Henninger & Windisch) Boekhout (1995)

Synonym:

Sterigmatomyces aphidis Henninger & Windisch (1975b)

Growth on 5% malt extract agar: After 5 days at 17°C, the cells are fusiform, variable in size, (5.0–33.0) × (1.8–3.0) µm, and contain many oil droplets. Budding is polar on short denticles. Hyphae are present with the cytoplasm retracted in the cells, (30–50) × (2.0–3.0) µm, and with sterigmata on which cylindrical to fusiform blastoconidia, (20–36) × (2.0–2.7) µm, are formed. Colonies are dimorphic, flat, velvety-velutinous, dull, whitish to pale yellowish-cream, zonate towards the margin, and with the margin fringed.

Growth on assimilation media (glucose): A ring, floating flocks, a film and a sediment are present.

Dalmu plate culture on morphology agar: After 5 days at 17°C, hyphae are abundant. Aerobic growth is whitish, dull, velvety-velutinous, flat, with the center somewhat pustulate, and the margin fringed. The aerial mycelium consists of ramifying and acropetal chains of fusiform blastoconidia.

Fermentation: absent.

Assimilation (25°C):

Co-Q: 10.

Mol% G+C: 61.5 (BD: Kurtzman 1990a).

Cell wall hydrolyzates: Not determined.

Origin of the strain studied: CBS 517.83, type strain of *Sterigmatomyces aphidis*, from secretion of Aphididae on leaves of *Solanum pseudocapsicum*, W. Henninger and S. Windisch, Germany.

Type strain: CBS 517.83.

Comments: *Pseudozyma aphidis* was suggested to be conspecific with *Pseudozyma antarcticus* and *Trichosporon oryzae* (Kurtzman 1990a). However, based on the 64–68% DNA–DNA similarity between *P. aphidis* and the remaining two species (Kurtzman 1990a), partial 26S ribosomal DNA sequences, and the presence of physiological differences, we regard *P. aphidis* as a separate species. The suggestion that this species belongs to the Ustilaginales (W. Henninger, unpublished data; Boekhout 1987) was confirmed by partial 26S rDNA sequences (Boekhout 1994, Boekhout et al. 1995a). The assimilation of methanol, ethanol, and galactitol, and growth in vitamin-free medium (Henninger and Windisch 1975b) were not confirmed by the present study.

103.3. *Pseudozyma flocculosa* (Traquair, Shaw & Jarvis) Boekhout & Traquair (Boekhout 1995)

Synonyms:

Stephanoascus flocculosus Traquair, Shaw & Jarvis (1988b)

Sporothrix flocculosa Traquair, Shaw & Jarvis (1988b)

Growth on 5% malt extract agar: After 5 days at 17°C, the cells are fusiform, variable in size and with many oil droplets. Two size classes appear apparent, viz. long elements, measuring (13–35) × (2.0–3.0) µm and shorter elements of (3.0–7.0) × (1.5–3.0) µm. Conidiogenesis is polar, on short denticles and with sympodial proliferation. Hyphae, which measure (25–37) × (1.8–2.2) µm, are characterized by retracted cytoplasm. The hyphae have sterigmata on which fusiform blastoconidia are formed. Colonies are flat with the center somewhat warty, dull, whitish, and finely pruinose, but toward the margin they are somewhat zonate, finely whitish pruinose and with the margin fringed.

Growth on the surface of assimilation media:

Floating flocks, a thick film and a sediment are formed.

Dalmu plate culture on morphology agar: After 5 days at 17°C, the cells are mostly lysed. Aerobic growth is whitish, dull and flat with the center warty to somewhat pustulate and covered with a thin aerial mycelium. Hyphae have the cytoplasm retracted in the cells and measure (20–65) × (1.5–2.0) µm. The hyphae are characterized by sterigmata on which ramifying acropetal chains of fusiform conidia occur, usually made up of two rows of long cylindrical to fusiform cells, (20–40) × (2.0–2.5) µm, and with a terminal whorl of shorter fusiform blastoconidia, (3.0–9.0) × (2.0–3.0) µm.

Fermentation: absent.

Assimilation (25°C):

Glucose	+	<i>N</i> -Acetyl-D-glucosamine	n

Co-Q: Not determined.**Mol% G + C:** Not determined.**Cell wall hydrolyzates:** Not determined.

Origin of the strain studied: CBS 167.88, leaf of clover (*Trifolium pratense*) infected with mildew (*Erysiphe polygoni*), J.A. Traquair, Ontario, Canada.

Type strain: CBS 167.88.

Comments: *Stephanoascus flocculosus* was described as a homothallic ascomycete forming thick, persistent asci with 2–4 galeate ascospores (Traquair et al. 1988b). However, this observation could not be confirmed by the present authors. The ascus-like structures illustrated by Traquair et al. (1988b) are probably chlamydospores. At present, there is substantial evidence that this fungus represents a heterobasidiomycete. The morphological appearance of the colonies, and the presence of branched chains of ramoconidia (Traquair et al. 1988b) is similar to those occurring in anamorphs of Ustilaginales (Boekhout 1987). The basidiomycetous nature of this fungus is supported by positive diazonium blue B and urease reactions, as well as partial nucleotide sequences of the 26S ribosomal DNA (Boekhout 1994, Boekhout et al. 1995a, Kurtzman and Robnett 1995). Molecular data support a close phylogenetic affiliation with the Ustilaginales, viz. *Ustilago maydis* (Boekhout et al. 1995a). Contrary to the data of Traquair et al. (1988b), we did not observe assimilation of lactose and ethanol. The species has potential to antagonize cucumber powdery mildew (*Sphaerotheca fuliginea*) (Jarvis et al. 1989).

103.4. *Pseudozyma fusiformata* (Buhagiar) Boekhout (1995)**Synonym:***Candida fusiformata* Buhagiar (1979)

Growth on 5% malt extract agar: After 5 days at 17°C, the cells are cylindrical, ellipsoidal to fusiform, (4.5–8.5) × (1.0–4.0) μ m, single, and usually contain 1–2 oil droplets. Conidiogenesis is polar and either sessile or on a short denticle. Short hyphae are present. Colonies are butyrous, smooth to wrinkled, glabrous, shiny, whitish, cream, light salmon to vinaceous-buff, and with the margin entire.

Growth on the surface of assimilation media (glucose): Absent, but a sediment is formed.

Dalmat plate culture on morphology agar: After 5 days at 17°C, short hyphal cells may occur. Hyphae usually are for the greater part lysed and have retraction septa. Aerobic growth is pinkish-cream to salmon, shiny, weakly venose or reticulate, and with the margin entire, straight or lobate. A thin aerial mycelium occurs, made up of acropetal chains of fusiform blastoconidia.

Fermentation: absent.**Assimilation (25°C):**

Co-Q: Not determined.**Mol% G + C:** 58.1 (T_m : Buhagiar 1979).**Cell wall hydrolyzates:** Mannose low (Weijman et al. 1988).

Origin of the strains studied: CBS 6232, leaves of barley, H. Fokkema, Netherlands; CBS 6951, cauliflower (*Brassica oleracea* var. *botrytis*), R.W.M. Buhagiar, Great Britain.

Type strain: CBS 6951.

Comments: The positive urease and diazonium blue B reactions clearly indicate the basidiomycetous nature of

this species, as has been suggested by Weijman et al. (1988). This fungus does not fit the current definitions of the anamorphic genera *Cryptococcus* and *Rhodotorula* because of its inability to synthesize extracellular starch-like compounds and its ability to assimilate *myo*-inositol. Partial 26S ribosomal DNA sequences strongly suggest that this species is an anamorph of the Ustilaginales (Boekhout et al. 1995a), which is supported by morphology, viz. the presence of an aerial mycelium made up of branched, acropetal chains of fusiform blastoconidia.

103.5. *Pseudozyma prolifica* Bandoni (1985)

Growth on 5% malt extract agar: After 5 days at 17°C, the cells are fusiform, variable in size, (7–50) × (1.5–2.5) µm, and contain many oil droplets. Conidiogenesis is polar, and on short denticles. Hyphae occur, with the cytoplasm retracted in cells, and measure (17–30) × (2.0–3.5) µm (ca. 1.0 µm wide hyphae occur as well). Sterigmata occur on which fusiform blastoconidia are formed. Colonies are dimorphic with the center somewhat raised and warty, dull, whitish to cream, and covered with fine hairs. Near the margin, growth is flat, finely hirsute, and with the margin fringed.

Growth on the surface of assimilation media (glucose): Floating flocks and a sediment are formed.

Dalmou plate culture on morphology agar: After 5 days at 17°C, hyphae are abundant, have the cytoplasm retracted in cells, and measure (24–50) × (2.0–3.0) µm. The hyphae have retraction septa and sterigmata on which fusiform blastoconidia, (12–37) × (2.0–3.0) µm in size, are formed. Aerobic growth is whitish, velvety-velutinous, flat to somewhat pustulate, and with the margin fringed.

Fermentation: absent.

Assimilation (25°C):

Co-Q: Not determined.

Mol% G + C: Not determined.

Cell wall hydrolyzates: Not determined.

Origin of the strain studied: CBS 319.87, litter of *Scirpus microcarpus*, growing in a seepage area on a steep hill side, Vancouver, R.J. Bandoni, B.C., Canada.

Type strain: CBS 319.87.

Comments: *Pseudozyma prolifica* has been described as a pleomorphic hyphomycete forming scolecoconidia, stauroconidia, blastoconidia, arthroconidia and chlamydospores (Bandoni 1985). This author noted similarities of the conidia to those of species of aquatic hyphomycetes, including species of *Articulospora*, *Vari-cosporium*, *Dendrospora* and *Tricladium*, but did not suggest a relationship for the taxon. However, the culture CBS 319.87 of *Pseudozyma prolifica*, deposited in the CBS collection, morphologically strongly resembles anamorphs of Ustilaginales. The basidiomycetous nature of *P. prolifica* is supported by positive diazotium blue B and urease reactions, and partial 26S ribosomal DNA nucleotide sequences (Boekhout et al. 1995a).

103.6. *Pseudozyma rugulosa* (Traquair, Shaw & Jarvis) Boekhout & Traquair (Boekhout 1995)

Synonyms:

Stephanoascus rugulosus Traquair, Shaw & Jarvis (1988b)

Sporothrix rugulosa Traquair, Shaw & Jarvis (1988b)

Growth on 5% malt extract agar: After 5 days at 17°C, the cells are ellipsoidal to fusiform, (8.0–20) × (2.0–2.5) µm, and with many oil droplets. Budding is polar on short denticles. Hyphae occur with the cytoplasm retracted in the cells, (25–42) × (1.8–2.5) µm, and have sterigmata on which ramifying chains of fusiform blastoconidia are formed.

Growth on the surface of assimilation media: A ring, floating flocks and a sediment are present.

Dalmou plate culture on morphology agar: After 5 days at 17°C, the cells grow poorly. Aerobic growth is pale yellowish-brown, dull, flat, venose to somewhat pustulate, covered with fine hairs, and with the margin entire to somewhat fringed. The aerial mycelium consists of ramifying acropetal chains of fusiform blastoconidia of variable shape, (5.0–20.0) × (1.8–3.0) µm,

gradually becoming smaller towards the end of the chain.

Fermentation: absent.

Mol% G + C: Not determined.

Cell wall hydrolyzates: Not determined.

Origin of the strain studied: CBS 707.88, leaf of maize (*Zea mays*) infected with molds, J.A. Traquair, Ontario, Canada.

Type strain: CBS 170.88.

Comments: *Stephanoascus rugulosus* was described as a homothallic ascomycete, forming globose asci with 2–4 galeate ascospores (Traquair et al. 1988b). However, the ascomycetous nature of this fungus was not confirmed by the present authors. On the contrary, there is substantial evidence that this fungus belongs to the Ustilaginales (Heterobasidiomycetes). This is supported by positive diazonium blue B and urease reactions, partial nucleotide sequences of the 26S ribosomal DNA (Boekhout 1994, Boekhout et al. 1995a, Kurtzman and Robnett 1995) and the mode of conidiogenesis, viz. the formation of acropetally and ramifying chains of fusiform blastoconidia (see Traquair et al. 1988b, Boekhout 1987). In our opinion the ascus-like structures, as depicted by Traquair et al. (1988b), were chlamydo-spores with oil droplets. The reported assimilation of lactose (Traquair et al. 1988b) could not be confirmed. *Pseudozyma rugulosus* has an antagonistic capacity against cucumber powdery mildew (Jarvis et al. 1989).

103.7. *Pseudozyma tsukubaënsis* (Onishi) Boekhout (1995)

Synonyms:

Candida tsukubaënsis Onishi (1972)

Vanrija tsukubaënsis (Onishi) R.T. Moore (1987a)

Cryptococcus tsukubaënsis (Onishi) Rodrigues de Miranda & Weijman (Weijman et al. 1988)

Growth on 5% malt extract agar: After 5 days at 17°C, the cells are ellipsoidal, (5.0–15) × (2.8–4.2) μ m, with 2–4 oil droplets, and single. Budding is polar and either sessile or on short denticles. Hyphae occur, with the cytoplasm retracted in cells and measure (10–80) × (1.0–3.0) μ m. Sterigmata occur on which cylindrical to fusiform blastoconidia are formed. Colonies are dimorphic, flat, with the central part yeastlike, glabrous, smooth to somewhat warty, and the margin flat and covered with acute hyphal fascicles, and toward the margin, growth becomes hirsute, dull, pale yellowish-brown, and with the margin fringed.

Growth on the surface of assimilation media (glucose): A ring and a sediment are formed.

Dalmau plate culture on morphology agar: After 5 days at 17°C, hyphae are formed, which are lysed for the most part. Aerobic growth is grayish-cream, dull, hirsute and with the margin fringed. Hyphae occur with the cytoplasm retracted in cells and with sterigma near the septa. Allantoidal blastoconidia, (12–23) × (2.5–3.5) μ m, occur on sterigmata, short denticles or are sessile on the hyphae. A thin aerial mycelium is made up of ramifying, acropetal chains of fusiform blastoconidia.

Fermentation: absent.

Assimilation (25°C):

Glucose	+	<i>N</i> -Acetyl-D-glucosamine	n
Galactose	s	Methanol	-
L-Sorbose	s	Ethanol	+
Sucrose	+	Glycerol	+
Maltose	+	Erythritol	+

Starch formation	-		

Co-Q: Not determined.

Mol% G+C: 53.3 (T_m : Barnett et al. 1990).

Cell wall hydrolyzates: Mannose, galactose, glucose, mannitol, inositol and probably arabinitol (H. Roelijmans and T. Boekhout, unpublished results).

Origin of the strain studied: CBS 6389, flower, H. Onishi, Japan.

Type strain: CBS 6389.

Comments: The positive diazonium blue B and urease tests clearly indicate the basidiomycetous nature of this species. The ability to assimilate *myo*-inositol and the inability to synthesize extracellular starch-like compounds also occur in *Pseudozyma fusiformata* and other related species. *Candida tsukubaënsis* has been transferred to *Cryptococcus* based on the presumed presence of xylose in whole-cell hydrolyzates (Weijman and Rodrigues de Miranda 1988, Weijman et al. 1988). However, the morphological appearance of this fungus is similar to that of anamorphs of Ustilaginales. Therefore, the cell wall composition was reinvestigated, and the presence of xylose could not be confirmed (H.J. Roelijmans, unpublished results). Moreover, analysis of partial nucleotide sequences of 26S ribosomal DNA strongly supports a close phylogenetic relationship with *Ustilago maydis* (Boekhout et al. 1995a).

103.8. *Ustilago maydis* (De Candolle) Corda (1842)

Growth on 5% malt extract agar: After 5 days at 17°C, the cells are fusiform, variable in size, (10–40) × (1.5–3.0) μm, with many oil droplets and polar conidiogenesis. Hyphae occur, with the cytoplasm retracted in cells, measure (20–40) × (2.0–3.0) μm, and have sterigmata on which fusiform blastoconidia are formed. Colonies are dimorphic, with the center flat, slightly pustulate to venose, dull, pale yellowish-brown to olivaceous yellow-brown, finely pruinose, but locally smooth and somewhat shiny, zonate towards the margin, radially fibrillar, and with the margin fringed.

Growth on the surface of assimilation media (glucose): Floating flocks and a sediment are formed.

Dalmau plate culture on morphology agar: After 5 days at 17°C, hyphae occur, with retracted cytoplasm, retraction septa and sterigmata on which fusiform to cylindrical blastoconidia measuring (9.0–20.0) × (2.0–3.0) μm are formed. Hyphae may disarticulate through dissolution of the cell wall between the cytoplasm-containing cells. Aerobic growth is grayish-white to gray, dull, finely velutinous, with the center raised, irregular to somewhat pustulate, and the margin fringed. The aerial mycelium consists of ramifying and acropetal chains of fusiform conidia.

Fermentation: absent.

Assimilation (25°C):

Co-Q: 10 (Boekhout et al. 1992b).

Mol% G+C: Not determined.

Cell wall hydrolyzates: Glucose, galactose, mannose and arabinose (Dörfler 1990).

Origin of the strain studied: CBS 504.76, from maize (*Zea mays*), Netherlands.

Type strain: None designated.

Comments: The description of the asexual state of *Ustilago maydis* is presented here for comparative purposes due to the close relationship between *U. maydis* (and probably other smuts occurring on monocotyledons) and the *Pseudozyma* species determined from phenotypic and molecular data.

Discussion on anamorphs of Ustilaginales: Species of *Pseudozyma*, which share morphological, physiological and biochemical characteristics, have been placed in various genera of fungi. Although there may be some disagreement regarding the introduction of anamorph names for holomorphic fungi, such as most species of the Ustilaginales, the frequent isolation of anamorphs that lack teleomorphs, requires a form-genus to tentatively categorize these anamorphs. Kurtzman (1990a) suggested that *Vanrija* R.T. Moore may be an appropriate genus for one of these anamorphs (viz. *Sporobolomyces antarcticus*). We do not favor this solution, as the genus *Vanrija* is poorly defined as a basidiomycetous counterpart of *Candida* and *Torulopsis* (Moore 1980). Recent molecular work has demonstrated that this genus is highly polyphyletic (Fell et al. 1992, 1995), and that the type species *Vanrija humicola* (Daszewska) R.T. Moore belongs to a different evolutionary lineage when compared with the anamorphs of Ustilaginales.

Pseudozyma is physiologically characterized by the

ability to assimilate *myo*-inositol and D-glucuronate, and the inability to form extracellular starch-like compounds. Morphologically, the strains usually have flat, rapidly expanding colonies, which frequently become zonate. The aerial mycelium consists of ramifying, acropetal chains of fusiform conidia; chlamydo-spores may be present, but ballistoconidia are absent. The available molecular data suggest that all these fungi belong to the Ustilaginales (Boekhout et al. 1995a), as has been suggested earlier based on comparative morphology (Boekhout 1987).

104. *Reniforma* Pore & Sorenson

W.G. Sorenson and R.S. Pore

Diagnosis of the genus

Asexual reproduction is by budding on a narrow base. Cells are kidney-shaped with a flat base circumscribed by a brim. The cells tend to be arranged in orderly stacks.

Sexual reproduction is unknown.

Sugars are not fermented. Neither nitrate nor *myo*-inositol is assimilated. Starch-like compounds are not produced. Diazonium blue B and urease reactions are positive.

Type species

Reniforma strues Pore & Sorenson

Species accepted

1. *Reniforma strues* Pore & Sorenson (1990)

Systematic discussion of the species

104.1. *Reniforma strues* Pore & Sorenson (1990)

Growth in glucose–yeast extract–peptone–water:

After 3 days at 25°C, the cells are kidney-shaped, (3–6 × 2.3–5 μm), and occur singly, in pairs, or small clusters. Reproduction is by budding (Figs. 408, 409). The cells have a flat base and tend to be arranged in stacks or layers. There is a brim radiating from the basal margin of the cell. A sediment is present but no pellicle. Growth is similar on 5% or 15% malt extract. After one month at 25°C, a yellowish-white, dull, wrinkled, creeping pellicle with sediment is formed.

Growth on the surface of assimilation media: Thin, climbing pellicles are formed.

Growth on yeast extract–malt extract (YM) agar:

Growth is rapid at 25–30°C. The colonies are waxy and spreading. On primary isolation media, the colonies are either spreading or yeastlike.

Dalmau plate culture on yeast morphology agar:

After 7 days at 25°C, growth under the coverglass is

sparse and thin. Aerobic growth is white to cream-colored, abundant, dry and pasty. The margin is irregular and pseudomycelium is not produced.

Fermentation: absent.

Assimilation:

Glucose	+	<i>N</i> -Acetyl-D-glucosamine	–
Galactose	–	Methanol	–
L-Sorbose	–	Ethanol	–
Sucrose	–	Glycerol	–

Fig. 409. *R. strues*, NRRL Y-17275. Transmission electron micrograph of the budding process. Budding may occur at other locations on the cell, but typically occurs as shown.

Additional assimilation tests and other growth characteristics:

Starch formation	–	Amylase	–
Urease	+	Growth at 37°C	–
DNAase	–		

Co-Q: Not determined.

Mol% G+C: Not determined.

Origin of the strains studied: NRRL Y-17275, and additional isolates were from a municipal wastewater treatment facility, West Virginia.

Type strain: NRRL Y-17275 (ATCC 66374, CBS 8263).

Comments on the genus

The lamellar cell wall, enteroblastic budding, and positive diazonium blue B and urease tests suggest a basidiomycetous affinity for *R. strues*. The remarkable kidney-shaped cells which produce miniature kidney-shaped buds distinguish *R. strues* from all other known yeasts.

105. *Rhodotorula* F.C. Harrison

J.W. Fell and A. Statzell-Tallman

Diagnosis of the genus

Cells are spheroidal, ovoidal or elongate. Reproduction is by multilateral or polar budding; pseudo- or true hyphae may develop. Ballistoconidia are not formed. Some strains synthesize red or yellow pigments in malt agar cultures.

Most, but not all, species lack the ability to assimilate inositol. When inositol is utilized, D-glucuronate is not assimilated. Starch-like substances are not synthesized by any of the species (see Table 85). Fermentative ability is lacking. Diazonium blue B reaction and presence of urease are positive. Coenzymes Q-9 and Q-10 are present. Xylose is lacking in cell hydrolyzates.

Some species may represent anamorphic stages of *Rhodosporidium*, *Leucosporidium* and other genera with simple septal pores.

Systematic discussion of the species

105.1. *Rhodotorula acheniorum* (Buhagiar & J.A. Barnett) Rodrigues de Miranda (1975)

Synonym:

Sterigmatomyces acheniorum Buhagiar & J.A. Barnett (1973)

Growth in 5% malt extract: After 3 days at 25°C, the cells are ellipsoidal, mostly elongate, (1.6–3.9) × (2.4–8.2) μm, and contain conspicuous fat globules. The bud may be borne on a short pedicel. After one month there is a ring and a sediment; no pellicle forms (Fig. 410).

Fig. 410. *R. acheniorum*, CBS 6386. Cells grown in glucose–yeast extract–peptone water, for 3 days at 25°C, budding on short pedicels. Bar = 10 μm.

Growth on 5% malt agar: After 3 days at 25°C, the colony is buff, occasionally pale yellowish-pink, and smooth to rough. After 3 weeks or longer, the colony is pale pink-vinaceous with well-defined margins.

Dalmau plate culture on corn meal agar: After one week, short chains of budding cells with sparse pseudomycelium are present.

Fermentation: absent.

D-Gluconate	–	Growth at 30°C	+
50% (w/w) Glucose–yeast extract agar	–	Growth at 37°C	–
10% NaCl/5% glucose	w		

Co-Q: 10 (Sugiyama et al. 1985).

Mol% G+C: 53.9, CBS 6386 (BD: Kurtzman, personal communication).

Cell hydrolyzates: Mannose low, malic acid (Weijman and Rodrigues de Miranda 1988).

Origin of the strain studied: Fresh strawberries in England (Buhagiar and Barnett 1973).

Type strain: CBS 6386.

Comments: The original isolations, from strawberries (Buhagiar and Barnett 1973), occurred in three successive years (1969, 1970 and 1971); in addition, the 1990 “CBS List of Yeasts” includes an isolate from the leaves of *Callistemon viminalis* in Australia from J.F. Brown. The original description reported that buds were formed on sterigmata, ~1 μm in length, and separation of the cell and its bud occurred at the cell, at the bud, or midway between the cells. This method of cell separation does not conform to the description in the diagnosis of the genus *Sterigmatomyces*, which is limited to mid-cell separation. Rodrigues de Miranda (1975) did not observe sterigmata and reported that the divided cells were connected by “sharp tips of both cells”. Based on this mode of cell separation and the red color of the colony, Rodrigues de Miranda (1975) transferred the species from *Sterigmatomyces* to *Rhodotorula*. Nucleotide sequence analysis in our laboratory (unpublished) indicates that this species is related to the Ustilaginales. This relationship is also suggested by the low level of mannose in the cell hydrolyzates, which is characteristic of the smut-related yeasts.

105.2. *Rhodotorula acuta* (S. Goto) Rodrigues de Miranda & Weijman (Weijman et al. 1988)

Synonyms:

Candida acutus S. Goto (1979a)

Candida dulciaminis Tokuoka, Ishitani, S. Goto & Komagata (1987)

Rhodotorula dulciaminis (Tokuoka, Ishitani, S. Goto & Komagata)

Roeijmans, van Eijk & Yarrow (1989)

Growth in 5% malt extract: After 3 days at 25°C, the cells are ovoidal to ellipsoidal, (2.7–5) × (3–8) μm, and some cells taper to a sharp point. Reproduction is by polar budding, often on a short pedicel; the cells occur singly, in pairs, chains and clusters. After one month a sediment is present; a thin pellicle or ring occurs.

Growth on 5% malt extract agar: After one month at 25°C, the colony is cream-colored, raised, the surface is dull becoming slightly rugoid, and the margin is smooth and entire.

Dalmau plate culture on corn meal agar: After one month at 19°C, a primitive pseudomycelium is present.

Fermentation: absent.

Assimilation:

5-Keto-D-gluconate	n	Starch formation	–
Saccharate	–	Urease	+
D-Gluconate	+	Gelatin liquefaction	–
50% (w/w) Glucose–yeast extract agar	+	Growth at 37°C	+

Co-Q: 9 (Goto 1979a).

Mol% G+C: 54.7 (T_m : Goto 1979a); 52.6 (HPLC: Tokuoka et al. 1987).

Cell hydrolyzates: Mannose dominant, hexitol (probably mannitol), pentitol (probably arabinitol), and tetritol (probably erythritol) (Weijman and Rodrigues de Miranda 1988).

Origin of the strain studied: Sulfited grape must of a Koshu variety grape in Japan, Oct. 1976 (Goto 1979a); sponge cake, Ibaraki Pref., Japan, May 1984 (Tokuoka strain 155-CA).

Type strain: CBS 7053 (Goto strain C 96-2).

Comments: Our assimilation results agree with the original description except for melezitose assimilation, which Goto (1979a) described as positive. Morphology, assimilation patterns and LSU rDNA sequence analysis indicate that *R. dulciaminis* is a synonym of *R. acuta*. These same criteria indicate that *R. acuta* is a synonym of *Sterigmatomyces elviae*.

105.3. *Rhodotorula araucariae* Grinbergs & Yarrow (1970b)

Growth in 5% malt extract: After 3 days at 24°C, the cells are ovoidal to subglobose, (3.0–6.0) × (3.4–7.4) μ m, single or budding. Grinbergs and Yarrow (1970b) report cell lengths to 11 μ m. After one month there is a ring and moderate sediment; there is no pellicle.

Growth on 5% malt agar: After 3 days at 24°C, the colony is pale yellowish-pink, smooth, and glistening. The

cross section is raised, the texture soft, the margin entire. After one month the color is more intense.

Dalmau plate culture on corn meal agar: Pseudomycelium is absent.

Fermentation: absent.

Assimilation:

Glucose	+	<i>N</i> -Acetyl-D-glucosamine	–
Galactose	s	Methanol	–
L-Sorbose	s	Ethanol	+

D-Gluconate	–	Growth at 30°C	+
50% (w/w) Glucose–yeast extract agar	–	Growth at 37°C	–
10% NaCl/5% glucose	–		

Co-Q: 10 (Sugiyama et al. 1985).

Mol% G+C: 64.6 (T_m : Sugiyama et al. 1985).

Cell hydrolyzates: Fucose and mannose dominant; hexitol (probably mannitol) and pentitol (probably arabinitol) present (Weijman and Rodrigues de Miranda 1988).

Origin of the strain studied: Rotting conifer, *Araucaria araucana*, in Llaima, Chile, in December 1968 (Grinbergs and Yarrow 1970b).

Type strain: CBS 6031 (Grinbergs strain number 1922).

Comments: Based on nucleotide sequence alignments of a region of the LSU rRNA (Fell et al. 1992), *R. araucariae* is closely related to *Rhodospiridium kratochvilovae*.

105.4. *Rhodotorula armeniaca* Shivas & Rodrigues de Miranda (1983b)

Growth in 5% malt extract: After 3 days at 25°C, the cells are ovoid to elongate, measuring (2–6.7) × (4–9.4) μ m, and occur singly or in pairs. After one month, a light sediment is present.

Growth on 5% malt extract agar: After one month at 19°C, the streak colony is orange, dull or semi-glistening, and butyrous with undulated margins.

Dalmau plate culture on corn meal agar: After one week at 19°C, pseudomycelium is not formed.

Fermentation: absent.

Co-Q: Not determined.**Mol% G + C:** Not determined.**Cell hydrolyzates:** Not determined.

Origin of the strain studied: One strain of this species was isolated in 1981 from the surface of leaves of the bottle brush, *Callistemon viminalis* (Soland ex Gaert.) G. Don ex Loud., growing at Armidale, New South Wales, Australia.

Type strain: CBS 8076.

Comments: To ensure survival, this strain must be transferred biweekly; otherwise, we recommend storage at -80°C or in the vapor phase of liquid nitrogen.

105.5. *Rhodotorula aurantiaca* (Saito) Lodder (1934)**Synonyms:***Torula aurantiaca* Saito (1922)*Torulopsis aurantiaca* (Saito) Ciferri & Redaelli (1925)*Chromotorula aurantiaca* (Saito) F.C. Harrison (1928)*Rhodotorula glutinis* (Fresenius) F.C. Harrison var. *aurantiaca* (Saito) Hasegawa (1958)*Mycotorula colostri* Castelli (1932)*Rhodotorula colostri* (Castelli) Lodder (1934)*Rhodotorula crocea* Shifrine & Phaff (1956)

Growth in 5% malt extract: After 3 days at 19°C, the cells are elongate ovoidal to cylindrical, (3-5) × (6-13) μ m, occasionally 16 μ m or longer; in pairs or single, sometimes in short chains; little sediment, but there may be a thin, partial ring. After one month, a thin to well-developed orange or red ring and a moderate amount of sediment are present.

Growth on 5% malt agar: The cell morphology is similar to that in malt extract, but cells may be

slightly longer. The streak culture after one month is reddish-orange, or dark yellow, finely wrinkled or smooth, semiglossy, soft, flat to low convex, with an entire to slightly irregular border.

Dalmu plate culture on corn meal agar: Pseudomycelium absent or rudimentary, consisting of short chains of elongate cells.

Fermentation: absent.**Assimilation:**

Co-Q: 10 (Yamada and Kondo 1973).**Mol% G + C:** 55.4, type strain (T_m : von Arx and Weijman 1979); strain *R. crocea*: 58.8 (T_m : Nakase and Komagata 1971c).**Cell hydrolyzates:** Mannose dominates, hexitol (probably mannitol) (Weijman and Rodrigues de Miranda 1988).**Origin of the strain studied:** Air in Japan.

Type strain: CBS 317, isolated from atmosphere by Saito (1922), was designated as the type strain by Lodder and Kreger-van Rij (1952).

Comments: Other strains have been isolated from Japan, Europe, North America, the Antarctic, Atlantic and Indian Oceans. Sources include: clinical (1), unknown (1), bark beetle (1), plants and soils (7), marine waters (10).

105.6. *Rhodotorula auriculariae* (Nakase) Rodrigues de Miranda & Weijman (Weijman et al. 1988)**Synonyms:***Torulopsis auriculariae* Nakase (1971a)*Candida auriculariae* (Nakase) S.A. Meyer & Yarrow (Yarrow and Meyer 1978)

Growth in glucose-yeast extract-peptone water: After 3 days at 25°C, the cells are spherical to ovoidal,

(3.4–8) × (4.7–11.4) μm, and occur singly, in pairs or in clusters. A sediment is formed. After one month a ring is present.

Growth on glucose–yeast extract–peptone agar: After one month at 25°C, the streak culture is cream-colored, mucoid, glistening, moist, convex and entire.

Dalmat plate culture on corn meal agar: Pseudomycelium is absent.

Fermentation: absent.

Mol% G + C: 54.4 (T_m : Nakase 1971a).

Cell hydrolyzates: Fucose, rhamnose, mannose dominant, hexitol (probably mannitol) (Weijman and Rodrigues de Miranda 1988).

Origin of the strain studied: Fruiting body of *Auricularia auricula-judae*, in Zaruga-take (Mt. Zaru), Hamanashi Prefecture, Japan, May 1965 (strain AJ 4404, IFO 1580).

Type strain: CBS 6379.

105.7. *Rhodotorula bacarum* (Buhagiar) Rodrigues de Miranda & Weijman (Weijman et al. 1988)

Synonyms:

Torulopsis bacarum Buhagiar (1975)

Candida bacarum (Buhagiar) S.A. Meyer & Yarrow (Yarrow and Meyer 1978)

Growth in 5% malt extract: After 4 days at 25°C, the cells are ovoidal and elongate, (2.5–4) × (5.5–10) μm. After one month a sediment and light ring are present.

Growth on 5% malt extract agar: After one month at 25°C, the streak culture is brownish or cream-colored,

smooth, convex, with an entire to slightly undulating margin.

Dalmat plate culture on corn meal agar: After one week at 25°C, the pseudomycelium is poorly developed, consisting of ramified chains of ovoid cells.

Fermentation: absent.

Assimilation:

Mol% G + C: 52.4 (T_m : Meyer et al. 1984).

Cell hydrolyzates: Mannose low, hexitol (probably mannitol), malic acid (Weijman and Rodrigues de Miranda 1988).

Origin of the strains studied: Black currants, raspberries (*Rubus idaeus* cultivar Malling Jewel) and strawberries (*Fragaria ananassa* cultivar Cambridge Favourite).

Type strain: CBS 6526, isolated from black currants (*Ribes nigrum* cultivar Baldwin) by Buhagiar (1975).

Comments: Other strains have been isolated from dolphin (mammal) skin near the Netherlands by M. Luykx (CBS 7102) and air in Portugal by N. van Uden (CBS 7415). Nucleotide sequence analysis (unpublished) in our laboratory indicates that this species is related to the Ustilaginales. This relationship is also suggested by the low level of mannose in the cell hydrolyzates, which is a characteristic of the smut-like yeasts.

105.8. *Rhodotorula bogoriensis* (Deinema) von Arx & Weijman (1979)

Synonyms:

Candida bogoriensis Deinema (1961)

Candida bogoriensis Deinema var. *lipolytica* Ruinen (1963)

Vanrija bogoriensis (Deinema) R.T. Moore (1980)

Growth in glucose–yeast extract–peptone water:

After 3 days at 25°C, the cells are ovoidal-elongate, (2.0–5) × (5–17) μm, and occur singly or in pairs. After one month, a thin ring and heavy sediment have formed.

Growth on glucose–yeast extract–peptone agar:

After one month at 25°C, the streak culture is cream to yellowish-brown, mucoid, soft and smooth.

Dalmu plate culture on corn meal agar: After one week at 25°C, there are branched chains of short pseudohyphae present.

Fermentation: absent.

Assimilation:

Mol% G + C: 57.3, type strain (T_m : Meyer and Phaff 1972).

Cell hydrolyzates: Fucose, rhamnose, mannose dominant (Weijman and Rodrigues de Miranda 1988).

Origin of the strain studied: Surface of leaves of the flowering shrub *Randia malleifera* in Bogor, Indonesia.

Type strain: CBS 4101.

Comments: The original description reports that growth in ethanol was negative, which differs from our results.

105.9. *Rhodotorula buffonii* (Ramírez Gómez) Roelijmans, van Eijk & Yarrow (1989)

Synonyms:

Torulopsis buffonii Ramírez Gómez (1957)

Paratorulopsis buffonii (Ramírez Gómez) Novák & Zsolt (1961)

Candida buffonii (Ramírez Gómez) van Uden & H.R. Buckley (1970)

Growth in glucose–yeast extract–peptone water:

After 3 days at 25°C, the cells are elongate, (2–3.5) × (10–22) μm. After one month, a ring, pellicle, and sediment have formed.

Growth on glucose–yeast extract–peptone agar:

After one month at 25°C, the streak culture is grayish-brown, glistening, soft and smooth. On potato agar the streak culture is mucoid.

Dalmu plate culture on corn meal agar: Pseudomycelium is abundantly formed, consisting of branched chains of elongate cells.

Fermentation: absent.

Assimilation:

10% NaCl/5% glucose	s	Growth at 25°C	+
Starch formation	–	Growth at 30°C	–
Urease	+		

Co-Q: Not determined.

Mol% G + C: 50.8, type strain (T_m : Meyer et al. 1984).

Cell hydrolyzates: Xylose absent, fucose and rhamnose present (Roelijmans et al. 1989).

Origin of the strain studied: Carpophore of *Boletus edulis* var. *alba* (Ramírez Gómez 1957) (1).

Type strain: ATCC 18813.

Comments: The type strain of *R. buffonii* was listed in van Uden and Buckley (1970), Barnett et al. (1983) and Meyer et al. (1984) as CBS 2838. Van Uden and Buckley (1970) and Meyer et al. (1984) depict elongate cells for this strain. In contrast, a photograph of CBS 2838 in Barnett et al. (1983) illustrates ovoid cells. Additionally, Barnett et al. (1983) reported that this strain is diazonium blue B negative, an atypical reaction for a basidiomycete. Barnett et al. (1990) list the type strain as CBS 7150 with elongate cells and a diazonium blue B positive reaction. According to Yarrow (personal communication) CBS 2838 was lost and CBS 7150, a subculture of CBS 2838, was substituted as the type strain. To add to the confusion, there are two strains of CBS 7150 in

circulation. One strain is diazonium blue B negative and the cells are ovoid, similar to the cell photograph of CBS 2838 in Barnett et al. (1983). Based on the diazonium blue B reaction and nucleotide sequence alignment data (Fell et al. 1992), that strain is an ascomycete. The other strain is probably an authentic strain of *Candida buffonii*; the diazonium blue B reaction is positive and the cells are elongate, similar to those in van Uden and Buckley (1970).

Because of the questionable identity of the type strain, we examined strain ATCC 18813, which ATCC lists as CBS 2838. We found that ATCC 18813 cells resemble the elongate cell descriptions of *Candida buffonii* and the diazonium blue B reaction is positive, which clarifies its position as a basidiomycete. Therefore, we selected ATCC 18813 to be the type strain, because it appears to represent the original CBS 2838. The standard description presented here (with the exceptions of the mol% G + C and cell hydrolyzates) is taken from observations and tests on ATCC 18813.

105.10. *Rhodotorula diffluens* (Ruinen) von Arx & Weijman (1979)

Synonyms:

Candida diffluens Ruinen (1963)

Vanrija diffluens (Ruinen) R.T. Moore (1980)

Growth in glucose–yeast extract–peptone water:

After 3 days at 25°C, the cells are subglobose, ovoid, or slightly irregular. (3–5) × (5–11) μm. The cells are encapsulated.

Growth on glucose–yeast extract–peptone agar:

After one month at 25°C, the streak culture is brownish cream-colored, glistening, soft, smooth, and mucoid.

Dalmu plate culture on corn meal agar: The pseudomycelium is either primitive, consisting of branched chains of cylindrical cells, or displays long pseudohyphal cells bearing spindle-shaped blastospores (Fig. 411).

Fermentation: absent.

Fig. 411. *R. diffluens*, CBS 5233. Cells grown on corn meal agar for 5 days at 25°C. Bar = 10 μm.

Mol% G + C: 60.5 (T_m : Nakase and Komagata 1971c).

Cell hydrolyzates: Fucose, rhamnose, mannose dominate, hexitol (probably mannitol) (Weijman and Rodrigues de Miranda 1988).

Origin of the strain studied: Leaf of *Tillandsia usneoides* (bromeliad) in Dutch Guyana (Ruinen 1963).

Type strain: CBS 5233.

105.11. *Rhodotorula ferulica* Sampaio & van Uden (1991)

Growth in 5% malt extract: After 3 days at 19°C, the cells are ovoidal to spherical, encapsulated, measuring (2.7–4.7) × (4.0–6.7) μm, and occur singly or in pairs. Buds may form on a short neck. After one month, there is a light sediment, but no ring or pellicle.

Growth on 5% malt extract agar: After one month at 19°C, the streak colony is cream-colored, mucoid, raised, glistening and the margin is entire.

Dalmu plate culture on corn meal agar: After one month at 19°C, both true and pseudomycelium are formed. Blastoconidia form laterally on the hyphal cells.

Fermentation: absent.

Mol% G+C: 66.1 (T_m : Sampaio and van Uden 1991).

Cell hydrolyzates: Xylose absent (Sampaio and van Uden 1991).

Origin of the strains studied: Three strains were isolated about one mile upstream from the mouth of the Tagus River, Oeiras, Portugal. The main source of pollution in this river is a tobacco processing plant (Sampaio and van Uden 1991).

Type strain: CBS 7416 (IGC 4524).

Comments: The original description noted growth at 30°C, which we were not able to confirm.

105.12. *Rhodotorula foliorum* (Ruinen) Rodrigues de Miranda & Weijman (Weijman et al. 1988)

Synonym:

Candida foliarum Ruinen (1963)

Growth in glucose–yeast extract–peptone water: After 3 days at 25°C, the cells are slender, ovoid-elongate

to cylindrical, (1.5–4) × (4–12) μ m. They may be single or in pairs and are encapsulated. A ring may be present.

Growth on glucose–yeast extract–peptone agar:

After one month at 25°C, the streak culture is yellowish, glistening, mucoid, smooth and entire.

Dalmau plate culture on corn meal agar: The abundant pseudomycelium is primitive, consisting of ramified chains of cylindrical cells.

Fermentation: absent.

Assimilation:

Co-Q: 10 (Sugiyama et al. 1985).

Mol% G+C: 56.0 (T_m : G.A. Poot, personal communication, in Barnett et al. 1990).

Cell hydrolyzates: Fucose, rhamnose, mannose dominate, hexitol (probably mannitol) (Weijman and Rodrigues de Miranda 1988).

Origin of the strain studied: Leaves of *Drymoglossum piloselloides* growing epiphytically in the Botanical Garden, Bogor, Indonesia (Ruinen 1963).

Type strain: CBS 5234.

Comments: The original specific epithet was incorrectly spelled *foliarum* and was changed by Yarrow (Barnett et al. 1983). According to the original description lactose was not assimilated, which differs from our results.

105.13. *Rhodotorula fragaria* (J.A. Barnett & Buhagiar) Rodrigues de Miranda & Weijman (Weijman et al. 1988)

Synonyms:

Torulopsis fragaria J.A. Barnett & Buhagiar (1971)

Candida fragariorum (J.A. Barnett & Buhagiar) S.A. Meyer & Yarrow (Yarrow and Meyer 1978)

Growth in glucose–yeast extract–peptone water:

After 3 days at 25°C, the cells are ovoidal or cylindrical. In defined medium with glucose as the sole carbon source, the cells measure (1.8–6.1) × (3.4–12.4) μm.

Growth on glucose–yeast extract–peptone agar:

After one month at 25°C, the streak culture is beige, smooth, shiny and flat with an entire or slightly irregular edge.

Dalmou plate culture on corn meal agar: Short chains of cells are present after one week.

Fermentation: absent.

Assimilation:

Glucose	+	<i>N</i> -Acetyl-D-glucosamine	+
Galactose	v	Methanol	–
L-Sorbose	+	Ethanol	+
Sucrose	+	Glycerol	v
Maltose	+	Erythritol	–

5-Keto-D-gluconate	n	Urease	+
Saccharate	–	Gelatin liquefaction	–
D-Gluconate	+	Growth at 25°C	+
50% (w/w) Glucose–yeast extract agar	–	Growth at 30°C	–
10% NaCl/5% glucose	–		

Co-Q: Not determined.

Mol% G + C: 56.6 (T_m : G.A. Poot, personal communication, in Barnett et al. 1990).

Cell hydrolyzates: Fucose, mannose dominate, hexitol (probably mannitol) and pentitol (probably arabinitol) (Weijman and Rodrigues de Miranda 1988).

Origin of the strain studied: Strawberries (CBS 6254).

Type strain: CBS 6254.

Comments: Thirty-five strains were isolated from fresh strawberries and five strains from black currants in the United Kingdom (Barnett and Buhagiar 1971). Based on standard carbon and nitrogen utilization tests, this species resembles *R. muscorum*. Molecular sequence alignment data confirms that the two species are closely related (unpublished data, Fell et al.). Taxonomically the two species can be separated on the following: *R. fragaria* assimilates L-arabinose slowly, *R. muscorum* does not. *R. muscorum* assimilates saccharate and slowly assimilates galactitol, *R. fragaria* does not assimilate either compound.

105.14. *Rhodotorula fujisanensis* (Soneda) Johnson & Phaff (1978)**Synonyms:**

Torulopsis fujisanensis Soneda (1959)

Candida fujisanensis (Soneda) S.A. Meyer & Yarrow (Yarrow and Meyer 1978)

Vanrija fujisanensis (Soneda) R.T. Moore (1980)

Growth in glucose–yeast extract–peptone water:

After 3 days at 19°C, the cells are long-ovoidal to cylindrical, (2.5–5) × (7–15) μm. A ring and an incomplete pellicle are present.

Growth on glucose–yeast extract–peptone agar:

After one month at 19°C, the streak culture is grayish-yellow, semi-dull, soft, smooth or finely punctate.

Dalmou plate culture on corn meal agar: A rudimentary pseudomycelium is formed that consists of ramified chains of ovoid cells.

Life cycle: Mixing of cells from strains CBS 6371 and CBS 4551 on potato dextrose agar, followed by incubation at 12–18°C for 18 days can result in the formation of hyphae with clamps (Fig. 412) and teliospores. The teliospores (Fig. 413) are globose, 10–26 μm diameter, to occasionally elongate. The formation of teliospores is inconsistent and attempts to induce germination have been unsuccessful.

Fermentation: absent.

Assimilation of carbon compounds:

Co-Q: 9 (Goto and Oguri 1983).

Mol% G + C: 63.4 (T_m : Goto and Oguri 1983).

Cell hydrolyzates: Fucose, rhamnose, mannose dominate, hexitol (probably mannitol), citric acid (Weijman and Rodrigues de Miranda 1988).

Fig. 412. *R. fujisanensis*, CBS 4551×CBS 6371. Cells of opposite mating types were mixed on potato dextrose agar and incubated at 12°C. After 8 days, hyphae with clamps and teliospores formed. Bar = 10 µm.

Fig. 413. *R. fujisanensis*, CBS 4551×CBS 6371. Cells of opposite mating types were mixed on potato dextrose agar and incubated at 12°C. Teliospore formed after 8 days. Bar = 10 µm.

Origin of the strains studied: Hare feces, Japan (1); leaves, France, by M.R. Bardiz (1).

Complementary mating types: CBS 4551, from feces of a hare in Japan, NI 7646, MT A1 (Soneda 1959), and CBS 6371, from leaves in France, MT A2.

Type strain: CBS 4551.

Comments: The species was originally described in the genus *Torulopsis*. Subsequently, Johnson and Phaff (1978) chemically extracted and characterized carotenoids from this species and transferred the species to *Rhodotorula*. The formation of sexually produced teliospores demonstrates that *R. fujisanensis* belongs in a teleomorphic genus. Generic placement and formal description has been delayed due to an inability to induce germination of the teliospores and complete the details of the life cycle. Nucleotide sequence analysis in our laboratory (unpublished) indicates that *R. fujisanensis* is a member of the Sporidiales with a closer affinity to *Leucosporidium* than to *Rhodospiridium*.

Several other strains have been isolated: frass of

Ruguloscolytus rugulosus, M.C. Pignal (1); wild grapes (*Vitis coignetiae*) mating type A1, CBS 8056, by Goto, Japan; leaves of the California laurel (*Umbellularia californica*), rotting *Opuntia* cactus tissue in Australia and fermenting soap berries (*Sapindus saponaria*) from Hawaii.

105.15. *Rhodotorula futronensis* (Ramírez & González) Roeijmans, van Eijk & Yarrow (1989)

Synonym:

Apiotrichum futronensis Ramírez & González (1984d)

Growth in glucose-yeast extract-peptone water: After 3 days at 25°C, the cells are ovoidal to elongate, measuring (2–5.4)×(3.4–9.4) µm. The cells reproduce by budding and occur singly, or in clusters. After one month, a ring and a heavy sediment are present.

Growth on 5% malt extract agar: After one month at 25°C, the colony is buff colored, flat in cross section, butyrous, the surface is dull, the margin is entire and fringed with pseudomycelium.

Dalmat plate culture on corn meal agar: After one month at 19°C, short pseudohyphae are present.

Fermentation: absent.

Co-Q: Not determined.

Mol% G + C: Not determined.

Cell hydrolyzates: Xylose absent, fucose and rhamnose present (Roeijmans et al. 1989).

Origin of the strain studied: Rotting wood of a laurel, *Laurelia sempervirens*, in the evergreen rainy Valdivian forest near Futrono, Chile.

Type strain: CBS 8163 (IJFM 6008), from rotting wood of *Laurelia sempervirens*.

Comments: A strain from the intestinal tract of a fly, *Scaptomyza multispinosa*, collected in Chile by Ramírez and González (1984d) was not included in this study.

**105.16. *Rhodotorula glutinis* (Fresenius)
F.C. Harrison (1928)**

This species has two varieties:

***Rhodotorula glutinis* (Fresenius) F.C. Harrison var. *glutinis* (1958)**

Synonyms:

- Blastodendron aeriis* Ciferri & Redaelli (1925)
Cryptococcus glutinis Fresenius (1850)
Saccharomyces glutinis (Fresenius) Cohn (1872)
Torula glutinis (Fresenius) Pringsheim & Bilewsky (1911)
Torulopsis glutinis (Fresenius) Dodge (1935)
Saccharomyces roseus Engel (1877)
Torulopsis roseus Engel (1877)
Saccharomyces fresenii Schroeter (1908)
Mycotorula rosea-coralina Scaramella (1928)
Torula rufula Saito (1922)
Torulopsis rufula (Saito) Ciferri & Redaelli (1925)
Rhodotorula rufula (Saito) F.C. Harrison (1928)
Rhodotorula glutinis (Fresenius) F.C. Harrison var. *rufula* (Saito) Lodder (1934)
Torulopsis bronchialis Ciferri & Redaelli (1925)
Rhodotorula bronchialis (Ciferri & Redaelli) Lodder (1934)
Cryptococcus bronchialis (Ciferri & Redaelli) Nannizzi (1934)
Torulopsis satoi Ciferri & Redaelli (1925)
Rhodotorula glutinis (Fresenius) F.C. Harrison var. *satoi* (Ciferri & Redaelli) Lodder (1934)
Torula miniata Okunuki (1931)
Torula suganii Okunuki (1931)
Torulopsis minuta (Saito) Ciferri & Redaelli var. *americana* Ciferri (1931a)
Rhodotorula suganii (Okunuki) Lodder (1934)
Rhodotorula glutinis (Fresenius) F.C. Harrison var. *lusitanica* Marcilla, Feduchy & Gomes (1945)
Rhodotorula terrea Sugiyama & S. Goto (1969)

***Rhodotorula glutinis* var. *dairenensis* Hasegawa & Banno (1958)**

Synonyms:

- Torula rubra* Schimon (1911)
Torula rubra Schimon var. α Saito (1922)

Growth in 5% malt extract: After 3 days at 25°C, the cells are ovoidal to globose, (2.3–5.0) × (4.0–10) μ m, or more elongate, (12–16 μ m), and wider (7 μ m). There is usually a thin ring and a light sediment. After one month a medium to heavy, pink to orange or salmon-colored ring and a heavy sediment are present.

Growth on 5% malt agar: After one month at 25°C, the cell morphology is similar to that in malt extract, except that the cells may be longer. The streak culture is coral-red to salmon or slightly orange. The surface varies from smooth, often with fine transverse striations, to wrinkled; the appearance is from highly glossy to semiglossy. The texture varies from mucoid to pasty to slightly tough. The cross section is flat to broad

convex, and the border is irregular to entire, often with rudimentary pseudomycelium.

Dalmat plate culture on corn meal agar: Pseudomycelium is usually absent or rudimentary; in some strains well-developed pseudohyphae or true hyphae with large, dark pigmented teliospores are present, which indicates self-sporulating strains of *Rhodospodium*.

Fermentation: absent.

Co-Q: 10 (Nakase and Komagata 1971a).

Mol% G + C: 60.0–61.2; 66.8–67.8 (T_m : Nakase and Komagata 1971a).

Cell hydrolyzates: Fucose, mannose dominate, hexitol (probably mannitol) (Weijman and Rodrigues de Miranda 1988).

Supplementary description of *R. glutinis* var. *dairenensis*:

The variety is similar to *R. glutinis* var. *glutinis* except that nitrate is assimilated weakly, 2-keto-D-gluconate is not assimilated and thiamine is required for growth. The nucleotide sequence analysis indicates that the variety *dairenensis* has a closer phylogenetic relationship to *R. mucilaginosa* (Fell et al. 1992) than to the variety *glutinis*.

Origin of the strains belonging to the variety *glutinis*:

370 strains from Japan, Sweden, U.S.A., Kenya, Germany, Spain, Canada, and the Atlantic, Indian and Antarctic Oceans. Sources included: air (6), human patient (1), wood pulp (20), brewery water (1), plant leaves (2), boric acid (1), brined pickles (1), olive brine (2), textiles (1), flowers (6), tree slime fluxes (4), marine (316), oil drillings (1), lake trout intestine (1),

brine shrimp (2), polluted water, sputum, unknown sources (4).

Type strain: CBS 20, isolated by Pringsheim (Berlin) from the atmosphere and sent to CBS around the year 1912.

Origin of the strain belonging to the variety *dairenensis*: The strain (CBS 4406) was isolated from the atmosphere by Saito (1922).

Type strain: CBS 4406.

Comments: *R. glutinis* var. *glutinis*, the type species of the genus, is world-wide in distribution, has been isolated from a wide variety of substrates and is probably the most prevalent species in the genus. Although some strains grow at 37°C, the species is not considered to be a human pathogen; it has been reported from skin diseases of chickens (Kwon-Chung and Bennett 1992). As indicated by the variability in taxonomic characteristics and the range of mol% G+C values, the species is polytypic, consisting of several sexually isolated species. To date, five species of *Rhodospiridium* (*R. babjevae*, *R. diobovatum*, *R. kratochvilovae*, *R. sphaerocarpum* and *R. toruloides*) have been described with phenotypic characteristics that would classify their anamorphic states as *Rhodotorula glutinis*. However, the type strain of *R. glutinis* does not mate with any of the sexual species. Based on our unpublished nucleotide sequence analyses of a partial region of the LSU rDNA, *R. glutinis* var. *glutinis* is a genetically distinct species that is more closely related to *Rhodospiridium babjevae* and *R. diobovatum* than the other three teleomorphic species. There is also a close relationship of *R. glutinis* var. *glutinis* and *R. graminis* (see *R. graminis* discussion). The variety *dairenensis* is more closely related to *R. mucilaginoso* than to the variety *glutinis*, consequently the variety *dairenensis* will probably be elevated to the rank of species when our study of the molecular systematics of the genus *Rhodotorula* is completed.

105.17. *Rhodotorula graminis* di Menna (1958a)

Synonyms:

Pichia rosa Nishiwaki (1910)

Rhodotorula rosa (Nishiwaki) S. Goto & Yokotsuka (1962a)

Growth in 5% malt extract: After 3 days at 25°C, the cells are globose to ovoidal or elongate, (2.5–7) × (4–15) μm, often having oil droplet inclusions and may occur singly, in pairs or in short chains or clusters. A thin ring and a light sediment are present. After one month a moderate to heavy pink ring, usually a heavy sediment, and occasionally moist islets may be present.

Growth on 5% malt agar: The cell morphology is similar to that in malt extract. After one month at 25°C, the streak culture is coral-red, the surface is smooth or rugose to corrugated and glossy; the texture is soft, occasionally mucoid, the cross section is flat to low convex and the margin is irregular with some rudimentary pseudomycelium.

Dalmau plate culture on corn meal agar: Pseudomycelium is absent or rudimentary for some strains, consisting of chains of elongate cells, while other strains have a well-developed, branched pseudomycelium growing into the agar.

Fermentation: absent.

Assimilation of carbon compounds:

Glucose	+	<i>N</i> -Acetyl-D-glucosamine	–
Galactose	+	Methanol	–
L-Sorbose	v	Ethanol	v
Sucrose	+	Glycerol	v
Maltose	v	Erythritol	–
Cellobiose	v	Ribitol	v
Trehalose	+	Galactitol	v
Lactose	–	D-Mannitol	v
Melibiose	–	D-Glucitol	v
Raffinose	+	α-Methyl-D-glucoside	v

D-Arabinose	v	Inositol	–
D-Ribose	v	Hexadecane	–
L-Rhamnose	v	Nitrate	+
D-Glucosamine	–	Vitamin-free	+

Additional assimilation tests and other growth characteristics:

2-Keto-D-gluconate	+	Starch formation	–
5-Keto-D-gluconate	–	Urease	+
Saccharate	+	Gelatin liquefaction	+
D-Gluconate	–	Growth at 30°C	+
50% (w/w) Glucose–yeast extract agar	–	Growth at 37°C	–
10% NaCl/5% glucose	+		

Co-Q: 10 (Yamada and Kondo 1973).

Mol% G+C: 67.0 (T_m : Sugiyama et al. 1985); 70.0 (BD: Storck et al. 1969).

Cell hydrolyzates: Fucose (trace), mannose dominate, hexitol (probably mannitol) (Weijman and Rodrigues de Miranda 1988).

Origin of the strains studied: 67 strains from New Zealand, Indonesia, North America, Japan, the Indian and Atlantic Oceans. Sources included: plants (6), marine waters (59), unknown (1), soil (1).

Type strain: CBS 2826 (di Menna strain 2K53), from pasture grass on the North Island of New Zealand (di Menna 1958a).

Comments: Di Menna (1958a) made her original isolations during summer collections on North Island, New Zealand, from the leaf surfaces of pasture grasses (*Lolium perenne*, *Anthoxanthum odoratum* and *Agrostis tenuis*). *R. graminis* appears to be closely related to *R. glutinis*; Kurtzman and Fell (1991) reported 30% nDNA relatedness between the two species. Fell et al. (1992), in a study of the nucleotide sequence alignments of a partial region of the LSU rRNA, found that the two species differed by one base position.

105.18. *Rhodotorula hinnulea* (Shivas & Rodrigues de Miranda) Rodrigues de Miranda & Weijman (Weijman et al. 1988)

Synonym:

Cryptococcus hinnuleus Shivas & Rodrigues de Miranda (1983a)

Growth in 5% malt extract: After 3 days at 25°C, the cells are ovoidal and measure (1.4–4.7) × (2.7–5.4) μm. They reproduce by budding and occur singly and in pairs. After one month, a thin ring and a little sediment are present.

Growth on 5% malt extract agar: After one month at 25°C, the streak colony is cream to buff-colored, flat in cross section, with a smooth, dull surface, pasty texture and a margin that is entire.

Dalmu plate culture on corn meal agar: After one month at 19°C, pseudomycelium and true mycelium are absent.

Fermentation: absent.

Assimilation:

Glucose	+	<i>N</i> -Acetyl-D-glucosamine	–
Galactose	–	Methanol	–
L-Sorbose	–	Ethanol	v
Sucrose	+	Glycerol	+
Maltose	+	Erythritol	+
Cellobiose	+	Ribitol	–
Trehalose	+	Galactitol	–
Lactose	–	D-Mannitol	+
Melibiose	–	D-Glucitol	+
Raffinose	+	α-Methyl-D-glucoside	s
Melezitose	+	Salicin	–
Inulin	–	D-Gluconate	–

5-Keto-D-gluconate	n	Urease	+
Saccharate	–	Gelatin liquefaction	–
D-Glucuronate	–	Growth at 25°C	+
50% (w/w) Glucose–yeast extract agar	–	Growth at 30°C	–
10% NaCl/5% glucose	–		

Co-Q: Not determined.

Mol% G + C: Not determined.

Cell hydrolyzates: Mannose low (Weijman and Rodrigues de Miranda 1988).

Origin of the strain studied: The surface of leaves of the honeysuckle, *Banksia collina* R. Br., growing at Armidale, New South Wales, Australia. Collections were made in 1981 (Shivas and Rodrigues de Miranda 1983a).

Type strain: CBS 8079.

Comments: This species and *R. phylloplana* are the only members of the genus that utilize inositol as a sole source of carbon. In the original description, the assimilation of α-methyl-D-glucoside was negative, soluble starch and

ribose were weak, in contrast to our results. The low amount of mannose in the cell hydrolyzates and nucleotide sequence analysis in our laboratory demonstrates that *R. hinnulea* is related to the yeastlike smut fungi.

105.19. *Rhodotorula hordea* Rodrigues de Miranda & Weijman (Weijman et al. 1988)

Synonym:

Candida graminis Rodrigues de Miranda & Diem (1974)

Growth in 5% malt extract: After 3 days at 25°C, the cells are ellipsoidal and elongate, (2.7–4.7) × (6–12) μm, and occur singly or in pairs. A ring and a sediment are present.

Growth on glucose–yeast extract–peptone agar: After one month at 25°C, the streak culture is beige, smooth, creamy to slightly mucoid with an entire margin.

Dalmu plate culture on corn meal agar: Pseudomycelium is sparse and consists of branched chains of elongated cells.

Fermentation: absent.

Assimilation of carbon compounds:

Glucose	+	<i>N</i> -Acetyl-D-glucosamine	–
Galactose	s	Methanol	–
L-Sorbose	+	Ethanol	–
Sucrose	+	Glycerol	+
Maltose	+	Erythritol	+
Cellobiose	+	Ribitol	+
Trehalose	+	Galactitol	–
Lactose	s	D-Mannitol	+
Melibiose	–	D-Glucitol	+

5-Keto-D-gluconate	n	Urease	+
Saccharate	–	Gelatin liquefaction	–
D-Glucuronate	+	Growth at 25°C	+
50% (w/w) Glucose–yeast extract agar	–	Growth at 30°C	–
10% NaCl/5% glucose	–		

Co-Q: Not determined.

Mol% G + C: 46.9 (Barnett et al. 1990).

Cell hydrolyzates: Fucose, mannose dominates (Weijman and Rodrigues de Miranda 1988).

Origin of the strain studied: Barley (*Hordei hexastichi* L.) leaves from an unspecified locale (Rodrigues de Miranda and Diem 1974).

Type strain: CBS 6403.

Comments: Since the specific epithet *Rhodotorula graminis* was in use, the name *Rhodotorula hordea* was

chosen to replace *Candida graminis* (Weijman et al. 1988).

105.20. *Rhodotorula hylophila* (van der Walt, van der Klift & D.B. Scott) Rodrigues de Miranda & Weijman (Weijman et al. 1988)

Synonym:

Candida hylophila van der Walt, van der Klift & D.B. Scott (1971a)

Growth in glucose–yeast extract–peptone water:

After 3 days at 25°C, the cells are spheroidal, ovoidal, ellipsoidal or cylindrical, (1.0–3.0) × (1.5–9.0) µm, occasionally triangular or irregular, and occur singly, in pairs, short chains and small clusters. Pseudomycelium is present. After one month a granular to floccose sediment, islets and an incomplete ring are present.

Growth on glucose–yeast extract–peptone agar:

After one month at 25°C, the streak culture is brownish-cream, moist, raised, lacy, with a fringed margin.

Dalmu plate culture on corn meal agar: The pseudomycelium consists of long slender pseudohyphae often curved and bearing few blastoconidia which are often triangular, and occur in clusters or short chains.

Fermentation: absent.

Assimilation of carbon compounds:

Glucose	+	<i>N</i> -Acetyl-D-glucosamine	–
Galactose	–	Methanol	–
L-Sorbose	v	Ethanol	+

50% (w/w) Glucose–yeast extract agar	–	Growth at 37°C	–
10% NaCl/5% glucose	–		

Co-Q: Not determined.

Mol% G+C: 48.3 (Barnett et al. 1990).

Cell hydrolyzates: Fucose and mannose dominate; pentitol (probably arabinitol), tetritol (probably erythritol) are also present (Weijman and Rodrigues de Miranda 1988).

Origin of the strain studied: One strain was isolated from material from the tunnels of the beetle

Xyleborus aemulus Woll. in a deciduous tree, *Rapanea melanophloeos* (L.) Mez., growing near Knysna, Cape Province in South Africa (van der Walt et al. 1971a).

Type strain: CBS 6226.

105.21. *Rhodotorula ingeniosa* (di Menna) von Arx & Weijman (1979)

Synonyms:

Torulopsis ingeniosa di Menna (1958b)

Candida ingeniosa (di Menna) S.A. Meyer & Yarrow (Yarrow and Meyer 1978)

Vanrija ingeniosa (di Menna) R.T. Moore (1980)

Growth in glucose–yeast extract–peptone water:

After 3 days at 25°C, the cells are ovoidal to cylindrical, single or in pairs and measure (2–3.5) × (3.5–8) µm. A thin capsule may be present. After one month, a ring is present.

Growth on glucose–yeast extract–peptone agar:

After one month at 25°C, the streak culture is yellowish, mucoid, glistening, soft and smooth.

Dalmu plate culture on corn meal agar: Pseudomycelium is absent.

Fermentation: absent.

Assimilation of carbon compounds:

Glucose	+	<i>N</i> -Acetyl-D-glucosamine	+

Mol% G+C: 55.6, type strain (T_m : Nakase and Komagata 1971c).

Cell hydrolyzates: Fucose, mannose dominate, hexitol (probably mannitol), pentitol (arabinitol) malic acid (Weijman and Rodrigues de Miranda 1988).

Origin of the strains studied: Pasture grass leaves and in lesser frequencies from the soil beneath the grass near Hamilton, New Zealand, isolated by di Menna (1958b).

Type strain: CBS 4240, di Menna strain TG27, collected in July 1957.

105.22. *Rhodotorula javanica* (Ruinen) von Arx & Weijman (1979)

Synonym:

Candida javanica Ruinen (1963)

Growth in glucose-yeast extract-peptone water:

After 3 days at 25°C, the cells are long-ovoidal to spindle-shaped, (1.5–3) × (7–24) µm. The cells are encapsulated; a thin ring may be present.

Growth on glucose-yeast extract-peptone agar:

After one month at 25°C, the streak culture is yellowish, glistening, slightly mucoid, soft and almost smooth.

Dalmau plate culture on corn meal agar: The pseudomycelium consists of branched chains of spindle-shaped cells in a tree-like arrangement.

Fermentation: absent.

Assimilation of carbon compounds:

50% (w/w) Glucose-yeast extract agar	–	Growth at 25°C	+
10% NaCl/5% glucose	s	Growth at 30°C	–

Co-Q: 9 (Sugiyama et al. 1985).

Mol% G+C: 59.0 (T_m : Stenderup et al. 1972).

Cell hydrolyzates: Fucose, rhamnose, mannose dominant; hexitol (probably mannitol) (von Arx and Weijman 1979).

Origin of the strain studied: Leaf of the flame flower, *Ixora coccinea*, growing in Botanical Garden, Java (Ruinen 1963).

Type strain: CBS 5236.

105.23. *Rhodotorula lactosa* Hasegawa (1959)

Growth in 5% malt extract: After 5 days at 20°C, the cells are single or in pairs, and short-ovoidal to long-ovoidal, (2.5–4.0) × (4.5–8.0) µm, or longer, (11–12.5) µm.

There is a thin incomplete ring and a light sediment. Growth is slow. After one month, there is a thin to moderate ring and a moderate sediment.

Growth on 5% malt agar: Cells in young cultures are larger than those grown in liquid malt extract. After one month at 20°C, the streak culture is pink, smooth, highly glossy, soft but not slimy, convex and shows little spreading; the margin is entire.

Dalmau plate culture on corn meal agar: Pseudomycelium is absent.

Fermentation: absent.

Assimilation of carbon compounds:

Starch formation	–		

Co-Q: 9 (Yamada and Kondo 1973).

Mol% G+C: 57.3, 57.6 (T_m : Nakase and Komagata 1971d).

Cell hydrolyzates: Mannose dominates, hexitol (probably mannitol) (Weijman and Rodrigues de Miranda 1988).

Origin of the strain studied: From air, isolated by Mikata (2).

Type strain: CBS 5826 (IFO 1423). According to the IFO catalog this strain was collected from air by R. Mikata and designated R-13-30. Apparently the original type strain (RT-82) collected by Hasegawa, from air in a cow shed or dairy, was lost (Phaff and Ahearn 1970).

105.24. *Rhodotorula lignophila* (Dill, Ramírez & González) Roelijmans, van Eijk & Yarrow (1989)

Synonym:

Candida lignophila Dill, Ramírez & González (1984)

Growth in 5% malt extract: After 3 days at 25°C, the cells are ovoidal, measuring (2.7–5) × (4–10) µm, and may be single, in pairs or short chains or clusters.

A few elongate cells may occur (up to 30 μm). Cells are encapsulated. After one month, a sediment is present.

Growth on 5% malt extract agar: After one month at 25°C, the streak colony is white, the texture is butyrous, the cross section is flat, surface is dull and the margin is entire. At 19°C, the streak colony is cream-colored, mucoid and glistening.

Dalmeu plate culture on corn meal agar: After one week at 19°C, pseudomycelium is absent (Fig. 414).

Fig. 414. *R. lignophila*, CBS 7109. Cells grown on corn meal agar after 5 days at 25°C. Bar = 15 μm .

Fermentation: absent.

Co-Q: Not determined.

Mol% G + C: Not determined.

Cell hydrolyzates: Xylose, absent; fucose and rhamnose, present (Roeijmans et al. 1989).

Origin of the strains studied: From trunks of the woody plant, *Drimys winteri*, that were in advanced stages of white rot decay (palo podrido) on the isle of Chiloe in South Chile. The habitat has a constant low temperature (annual mean temperature of 10–12°C) and high humidity (annual mean rainfall 2000–3000 mm) (Dill et al. 1984).

Type strain: CBS 7109 (Dill et al. 1984, strain S7/20).

105.25. *Rhodotorula marina* Phaff, Mrak & Williams (1952)

Growth in 5% malt extract: After 3 days at 25°C, the cells are single or in pairs and ovoid to globose, (2–4) \times (4.0–10.1) μm . A thin ring begins to form.

Growth on 5% malt extract agar: After one month at 25°C, the streak colony is orange-pink, glistening, smooth. The texture is pasty to soft. The cross-section is convex, the border entire.

Dalmeu plate culture on corn meal agar: Pseudomycelium is absent.

Fermentation: absent.

Co-Q: 10 (Sugiyama et al. 1985).

Mol% G + C: 53.9 (T_m : Sugiyama et al. 1985).

Cell hydrolyzates: Mannose dominant, hexitol (probably mannitol) (Weijman and Rodrigues de Miranda 1988).

Origin of the strains studied: Surface washings of shrimp in Aransas Bay near Rockport, Texas, January 1950 (Phaff et al. 1952).

Type strain: CBS 2365 (strain 48-23P of Phaff et al. 1952).

Comments: Based on standard taxonomic tests, this species was considered to be a synonym of *R. minuta* (Fell et al. 1984b, Barnett et al. 1990). However, nucleotide sequence analysis of a region of the LSU rRNA demonstrated that the two species are distinct, differing by 53 base positions (Fell et al. 1992). Therefore, we reestablished *R. marina* as a separate species. *R. marina* differs from *R. minuta* on the following: *R. marina* assimilates L-rhamnose, galactitol and citrate and does not utilize either *N*-acetyl-D-glucosamine, 2-keto-D-gluconate or 5-keto-D-gluconate as sole sources of carbon. Based on standard taxonomic tests, *R. marina* is difficult to distinguish from *R. mucilaginoso*; results of testing for growth at 30°C are positive for *R. mucilaginoso*, negative for *R. marina*. Based on nucleotide sequence analysis, *R. marina* and *R. mucilaginoso* are distinct species (Fell et al. 1992). Mol% G+C differs for the two species (*R. marina*, 54; *R. mucilaginoso*, 59–63). We listed growth on maltose and lactose as variable, which is based on the report of Phaff and Ahearn (1970) that the assimilation of those carbon compounds occurs after adaptation and is unstable; also, they listed D-arabinose as positive but latent.

105.26. *Rhodotorula minuta* (Saito) F.C. Harrison (1928)

Synonyms:

- Torula minuta* Saito (1922)
Torulopsis minuta (Saito) Ciferri & Redaelli (1925)
Mycotorula muris Ciferri & Redaelli (1925)
Proteomyces muris (Ciferri & Redaelli) Dodge (1935)
Rhodotorula texensis Phaff, Mrak & Williams var. *minuta* (Saito) Hasegawa, Banno & Yamauchi (1960)
Rhodotorula pallida Lodder (1934)
Rhodotorula texensis Phaff, Mrak & Williams (1952)
Rhodotorula minuta (Saito) F.C. Harrison var. *texensis* (Phaff, Mrak & Williams) Phaff & Ahearn (1970)
Rhodotorula tokyoensis Kobayashi (1953)
Rhodotorula laryngis Reiersøl (1955)
Rhodotorula slooffiae Novák & Vörös-Felkai (1962)
Rhodotorula zsolitii Galgóczy & Novák (1965)

Growth in 5% malt extract: After 3 days at 25°C, the cells are ovoidal, globose or elongate, (2.3–4.5) × (3.5–6.5) μm, single and in pairs. There is a thin, pink ring and a little sediment. After one month, a moderate orange to red ring and a light sediment are present.

Growth on 5% malt agar: The cell morphology is similar to that in malt extract. After one month at 25°C, the streak culture is pink, smooth, glossy, soft but not mucoid, the cross section is flat to low convex and the margin entire.

Dalmau plate culture on corn meal agar: Pseudomycelium is absent.

Fermentation: absent.

Co-Q: 10 (Hamamoto et al. 1987).

Mol% G+C: 51.0–54.0 (BD: Storck et al. 1969; T_m : Nakase and Komagata 1971c); 48.2–50.1 (T_m : Hamamoto et al. 1987).

Cell hydrolyzates: Mannose dominant, hexitol (probably mannitol), pentitol (probably arabinitol) (Weijman and Rodrigues de Miranda 1988).

Origin of the strains studied: 151 strains from Japan, Europe, North America, New Zealand, Antarctica. Sources include: air (1), clinical (23), terrestrial plants and animals (8), marine water, plants and animals (115), pickles (1), fresh water (1), unknown sources (3).

Type strain: CBS 319, isolated by Saito from the atmosphere in Tokyo.

Comments: This species is prevalent and has a widespread occurrence on a variety of substrates. However, the physiological variability as expressed in the standard tests and the differences in mol% G+C values, suggest that strains identified as *R. minuta* may represent a diversity of species. This observation should be tested by nucleotide sequence analysis.

105.27. *Rhodotorula mucilaginoso* (Jørgensen) F.C. Harrison (1928)

Rhodotorula grinbergii Ramírez & González (1984b)
Mycotorula cisnerosi nom. nud. (cf. Fell et al. 1984b)
Mycotorula germanica nom. nud. (cf. Fell et al. 1984b)

Growth in 5% malt extract: After 3 days at 25°C, the cells are ovoidal to spherical, measuring (2–8) × (2–12) µm; reproduction is by multilateral budding and cells may occur singly, in pairs, in short chains or small clusters. There may be a light strawberry-pink ring and a light to

moderate sediment. After one month, there may be islets and a light to heavy ring that is pink to salmon-colored with a moderate to heavy sediment.

Growth on 5% malt extract agar: After one month at 25°C, the streak colony color varies from saffron-orange, pink-salmon to deep coral. The cross section is flat, the surface varies from smooth to rugoid, and dull to glistening. The margin is entire.

Dalmat plate culture on corn meal agar: After one month at 19°C, pseudomycelium is absent or rudimentary, consisting of chains of elongate cells.

Fermentation: absent.

Co-Q: 10 (Hamamoto et al. 1987).

Mol% G + C: 59.0–59.7 (T_m : Hamamoto et al. 1987); 60–63.5 (T_m : Nakase and Komagata 1968a, 1971c, Marmur and Doty 1962).

Cell hydrolyzates: Fucose, mannose dominant, hexitol (probably mannitol), pentitol (probably arabinitol) (Weijman and Rodrigues de Miranda 1988).

Origin of the strains studied: Powdered red pepper, *Capsicum frutescens*, Spain (1); larvae of fruit fly (*Drosophila pilimanae*), Hawaii (1); rotten *Eucryphia cordifolia*, Chile (1); smut infected leaves in southern France (1). Of the 32 strains studied for the original description of *R. mucilaginoso*, 10 were isolated from humans, pasteurized beer, air in Tokyo and Italy.

Type strain: CBS 316. This strain was supplied to CBS in 1934 by the National Collection of Type Cultures in London, which obtained it from Bierberg (Germany) in 1912 as the type strain of *R. mucilaginoso* (Lodder 1970).

Comments: *Rhodotorula mucilaginoso* has a world-wide distribution in terrestrial, aquatic and marine habitats,

from a wide variety of substrates. The species is frequently isolated from human sources, and *R. mucilaginoso* is possibly the only species of *Rhodotorula* that causes human infections (Kwon-Chung and Bennett 1992). Sexual cycles in *R. mucilaginoso* have not been reported. We tested a large number of strains from marine environments for mating responses and we did not observe any positive results.

In the last two editions of "The Yeasts", *R. mucilaginoso* was included as a synonym of *R. rubra*. According to Barnett et al. (1990), the epithet *R. mucilaginoso* has priority and the reason is as follows: Demme (1889) described *Saccharomyces ruber* based on CBS 17. Vuillemin (1901) transferred the species to *Cryptococcus*, then Lodder (1934) created the combination *Rhodotorula rubra*. In the meantime, Saito (1923) described *Torulopsis rubra* based on CBS 2366, a species that Harrison (1928) transferred to *Rhodotorula* as *R. rubra* (Saito) Harrison. CBS 2366, however, was found to be a strain of *Rhodotorula glutinis* (Barnett et al. 1990) and it is taxonomically distinct from CBS 17 (*Rhodotorula rubra* Lodder). Because *R. rubra* (Saito) Harrison was the first usage of that species epithet in the genus, the name is no longer available. Hence, *R. rubra* Lodder cannot be used. Because CBS 17 and the type strain of *R. mucilaginoso* (CBS 316) are taxonomically identical (Barnett et al. 1990, Fell et al. 1992), the nomenclature, *R. mucilaginoso*, is correct.

R. mucilaginoso has a long list of synonyms, which is due to the variability among strains in the utilization of the majority of the test carbon compounds. Some of this strain variability could signify separate species, a possibility that should be examined by nucleotide sequence analysis. Our examination (Fell et al. 1992) of a region of the LSU rRNA from the type strains of *Sporobolomyces alborubescens*, *R. grinbergssii*, *R. rubra*, *R. pilimanae*, *R. matritensis* and *R. mucilaginoso* demonstrated identical sequence alignments, which indicates synonymous species among these taxa. Our inclusion of *S. alborubescens* is at variance with Boekhout's (1991a) retention of that species in *Sporobolomyces*. The only report of ballistoconidia in *S. alborubescens* is found in the original description. Our attempts to induce ballistoconidia have not been successful with that strain or other strains of *R. mucilaginoso*.

Barnett et al. (1990) reported variable reactions in nitrate assimilation. The positive reactions were attributed to a report by Hamamoto et al. (1987) who found high (66–82%) relative binding of DNA between three strains (YK 114, 115, 116) of *R. glutinis* and the type strain *R. rubra*, but not between the type strains of the two species. Our inspection of their data suggested that the three YK strains belong to *R. rubra* rather than *R. glutinis*. Hamamoto et al. did not present the nitrate assimilation data for their test strains, however, two of the strains (YK 115 and 116) demonstrated low (33–34%) relative binding with the type strain of *R. glutinis*. The third

strain YK 114, which was tested against YK 115, resulted in 99% binding. Because we have not observed nitrate-assimilating strains of *R. mucilaginoso* and because we find that strains of the two species are significantly different in nucleotide sequence alignments (Fell et al. 1992), nitrate-assimilating strains are not included in the species description.

105.28. *Rhodotorula muscorum* (di Menna) von Arx & Weijman (1979)

Synonyms:

Candida muscorum di Menna (1958a)

Azymocandida muscorum (di Menna) Novák & Zsolt (1961)

Growth in glucose–yeast extract–peptone water:

After 3 days at 25°C, the cells are ovoidal to irregularly elongate, (2–3) × (5–10.7) µm. After one month, a ring and heavy sediment are present.

Growth on glucose–yeast extract–peptone agar:

After one month at 25°C, the streak culture is yellowish cream-colored, semi-glistening, mucoid, soft, and smooth; warty outgrowths may be present.

Dalmau plate culture on corn meal agar: After 7 days at 19°C, pseudomycelium, consisting of ramified chains of cells bearing few blastoconidia, is present.

Fermentation: absent.

50% (w/w) Glucose–yeast extract agar	–	Growth at 25°C	+
10% NaCl/5% glucose	+	Growth at 30°C	–

Co-Q: 10 (Sugiyama et al. 1985).

Mol% G + C: Not determined.

Cell hydrolyzates: Fucose and mannose are dominant; hexitol (probably mannitol) and pentitol (probably arabinitol) are present as well (Weijman and Rodrigues de Miranda 1988). According to Sugiyama et al. (1985), xylose is present.

Origin of the strains studied: Rotting layer of sphagnum overlying a peat bog at Paraparumu in the Wellington district, New Zealand and forest soils from Chatham Island, 700 miles east of New Zealand (di Menna 1958a) (1); barley leaf (1).

Type strain: CBS 6921. Meyer et al. (1984) reported that the type strain, CBS 2912 (di Menna strain PS2) no longer agreed with the description and was replaced with CBS 6921. Both cultures were derived from the di Menna strains.

Comments: Based on standard carbon and nitrogen utilization tests, this species resembles *R. fragaria*. The two species are distinct and can be separated taxonomically by the following: *R. muscorum* assimilates saccharate and slowly assimilates galactitol; *R. fragaria* does not assimilate either compound. *R. muscorum* does not assimilate L-arabinose, *R. fragaria* assimilates it slowly. Nucleotide sequence analysis in our laboratory (unpublished) indicates that *R. fragaria*, *R. muscorum* and *Leucosporidium scottii* are closely related, yet distinct species.

105.29. *Rhodotorula nothofagi* (Ramírez & González) Røijmans, van Eijk & Yarrow (1989)

Synonym:

Apiotrichum nothofagi Ramírez & González (1984d)

Growth in glucose–yeast extract–peptone water: After 3 days at 25°C, the cells are ovoidal to elongate, (2–6) × (4.7–8.7) μm, single or in pairs. After one month, islets and a heavy sediment are present.

Growth on 5% malt extract agar: After one month at 25°C, the streak colony is light yellowish-pink, smooth, slightly glistening; the texture is butyrous, the cross section is flat, and the margin is entire.

Dalmu plate culture on corn meal agar: After one week at 19°C, pseudomycelium is absent.

Fermentation: absent.

Assimilation:

Glucose	+	<i>N</i> -Acetyl-D-glucosamine	–
Galactose	+	Methanol	–
L-Sorbose	+	Ethanol	+
Sucrose	–	Glycerol	s

Additional assimilation tests and other growth characteristics:

2-Keto-D-gluconate	n	Starch formation	–
5-Keto-D-gluconate	n	Urease	+
Saccharate	–	Gelatin liquefaction	–
D-Gluconate	–	Growth at 30°C	+
50% (w/w) Glucose–yeast extract agar	+	Growth at 37°C	–
10% NaCl/5% glucose	s		

Co-Q: Not determined.

Mol% G+C: Not determined.

Cell hydrolyzates: Xylose absent, fucose and rhamnose positive (Røijmans et al. 1989).

Origin of the strain studied: Ramírez and González (1984d) isolated a single strain of this species in 1980 from decayed wood of *Nothofagus obliqua* (Mirb.) Blume in the evergreen rainy Valdivian forest of southern Chile, near the locality of Futrono.

Type strain: CBS 8166 (Ramírez and González number IFJM 6018).

Comments: Ramírez and González (1984d) reported that L-rhamnose was assimilated and that D-xylose, L-arabinose, D-arabinose, and D-ribose were not assimilated; we were unable to confirm these results.

105.30. *Rhodotorula philyla* (van der Walt, van der Klift & D.B. Scott) Rodrigues de Miranda & Weijman (Weijman et al. 1988)

Synonyms:

Torulopsis philyla van der Walt, van der Klift & D.B. Scott (van der Walt et al. 1971b)

Candida philyla (van der Walt, van der Klift & D.B. Scott) S.A. Meyer & Yarrow (Yarrow and Meyer 1978)

Vanrija philyla (van der Walt, van der Klift & D.B. Scott) R.T. Moore (1980)

Growth in glucose–yeast extract–peptone water: After 3 days at 25°C, the cells are ellipsoidal to ovoidal, (2–4.7) × (3.3–6) μm, and occur singly, in pairs, or in chains. A thin ring and sediment are present. After one month at 20°C, a ring and sediment are present.

Growth on glucose–yeast extract–peptone agar: After one month at 25°C, the streak culture is cream-colored, glistening, smooth, mucoid, and the margin is entire.

Dalmu plate culture on corn meal agar: After one week at 19°C, no pseudomycelium is formed.

Fermentation: absent.

Assimilation of carbon compounds:

Glucose	+	<i>N</i> -Acetyl-D-glucosamine	+
Galactose	-	Methanol	-
L-Sorbose	-	Ethanol	+
Sucrose	-	Glycerol	-
Maltose	-	Erythritol	-

5-Keto-D-gluconate	n	Urease	+
Saccharate	-	Gelatin liquefaction	-
D-Glucuronate	+	Growth at 30°C	+
50% (w/w) Glucose-yeast extract agar	-	Growth at 37°C	-
10% NaCl/5% glucose	-		

Co-Q: 10 (Sugiyama et al. 1985).

Mol% G+C: 62.9, type strain (T_m : Meyer et al. 1984).

Cell hydrolyzates: Fucose, rhamnose, mannose dominant, hexitol (probably mannitol) and pentitol (probably arabinitol) (Weijman and Rodrigues de Miranda 1988).

Origin of the strain studied: Tunnels of the beetle *Xyleborus ferrugineus* F. infecting an indigenous tree, *Harpophyllum caffrum* Bernh. ex Krass, near Mtunzini, Natal (van der Walt et al. 1971b).

Type strain: CBS 6272.

105.31. *Rhodotorula phylloplana* (Shivas & Rodrigues de Miranda) Rodrigues de Miranda & Weijman (Weijman et al. 1988)

Synonym:

Cryptococcus phylloplanus Shivas & Rodrigues de Miranda (1983a)

Growth in 5% malt extract: After 3 days at 25°C, the cells are ovoidal to cylindrical, (2.3–3.3) × (4.7–9.4) μ m, and occur singly or in pairs. After one month, a very light ring and sediment have formed.

Growth on 5% malt extract agar: After one month at 19°C, the streak colony is buff-colored, smooth, semi-glistening, butyrous, and the margin is entire.

Dalmau plate culture on corn meal agar: After one week at 19°C, pseudo- and true mycelium have not formed.

Fermentation: absent.

Assimilation:

Glucose	+	<i>N</i> -Acetyl-D-glucosamine	-
Galactose	-	Methanol	-
L-Sorbose	-	Ethanol	+
Sucrose	+	Glycerol	+
Maltose	+	Erythritol	+
Cellobiose	-	Ribitol	-
Trehalose	-	Galactitol	-
Lactose	-	D-Mannitol	+
Melibiose	-	D-Glucitol	+
Raffinose	+	α -Methyl-D-glucoside	+
Melezitose	+	Salicin	-
Inulin	-	D-Gluconate	-
Soluble starch	-	DL-Lactate	-
D-Xylose	-	Succinate	+
L-Arabinose	+	Citrate	-
D-Arabinose	-	Inositol	s
D-Ribose	-	Hexadecane	-
L-Rhamnose	-	Nitrate	+
D-Glucosamine	-	Vitamin-free	+

Additional assimilation tests and other growth characteristics:

2-Keto-D-gluconate	n	Starch formation	-
5-Keto-D-gluconate	n	Urease	+
Saccharate	-	Gelatin liquefaction	-
D-Glucuronate	-	Growth at 25°C	+
50% (w/w) Glucose-yeast extract agar	-	Growth at 30°C	-
10% NaCl/5% glucose	-		

Co-Q: Not determined.

Mol% G+C: Not determined.

Cell hydrolyzates: Mannose low, malic acid (Weijman and Rodrigues de Miranda 1988).

Origin of the strain studied: Surface of leaves of the honeysuckle, *Banksia collina* R. Br., growing at Armidale, New South Wales, Australia, collected in 1981 (Shivas and Rodrigues de Miranda 1983a).

Type strain: CBS 8073.

Comments: *R. phylloplana* and *R. hinnulea* are the only species in the genus that demonstrate growth on inositol. The two species can be separated by their differences in utilizing cellobiose and trehalose. Shivas and Rodrigues de Miranda (1983a) reported that cellobiose, trehalose and soluble starch were assimilated weakly, and xylose, salicin and DL-lactic acid were assimilated strongly; we were unable to confirm these results. Nucleotide sequence analysis in our laboratory (unpublished) indicates that *R. phylloplana* is related to the Ustilaginales. This relationship is also suggested by the low level of mannose in the cell hydrolyzates, which is characteristic of the smut-like yeasts.

105.32. *Rhodotorula pilati* (F.H. Jacob, Faure-Raynaud & Berton) J.A. Barnett, Payne & Yarrow (1983)

Synonym:

Torulopsis pilati F.H. Jacob, Faure-Raynaud & Berton (1979)

Growth in 5% malt extract: After 3 days at 25°C, the cells are ovoidal, single or in pairs, measuring (4.0–6.0) × (5.0–12.7) μ m. After one month a sediment and a ring have formed.

Growth on 5% malt extract agar: After one month at 25°C, the colony is cream-colored, the cross section

is raised, the surface is glistening and smooth, and the margin is entire.

Dalmau plate culture on corn meal agar: After one month at 25°C, neither true nor pseudomycelium is present.

Fermentation: absent.

Assimilation:

Glucose	+	<i>N</i> -Acetyl-D-glucosamine	-
Galactose	-	Methanol	-
L-Sorbose	-	Ethanol	-
Sucrose	+	Glycerol	+
Maltose	+	Erythritol	-
Cellobiose	+	Ribitol	-
Trehalose	+	Galactitol	-
Lactose	v	D-Mannitol	+
Melibiose	-	D-Glucitol	-
Raffinose	-	α -Methyl-D-glucoside	-
Melezitose	+	Salicin	-
Inulin	-	D-Gluconate	+
Soluble starch	-	DL-Lactate	-
D-Xylose	-	Succinate	-
L-Arabinose	-	Citrate	-
D-Arabinose	-	Inositol	-
D-Ribose	-	Hexadecane	-
L-Rhamnose	-	Nitrate	+
D-Glucosamine	-	Vitamin-free	-

Additional assimilation tests and other growth characteristics:

2-Keto-D-gluconate	n	Starch formation	-
5-Keto-D-gluconate	n	Urease	+
Saccharate	-	Gelatin liquefaction	-
D-Gluconate	-	Growth at 25°C	+
50% (w/w) Glucose-yeast extract agar	-	Growth at 30°C	-
10% NaCl/5% glucose	-		

Co-Q: Not determined.

Mol% G + C: Not determined.

Cell hydrolyzates: Fucose, rhamnose, mannose dominant, hexitol (probably arabinitol) and pentitol (probably mannitol) (Weijman and Rodrigues de Miranda 1988).

Origin of the strains studied: Leaf litter of fir tree *Abies alba* located at an altitude of 1100 m at Massif du Pilat, Loire, France (Jacob et al. 1979); decaying tree trunk, Portugal.

Type strain: CBS 7039 (strain LYJ 382 of Jacob et al. 1979).

Comments: The original description stated that nitrate was not assimilated, that growth occurred in the absence of vitamins and that α -methyl-D-glucoside was utilized as a sole carbon source, characteristics that we were unable to confirm.

105.33. *Rhodotorula pustula* (Buhagiar) Rodrigues de Miranda & Weijman (Weijman et al. 1988)

Synonyms:

Torulopsis pustula Buhagiar (1975)

Candida pustula (Buhagiar) S.A. Meyer & Yarrow (Yarrow and Meyer 1978)

Growth in glucose-yeast extract-peptone water: After 3 days at 25°C, the cells are ovoidal, long-ovoidal

Fig. 415. *R. pustula*, CBS 6527. Cells grown on corn meal agar at 25°C after 5 days. Bar = 10 μ m.

to cylindrical, and pear-shaped, (3.4–5.6) \times (8.4–10.6) μ m. After one month a ring and sediment are present.

Growth on glucose-yeast extract-peptone agar: After one month at 25°C, the streak is white to tan-white, mucoid, glossy, smooth, and convex with an entire margin.

Dalmau plate culture on corn meal agar: Branched chains of long, ovoidal cells are formed with short chains of blastoconidia (Fig. 415).

Fermentation: absent.

Assimilation of carbon compounds:

Glucose	+	<i>N</i> -Acetyl-D-glucosamine	+
Galactose	v	Methanol	-
L-Sorbose	+	Ethanol	+
Sucrose	-	Glycerol	s
Maltose	-	Erythritol	-
Cellobiose	+	Ribitol	+
Trehalose	+	Galactitol	-
Lactose	-	D-Mannitol	+
Melibiose	-	D-Glucitol	+
Raffinose	-	α -Methyl-D-glucoside	-
Melezitose	-	Salicin	+
Inulin	-	D-Gluconate	+
Soluble starch	-	DL-Lactate	-
D-Xylose	+	Succinate	+
L-Arabinose	+	Citrate	+
D-Arabinose	+	Inositol	-
D-Ribose	s	Hexadecane	-
L-Rhamnose	-	Nitrate	+
D-Glucosamine	+	Vitamin-free	-

Additional assimilation tests and other growth characteristics:

2-Keto-D-gluconate	n	Starch formation	-
5-Keto-D-gluconate	n	Urease	+
Saccharate	-	Gelatin liquefaction	-
D-Gluconate	+	Growth at 25°C	+
50% (w/w) Glucose-yeast extract agar	-	Growth at 30°C	-
10% NaCl/5% glucose	-		

Co-Q: Not determined.

Mol% G + C: 51.0, type strain (T_m : Meyer et al. 1984).

Cell hydrolyzates: Fucose, rhamnose, mannose dominant, hexitol (probably arabinitol and pentitol (probably mannitol) present (Weijman and Rodrigues de Miranda 1988).

Origin of the strains studied: Black currants (*Ribes nigrum* cultivar Baldwin) collected in 1971 and 1972 in England.

Type strain: CBS 6527.

Comments: The original description noted that hexadecane utilization was delayed, a characteristic that we were unable to confirm.

105.34. *Rhodotorula sonckii* (Hopsu-Havu, Tunnela & Yarrow) Rodrigues de Miranda & Weijman (Weijman et al. 1988)

Synonym:

Candida sonckii Hopsu-Havu, Tunnela & Yarrow (1978)

Growth in glucose-yeast extract-peptone water:

After 3 days at 25°C, the cells are ellipsoidal to cylindrical, (2.5–4.0) × (7.0–12.0) µm, single or in pairs. A sediment is formed. After one month at room temperature, a sediment is present.

Growth on glucose-yeast extract-peptone agar:

After one month at 25°C, the streak culture is cream-colored, smooth, glistening and flat. The margins are entire. Growth is slow.

Dalmu plate culture on corn meal agar: After one week, pseudomycelium is not formed.

Fermentation: absent.

Assimilation:

Glucose	+	<i>N</i> -Acetyl-D-glucosamine	–
Galactose	+	Methanol	–
L-Sorbose	s	Ethanol	–
Sucrose	–	Glycerol	s
Maltose	–	Erythritol	–

50% (w/w) Glucose-yeast extract agar	–	Growth at 30°C	–
10% NaCl/5% glucose	–		

Co-Q: Not determined.

Mol% G + C: 44.1 (T_m : Hopsu-Havu et al. 1978).

Cell hydrolyzates: Fucose, mannose dominant (Weijman & Rodrigues de Miranda 1988).

Origin of the strains studied: Wall of a bathing pool during a routine check of hospital hygiene in the pediatric

department of the University Hospital of Turku, Finland in Oct. 1973 (CBS 6713, Hopsu-Havu et al. 1978); from the arm of a patient in Finland (CBS 8115), strain submitted to CBS by Hopsu-Havu.

Type strain: CBS 6713.

Comments: The original description noted that ribitol could not support growth as the sole source of carbon, a characteristic that we were unable to confirm.

Comments on the genus

Species in the genus *Rhodotorula* date to Fresenius (1850) with the description of *Cryptococcus glutinis*. The genus was formally described by Harrison (1928) to include red pigmented asporogenous yeasts. Other pigmented yeasts were placed in *Chromotorula*. The latter genus was rejected by Lodder (1934) who placed all of the carotenoid species in *Rhodotorula*. In the first edition of *The Yeasts, A Taxonomic Study* (Lodder and Kreger-van Rij 1952), *Rhodotorula* was distinguished as occasionally having a primitive pseudomycelium, producing carotenoid pigments and lacking the ability to ferment. Seven species were accepted. There was little change in the generic descriptions through the 2nd edition of “*The Yeasts*” with the exception that *Rhodotorula* species were described as not having the capacity to assimilate inositol nor synthesize starch-like compounds. Nine species were recorded in the genus. The major informative step, by this time, was the confirmation of the basidiomycetous nature of this genus, particularly the observations of teleomorphic stages described in the genus *Rhodospiridium*. The next major change was a result of an altered definition of *Candida*. Ascomycetous species were retained in *Candida* and the basidiomycetous species were separated based on the composition of cell hydrolyzates (Weijman and Rodrigues de Miranda 1983). Species with xylose in the cell hydrolyzates were placed in *Cryptococcus* and species which lacked xylose were relegated to *Rhodotorula*.

The genus, as currently defined, includes 34 species that comprise a polyphyletic group of organisms. The separation of these species is based on 2 morphological characters, 19 physiological tests and one growth temperature test. To eliminate some of these tests, we present Tables 86–91, which employ a reduced number of characteristics. These tables include the teleomorphic species that could be identified with these tests.

Our suggestion for an orderly identification procedure includes a preliminary screening with the following tests: assimilation of inositol, D-gluconate and nitrate and the synthesis of starch. After comparing the results with Table 85, the next step is to examine the appropriate Table and use those tests. It is also valuable, in the initial stages of identification, to examine colony color, cell morphology and potential formation of mycelium and teliospores. Through the use of these identification shortcuts, it should not be necessary, for routine identifications, to employ all of the tests listed in Table 86. Mating tests

should be undertaken when multiple strains of a species are available, because many of the *Rhodotorula* species are anamorphic strains of described and undescribed teleomorphic species. These mating tests consist of mixing multiple strains together on a complex nutrient medium such as corn meal agar. If mating occurs, the number of strains can be reduced in subsequent crosses to find the mating pairs.

Our laboratory is currently studying the molecular systematics of this genus. Some of the unpublished results, which were obtained after the completion of this manuscript, are included in the species comments. The results indicate diverse phylogenetic origins of species in the genus and that closely related anamorphic

species include members of the genera *Bensingtonia*, *Sporobolomyces* and *Sterigmatomyces*. Some species, particularly *R. acheniorum*, *R. bacarum*, *R. hinnulea* and *R. phylloplana*, may be related to the smut-like species in the Ustilaginales. In the near future, we plan to present an integrated view of the genus based on molecular and phenotypic data, which we hope will eliminate some of the taxonomic problems in *Rhodotorula*.

Species not examined: The following species were not included because they came belatedly to the attention of the authors:

Rhodotorula cresolica Middelhoven and Spaaij (1997)

Rhodotorula vanillica J.P. Sampaio (1994)

106. *Sporobolomyces* Kluyster & van Niel

T. Boekhout and T. Nakase

Diagnosis of the genus

Cells are ellipsoidal, subglobose, fusiform or cylindroidal. Budding is mostly polar, rarely lateral or multilateral, with buds sessile or on short denticles, enteroblastic, and with percurrent or sympodial proliferation. Ballistoconidia are bilaterally symmetrical, ellipsoidal, falcate, allantoid, lacrymoid or amygdaliform. Colonies are salmon-pink, orange-red, red, cream, or yellow-brown. Hyphae and pseudohyphae may be present.

Sugars are not fermented. Diazonium blue B and urease reactions are positive. Xylose is absent from whole-cell hydrolyzates. The major ubiquinone is Q-10 or Q-10(H₂).

Type species

Sporobolomyces salmonicolor (Fischer & Brebeck) Kluyster & van Niel

Species accepted

1. *Sporobolomyces alborubescens* Derx (1930)
2. *Sporobolomyces elongatus* Shivas & Rodrigues de Miranda (1983)
3. *Sporobolomyces falcatus* Nakase, M. Itoh & M. Suzuki (1987)
4. *Sporobolomyces foliicola* Shivas & Rodrigues de Miranda (1983)
5. *Sporobolomyces gracilis* Derx (1930)
6. *Sporobolomyces griseoflavus* Nakase & M. Suzuki (1987)
7. *Sporobolomyces inositolophilus* Nakase & M. Suzuki (1987)
8. *Sporobolomyces kluysteri-nielii* van der Walt (1986)
9. *Sporobolomyces lactophilus* Nakase, M. Itoh, M. Suzuki & Bandoni (1990)
10. *Sporobolomyces oryzicola* Nakase & M. Suzuki (1986)
11. *Sporobolomyces phyllomatis* van der Walt & Y. Yamada (1988)
12. *Sporobolomyces roseus* Kluyster & van Niel (1924)
13. *Sporobolomyces ruber* (Nakase, Okada & Sugiyama) Boekhout (1991)
14. *Sporobolomyces salicinus* (Johri & Bandoni) Nakase & M. Itoh (1988)
15. *Sporobolomyces salmonicolor* (Fischer & Brebeck) Kluyster & van Niel (1924): see *Sporidiobolus johnsonii*, p. 694
16. *Sporobolomyces sasicola* Nakase & M. Suzuki (1987)
17. *Sporobolomyces shibatanius* (Okunuki) Verona & Ciferri (1938): see *Sporidiobolus pararoseus*, p. 694
18. *Sporobolomyces singularis* Phaff & do Carmo-Sousa (1962)
19. *Sporobolomyces subbrunneus* Nakase & M. Suzuki (1985)
20. *Sporobolomyces tsugae* (Phaff & do Carmo-Sousa) Nakase & M. Itoh (1988)
21. *Sporobolomyces xanthus* (Nakase, Okada & Sugiyama) Boekhout (1991)

Key to species

See Table 92.

1. a Self-sporulating formation of teliospores present see *Sporidiobolus*: p. 693
 b Self-sporulating formation of teliospores absent → 2
- 2(1). a Nitrate assimilated → 3
 b Nitrate not assimilated → 17

Systematic discussion of the species

106.1. *Sporobolomyces alborubescens* Derx (1930)

Growth on 5% malt extract agar: After 5 days at 25°C, the cells are ellipsoidal, (6.0–9.0)×(4.0–6.5) µm, and single. Budding is polar, and buds are sessile or on short denticles. Colonies are butyrous, smooth, glabrous, shiny, pinkish-red or red, and with the margin entire, straight or somewhat crenulate.

Growth on the surface of assimilation media (glucose): A ring, islets and a sediment are formed.

Dalmou plate culture on morphology agar: After 7 days at 25°C, part of the cells form short, irregular hyphal outgrowths. Aerobic growth is red (brick red), shiny, butyrous, smooth or weakly ridged or grooved, somewhat raised, and with the margin entire.

Formation of ballistoconidia: Ballistoconidia were not observed. According to Derx (1930) they measure 9.5–11.0×4 µm.

Fermentation: absent.

Co-Q: 10 (Nakase 1989).

Mol% G+C: 63.0, CBS 482 (BD: Storck et al. 1969).

Origin of the strains studied: CBS 482 (ATCC 24216, JCM 5352, NRRL Y-6683, UCD-FST 68-329), leaf infected with rusts, H.G. Derx, France; CBS 6239, dialysis equipment, M. Bruining, Netherlands.

Type strain: CBS 482.

Comments: The two strains of *S. alborubescens* studied

have lost the capacity to form ballistoconidia. Therefore, the species may be confused with species of *Rhodotorula*. Physiologically closely related *Rhodotorula* species are *R. minuta* and *R. mucilaginoso*. *Rhodotorula minuta* differs by a lower mol% G+C of 50.2–54.5 (Storck et al. 1969, Nakase and Komagata 1971c). *Rhodotorula mucilaginoso* is very similar, but can be differentiated by its lack of growth on salicin.

106.2. *Sporobolomyces elongatus* Shivas & Rodrigues de Miranda (1983b)

Growth on 5% malt extract agar: After 5 days at 25°C, the cells are ellipsoidal, cylindrical to subglobose, (6.0–16.0)×(3.0–9.0) µm, and single. Budding is polar or lateral, and buds are sessile or on short denticles. Colonies are butyrous, smooth, shiny, salmon-pink, and with the margin entire.

Growth on the surface of assimilation media (glucose): Absent, but a sediment is formed.

Dalmou plate culture on morphology agar: After 7 days at 25°C, hyphae and pseudohyphae are absent. Cells are ellipsoidal to cylindrical. Aerobic growth is orange-pink to salmon, shiny, butyrous, smooth, with the center somewhat raised, and the margin entire.

Formation of ballistoconidia: Ballistoconidia were not observed. According to Shivas and Rodrigues de Miranda (1983b), they are kidney-shaped, (5.0–8.0)×(2.5–4.0) µm.

Fermentation: absent.

Assimilation:

Glucose	+	<i>N</i> -Acetyl-D-glucosamine	n
Galactose	–	Methanol	–
L-Sorbose	+	Ethanol	–
Sucrose	+	Glycerol	+
Maltose	+	Erythritol	–

D-Glucosamine	–	Vitamin-free	–

Additional assimilation tests and other growth characteristics:

2-Keto-D-gluconate	–	Nitrite	–
50% (w/w) Glucose	–	Growth at 25°C	+
Starch formation	–	Growth at 30°C	–
Urease	+		

Co-Q: 10(H₂) (Nakase and Suzuki 1986d).

Mol% G + C: 56.5 (Nakase 1989).

Origin of the strain studied: CBS 8080 (ATCC 52908), leaf of *Callistemon viminalis*, J.F. Brown, Australia.

Type strain: CBS 8080.

Comments: *Sporobolomyces elongatus* differs from all other *Sporobolomyces* species by the presence of Co-Q 10(H₂) (Nakase and Suzuki 1986d). Ballistoconidium formation seems an easily lost feature of this species. *Rhodotorula minuta* is physiologically similar, but differs by its growth on ribitol and ethanol.

106.3. *Sporobolomyces falcatus* Nakase, M. Itoh & M. Suzuki (1987a)

Growth on 5% malt extract agar: After 5 days at 25°C, the cells are ellipsoidal, (4.0–8.5) × (1.5–3.5) μm, and single. Budding is usually polar, but also lateral, and with buds sessile or on short denticles and with sympodial or percurrent proliferation. Cells may form branched hyphae. Colonies are butyrous, shiny or dull, cream or grayish-white, with the margin entire or somewhat eroded.

Growth on the surface of assimilation media (glucose): A ring and a sediment are formed.

Dalmu plate on morphology agar: After 7 days at 25°C, no hyphae or pseudohyphae occur. However, short hyphae are formed on malt extract agar. Aerobic growth is pale cream, shiny, butyrous, smooth and slightly striated near the margin, with the center somewhat raised, and the margin entire, straight or crenulate.

Formation of ballistoconidia: Ballistoconidia are formed on malt extract agar and corn meal agar. They are falcate or amygdaliform, (5.0–12.0) × (1.5–3.0) μm (Fig. 416).

Fermentation: absent.

Fig. 416. *S. falcatus*, CBS 7368. Ballistoconidia on malt extract agar. Bar = 10 μm.

Assimilation:

Glucose	+	<i>N</i> -Acetyl-D-glucosamine	n
Galactose	+	Methanol	–
L-Sorbose	–	Ethanol	+
Sucrose	–	Glycerol	+

Additional assimilation tests and other growth characteristics:

2-Keto-D-gluconate	+	Nitrite	+
50% (w/w) Glucose	–	Growth at 30°C	+
Starch formation	–	Growth at 37°C	–
Urease	+		

Co-Q: 10 (Nakase et al. 1987a).

Mol% G + C: 53.1, JCM 6838 (*T_m*: Nakase et al. 1987a).

Origin of the strain studied: CBS 7368 (ATCC 64693, JCM 6838), dead leaf of *Miscanthus sinensis*, T. Nakase, Japan.

Type strain: JCM 6838.

Comments: *Sporobolomyces falcatus* belongs to a group of species characterized by pale colonies and growth on 2-keto-D-gluconate (“*singularis* group” according to Nakase 1989). *Sporobolomyces falcatus* is characterized by growth on D-glucosamine, and lack of growth on sucrose, maltose and melezitose.

106.4. *Sporobolomyces foliicola* Shivas & Rodrigues de Miranda (1983b)

Growth on 5% malt extract agar: After 5 days at 25°C, the cells are ellipsoidal to subglobose, (7.5–16.5) × (5.0–13.0) μm, and single. Budding is polar or multilateral, and with percurrent or sympodial proliferation. Colonies are butyrous, smooth, somewhat shiny, red (incarnate), and with the margin entire.

Growth on the surface of assimilation media (glucose): Islets and a sediment are formed.

Dalmu plate culture on morphology agar: After 7 days at 25°C, no hyphae or pseudohyphae are formed. Aerobic growth is red (incarnate), somewhat dull, butyrous, smooth, with the center somewhat raised, and the margin entire.

Formation of ballistoconidia: Ballistoconidia are formed on corn meal agar. They are ellipsoidal, (6.5–9.5) × (4.0–) μm (Fig. 417).

Fig. 417. *S. foliicola*, CBS 8075. Ballistoconidia on corn meal agar. Bar = 5 μm .

Fermentation: absent.

Origin of strain studied: CBS 8075 (ATCC 52909, JCM 5355), leaf of *Banksia collina*, J.F. Brown, Australia.

Type strain: CBS 8075.

106.5. *Sporobolomyces gracilis* Derx (1930)

Growth on 5% malt extract agar: After 5 days at 17°C, the cells are cylindrical or ellipsoidal, (5.5–15.0) × (3.0–5.5) μm , and single. Budding is polar or lateral with buds sessile or on short denticles and with sympodial or percurrent proliferation. Colonies are butyrous, smooth or somewhat warty, shiny or dull, red (brick red), and with the margin entire, straight or crenulate.

Growth on the surface of assimilation media: Absent, but a sediment is formed.

Dalmeu plate culture on morphology agar: After

7 days at 17°C, hyphae or pseudohyphae are absent. CBS 7028 forms short hyphal outgrowths on corn meal agar. Aerobic growth is red, shiny, butyrous, smooth, flat or with the center somewhat raised, and the margin entire.

Formation of ballistoconidia: Ballistoconidia were not observed. According to Derx (1930), they are pyriform, nearly symmetrical, (8.0–10.5) × (3.0–4.0) μm .

Fermentation: absent.

Assimilation (17°C):

Glucose	+	<i>N</i> -Acetyl-D-glucosamine	n
Galactose	-	Methanol	-
L-Sorbose	-	Ethanol	-
Sucrose	-	Glycerol	+

50% (w/w) Glucose	-	Growth at 25°C	v
Starch formation	-	Growth at 30°C	-
Urease	+		

Co-Q: 10 (Nakase and Suzuki 1986d).

Mol% G+C: 50.9 (Nakase 1989).

Origin of the strains studied: CBS 71 (ATCC 24258, IFO 1033, JCM 2936, NRRL Y-5504, VKM Y-677, NI 7598, NI 7615), rotten leaves, H.G. Derx; CBS 7028 (UCD-FST 78-52), M. Miranda; CBS 7123, leaf of *Phertinia glabra*, K. Wickremasinghe, Australia.

Type strain: CBS 71.

Comments: *Sporobolomyces gracilis* is characterized by its inability to assimilate galactose, L-sorbose, sucrose, nitrate and nitrite. Since ballistoconidium formation is now absent in the strains studied, *S. gracilis* may be confused with species of *Rhodotorula*. Physiologically similar *Rhodotorula* species are *R. aurantiaca*, *R. minuta* and *R. mucilaginosa*. *Rhodotorula aurantiaca* differs by assimilation of nitrate and nitrite; *R. minuta* can be differentiated by growth on L-arabinose, sucrose and melezitose, whereas *R. mucilaginosa* differs by growth on sucrose and raffinose.

106.6. *Sporobolomyces griseoflavus* Nakase & M. Suzuki (1987b)

Growth on 5% malt extract agar: After 5 days

at 25°C, the cells are ellipsoidal to fusiform, (7.5–10.0)×(2.0–3.5)µm, and single. Budding is polar, with buds sessile or on short denticles and with sympodial proliferation. Colonies are butyrous to mucoid, smooth, shiny, grayish-white to yellowish-cream, and with the margin entire and finely crenulate.

Growth on assimilation media (glucose): Absent, but a sediment is formed.

Dalmou plate culture on morphology agar: After 7 days at 25°C, no hyphae or pseudohyphae are formed. Aerobic growth is pale yellowish-brown, shiny, butyrous or mucoid, smooth, flat or with the center somewhat raised, and the margin entire.

Formation of ballistoconidia: Formation of ballistoconidia is poor. Ballistoconidia are allantoid to falcate, (5.0–6.0)×(2.0)µm. According to Nakase and Suzuki (1987b) they are abundantly formed, kidney- to sickle-shaped, and (4.5–8.5)×(2.0–3.5)µm.

Fermentation: absent.

Assimilation:

Glucose	+	<i>N</i> -Acetyl-D-glucosamine	n
Galactose	+	Methanol	–
L-Sorbose	–	Ethanol	+

2-Keto-D-gluconate	+	Nitrite	+
50% (w/w) Glucose	–	Growth at 25°C	+
Starch formation	–	Growth at 30°C	–
Urease	+		

Co-Q: 10 (Nakase and Suzuki 1987b).

Mol% G + C: 60.8–60.9, JCM 5653 (T_m : Nakase and Suzuki 1987b).

Origin of the strain studied: CBS 7284 (JCM 5653), dead leaves of *Sasa* species, T. Nakase, Japan.

Type strain: JCM 5653.

Comments: *Sporobolomyces griseoflavus* belongs to the “*singularis*” group, which is characterized by pale colonies and assimilation of 2-keto-D-gluconate. Among species belonging to this group, *S. griseoflavus* can be differentiated by growth on galactose, D-xylose, melezitose and starch, *S. falcatus* differs by lack of growth on D-arabinose, sucrose, maltose, melezitose and starch. Non-ballistoconidium forming species with a similar physiology are *Cryptococcus albidus*, *Rhodotorula*

aurantiaca, *R. glutinis* and *R. pilati*. *Cryptococcus albidus* differs by growth on L-arabinose, and the *Rhodotorula* species do not assimilate starch.

106.7. *Sporobolomyces inositophilus* Nakase & M. Suzuki (1987e)

Growth on 5% malt extract agar: After 5 days at 25°C, the cells are ellipsoidal to fusiform, (6.0–14.0)×(2.0–3.0)µm, and single. Cells sometimes form hyphal outgrowths. Budding is polar with buds sessile or on short denticles that show sympodial proliferation. Colonies are mucoid, smooth, shiny, grayish-cream, and with the margin entire, straight or somewhat undulate.

Growth on the surface of assimilation media: Islets and a sediment are formed.

Dalmou plate culture on morphology agar: After 7 days at 25°C, no hyphae or pseudohyphae are formed. On corn meal agar and malt extract agar hyphal outgrowths of up to 50µm are present. Aerobic growth is whitish to yellowish-cream, shiny, butyrous, smooth, slightly striate, with the center somewhat raised, and with the margin entire.

Formation of ballistoconidia: Ballistoconidia are formed on corn meal agar and are reniform to falcate, (6.0–9.0)×(1.0–3.0)µm (Fig. 418).

Fermentation: absent.

Assimilation (17°C):

Glucose	+	<i>N</i> -Acetyl-D-glucosamine	n
Galactose	–	Methanol	–
L-Sorbose	–	Ethanol	+
Sucrose	+	Glycerol	+
Maltose	+	Erythritol	–

Additional assimilation tests and other growth characteristics:

2-Keto-D-gluconate	+	Nitrite	+
50% (w/w) Glucose	-	Growth at 25°C	+
Starch formation	-	Growth at 30°C	-
Urease	+		

Co-Q: 10 (Nakase and Suzuki 1987e).

Mol% G+C: 58.1, JCM 5654 (T_m : Nakase and Suzuki 1987e).

Origin of the strain studied: CBS 7310 (JCM 5654), dead leaf of *Sasa* species, T. Nakase, Japan.

Type strain: JCM 5654.

Comments: *Sporobolomyces inositophilus* belongs to the "singularis" group. The species can be differentiated from other species by assimilation of inositol.

106.8. *Sporobolomyces kluveri-nielii* van der Walt (van der Walt et al. 1986a)

Growth on 5% malt extract agar: After 5 days at 25°C, the cells are ellipsoidal, (8.5–10.0) × (4.0–6.5) μm, and single. Budding is polar, with buds sessile or on short denticles and with percurrent and sympodial proliferation. Colonies are butyrous, smooth, dull, brownish-orange, and with the margin entire, straight or undulate.

Growth on the surface of assimilation media (glucose): Islets and a sediment are formed.

Dalmu plate culture on morphology agar: After 7 days at 25°C, no hyphae or pseudohyphae are formed. On corn meal agar, irregularly branched hyphae occur. Aerobic growth is orange, dull, butyrous, slightly warty to low pustulate, with the center somewhat raised, and the margin entire, straight or crenulate.

Formation of ballistoconidia: Ballistoconidia occur on corn meal agar. They are allantoid or reniform, (10.0–20.0) × (4.0–8.5) μm (Fig. 419).

Fermentation: absent.

Assimilation:

Glucose	+	<i>N</i> -Acetyl-D-glucosamine	n
Galactose	+	Methanol	-
L-Sorbose	-	Ethanol	+
Sucrose	-	Glycerol	+

2-Keto-D-gluconate	+	Nitrite	+
50% (w/w) Glucose	-	Growth at 25°C	+
Starch formation	-	Growth at 30°C	-
Urease	+		

Co-Q: 10 (Nakase 1989).

Mol% G+C: 53.8, CBS 7168 (T_m : van der Walt et al. 1986a).

Origin of the strain studied: CBS 7168, leaves of *Dombeya rotundifolia* J.P. van der Walt, South Africa.

Type strain: CBS 7168.

Comments: *Sporobolomyces kluveri-nielii* can be identified by an orange colony color, no assimilation of trehalose, cellobiose, and by formation of large ballistoconidia.

106.9. *Sporobolomyces lactophilus* Nakase, M. Itoh, M. Suzuki & Bandoni (1990b)

Growth on 5% malt extract agar: After 5 days at 25°C, the cells are ellipsoidal, allantoid or cylindroidal, (8.5–22.0) × (2.0–3.5) μm, and single. Budding is polar or lateral, with buds sessile, on denticles or on elongated stalks and showing sympodial proliferation. Colonies are butyrous or rather firm, flat, somewhat warty or reticulate, dull, cream, with the margin entire and crenulate.

Growth on the surface of assimilation media: Absent, but a sediment is formed.

Dalmu plate culture on morphology agar: After 7 days at 25°C, poorly developed pseudohyphae and short hyphal elements are present. Aerobic growth is yellowish-cream, dull, butyrous to rather firm, smooth, ridged, slightly warty or reticulate, flat or with the center somewhat raised, and with the margin entire and crenulate.

Formation of ballistoconidia: Ballistoconidia occur on corn meal agar. They are ellipsoidal, amygdaliform or falcate, (5.5–10.0) × (1.0–4.0) μm (Fig. 420).

Fermentation: absent.

Fig. 420. *S. lactophilus*, CBS 7527. Ballistoconidia on corn meal agar. Bar = 5 μm.

Assimilation (17°C):

Glucose	+	<i>N</i> -Acetyl-D-glucosamine	n
Galactose	-	Methanol	-
L-Sorbose	v	Ethanol	v
Sucrose	+	Glycerol	+
Maltose	+	Erythritol	v
Cellobiose	+	Ribitol	+
Trehalose	+	Galactitol	-
Lactose	+	D-Mannitol	+
Melibiose	-	D-Glucitol	v
Raffinose	-	α -Methyl-D-glucoside	v
Melezitose	+	Salicin	-
Inulin	-	D-Gluconate	-
Soluble starch	+	DL-Lactate	+
D-Xylose	+	Succinate	+
L-Arabinose	-	Citrate	+

Additional assimilation tests and other growth characteristics:

2-Keto-D-gluconate	-	Nitrite	+
50% (w/w) Glucose	-	Growth at 30°C	+
Starch formation	-	Growth at 35°C	-
Urease	+		

Co-Q: 10 (Nakase et al. 1990b).

Mol% G + C: 56.3–57.1, two strains, JCM 7595, JCM 7596 (T_m : Nakase et al. 1990b); 53.8–55.3, two strains, JCM 7595, JCM 7596 (HPLC: Nakase et al. 1990b).

Origin of the strains studied: CBS 7527 (JCM 7595), JCM 7594, JCM 7597, all from dead branches of *Abies firma*, T. Nakase, Japan.

Type strain: JCM 7595.

Comments: Conidiogenesis on long stalks as it occurs in *S. lactophilus* is similar to that described for the genus *Ballistosporomyces* (Nakase et al. 1989b). Among the species with pale colonies and lack of growth with 2-keto-D-gluconate, *S. lactophilus* can be differentiated by absence of growth on raffinose and presence of growth on butanediol-2,3 (Boekhout 1991a).

106.10. *Sporobolomyces orydicola* Nakase & M. Suzuki (1986b)

Growth on 5% malt extract agar: After 5 days at 25°C, the cells are ellipsoidal or cylindroidal, (7.0–9.0) × (3.0–5.0) μ m, and single. Budding is polar, with buds sessile and with percurrent proliferation. Colonies are butyrous to mucoid, smooth, shiny, salmon-red, and with the margin entire.

Growth on the surface of assimilation media (glucose): A ring and a sediment are formed.

Dalmau plate culture on morphology agar: After 7 days at 25°C, hyphae or pseudohyphae are absent. Aerobic growth is dark red, shiny, butyrous, smooth, and with the center somewhat raised and the margin entire.

Formation of ballistoconidia: Ballistoconidia occur on corn meal agar. They are ellipsoidal, (10.0–13.5) × (4.0–5.0) μ m (Fig. 421).

Fig. 421. *S. orydicola*, CBS 7228. Ballistoconidia on corn meal agar. Bar = 5 μ m.

Fermentation: absent.

Assimilation:

Glucose	+	<i>N</i> -Acetyl-D-glucosamine	n
Galactose	+	Methanol	-
L-Sorbose	+	Ethanol	-
Sucrose	+	Glycerol	+
Maltose	+	Erythritol	-
Cellobiose	+	Ribitol	+
Trehalose	+	Galactitol	-
Lactose	-	D-Mannitol	+
Melibiose	-	D-Glucitol	+
Raffinose	+	α -Methyl-D-glucoside	+
Melezitose	+	Salicin	+
Inulin	-	D-Gluconate	+
Soluble starch	-	DL-Lactate	+

L-Arabinose	+	Citrate	+
D-Arabinose	+	Inositol	-
D-Ribose	+	Hexadecane	n
L-Rhamnose	-	Nitrate	-
D-Glucosamine	-	Vitamin-free	-

Additional assimilation tests and other growth characteristics:

2-Keto-D-gluconate	+	Nitrite	-
50% (w/w) Glucose	-	Growth at 30°C	+
Starch formation	-	Growth at 37°C	-
Urease	+		

Co-Q: 10 (Nakase and Suzuki 1986b).

Mol% G + C: 61.1, JCM 5299 (T_m : Nakase and Suzuki 1986b).

Origin of the strain studied: CBS 7228 (IFO 10180, JCM 5299), dead leaf of rice (*Oryza sativa*), T. Nakase, Japan.

Type strain: JCM 5299.

Comments: *Sporobolomyces orydicola* is physiologically rather similar to *S. alborubescens*. This latter species can be differentiated by a slightly higher mol% G + C (61 vs. 63), growth on ethanol, and lack of growth on α -methyl-D-glucoside.

106.11. *Sporobolomyces phyllo-matis* van der Walt & Y. Yamada (van der Walt et al. 1988)

Growth on 5% malt extract agar: After 5 days at 25°C, the cells are ellipsoidal, ovoidal or cylindroidal, (8.0–16.0) × (3.0–7.0) μ m, and single, or in short chains. Budding is polar, with buds sessile and with percurrent proliferation. Scars are distinct. Cells occasionally develop hyphae of up to ca. 55 μ m long. Colonies are butyrous, smooth, shiny, orange-brown or pinkish-orange, and with the margin entire.

Growth on the surface of assimilation media: A ring and a sediment are formed.

Dalmau plate culture on morphology agar: After 7 days at 25°C, short hyphae and pseudohyphae occur (Fig. 422A). Aerobic growth is orange, brownish-orange or pinkish-orange, dull or shiny, smooth or slightly striate, flat or with the center somewhat raised, and with the margin entire.

Formation of ballistoconidia: Ballistoconidia are formed on corn meal agar. They are ellipsoidal to allantoidal, (7.0–13.0) × (3.0–5.0) μm (Fig. 422B).

Fermentation: absent.

Assimilation:

Co-Q: 10 (van der Walt et al. 1988).

Mol% G+C: 47.4, CBS 7198 (T_m : van der Walt et al. 1988).

Origin of the strains studied: CBS 7198 (JCM 7549), CBS 7199, both from leaf of *Dombeya rotundifolia*, J.P. van der Walt, South Africa.

Type strain: CBS 7198.

Comments: *Sporobolomyces phyllomatis* shares with *S. kluyveri-nielii* and *S. salicinus* the characteristics of orange colonies and large ballistoconidia. *Sporobolomyces phyllomatis* can be differentiated from *S. kluyveri-nielii* by growth on L-rhamnose, sucrose, maltose, trehalose and melezitose, and lack of growth on nitrate and nitrite. *Sporobolomyces salicinus* differs by lack of growth on L-rhamnose, maltose, melezitose, 2-keto-D-gluconate, D-gluconate, and growth on nitrate and nitrite.

106.12. *Sporobolomyces roseus* Kluyver & van Niel (1924)

Synonyms:

?*Torula cinnabarina* Jörgensen (1909)

Sporobolomyces tenuis Kluyver & van Niel (1924)

Cryptococcus pulverulentus Beyerinck (nom. nud.) ex Kluyver and van Niel (1924)

Torula photographa Biourge (nom. nud.) ex Kluyver and van Niel (1924)

Sporobolomyces photographus (Biourge) Ciferri & Redaelli (1925)

Amphierna rubra Grüss (1926)

Sporobolomyces salmoneus Derx var. *salmoneus* Derx (1930)

Torulopsis somala Verona (1935)

Sporobolomyces pollaccii Verona & Ciferri (1938)

Sporobolomyces miniatis Yamasaki & Fujii (1950) nom. illeg.

Sporobolomyces ruberrimus Yamasaki & Fujii (1950) var. *ruberrimus* nom. illeg.

Sporobolomyces ruberrimus Yamasaki & Fujii (1950) var. *albus* Yamasaki & Fujii (1950) nom. illeg.

Sporobolomyces roseus Kluyver & van Niel var. *maduræ* A. Janke (1954)

Sporobolomyces boleticola C. Ramírez Gómez (1957)

Growth on 5% malt extract agar: After 5 days at 25°C, the cells are ellipsoidal to cylindroidal, (9.0–24.0) × (3.0–8.5) μm, and single. Budding is usually polar, with buds sessile or on short denticles and with percurrent or sympodial proliferation. Cells sometimes germinate with slender hyphae. Hyphae and pseudohyphae are sometimes present. Colonies are butyrous or tending to mucoid, smooth, warty, venose to reticulate, sometimes striate, flat to raised, shiny or dull, orange to salmon-pink, and with the margin eroded, or entire and crenulate.

Fig. 423. *S. roseus*, CBS 485. Ballistoconidia on morphology agar. Bar = 5 μm .

Growth on the surface of assimilation media (glucose): A ring, a film and a sediment are formed.

Dalmu plate culture on morphology agar: After 7 days at 25°C, hyphae and pseudohyphae sometimes occur. Large globose to subglobose cells frequently occur, (8.0–25.0) × (7.0–16.0) μm . Aerobic growth is pinkish-red, orange-red or brownish-orange, dull or shiny, butyrous, smooth, reticulate or warty, flat, and with the margin eroded or entire.

Formation of ballistoconidia: Ballistoconidia are formed on many artificial media. They are ellipsoidal or allantoid, (7.0–14.0) × (3.0–6.0) μm (Fig. 423). Sterigmata frequently are sympodially branched.

Fermentation: absent.

Assimilation:

Glucose	+	<i>N</i> -Acetyl-D-glucosamine	n

Co-Q: 10 (Nakase and Suzuki 1986d).

Mol% G + C: 50 (BD: Storck 1966); 53.5–56 (BD: Storck et al. 1969); 50.5–56.0 (Nakase 1989); 49.5–52.1, 6 strains (T_m : Boekhout 1991a).

Origin of the strains studied: CBS 485 (IFO 1037, NRRL Y-5480, NI 7593), mycotic lesion of mucous membranes, G. Pollacci, Italy; CBS 486 (ATCC 24257, JCM 5353, MUCL 30251, NRRL Y-5506, UCD-FST 68-353), M.W. Beyerinck; CBS 488 (IFO 1105, NRRL Y-5482, VKM Y-683), etiolated grass, H.G. Derx, Netherlands; CBS 492 (IFO 1040, NRRL Y-5485, NI 7601), diseased

potatoes, M.W. Beyerinck, Netherlands; CBS 493 (NRRL Y-5477, VKM Y-686), nectar of *Linaria* sp., J. Grüss, Germany; CBS 494 (NRRL Y-5486), air, S.L. Schouten, Netherlands; CBS 993, soil, O. Verona, Somalia; CBS 2641, air, J.H. Becking, Netherlands; CBS 1036, wood pulp, P. Redaelli; CBS 2646, madura foot, A. Janke, Austria; CBS 5004, J. Ruinen, Indonesia; CBS 7500, A. Shiraiishi, Japan; CBS 7501, pale mutant of CBS 7500.

Type strain: CBS 486.

Comments: *Sporobolomyces roseus* agrees in many aspects with *S. shibatanus*, the anamorph of *Sporidiobolus pararoseus*. They agree in the color of the colony, mol% G + C, partial 18S rRNA sequences (Takematsu et al. 1990), and many physiological test results. Mating experiments among isolates of *S. roseus* were negative (Boekhout 1991a). From a practical point of view, *S. roseus* can be differentiated from *S. shibatanus* by growth with nitrate and nitrite.

Sporobolomyces roseus occurs in the phyllosphere (Derx 1930, Tubaki 1953, Last 1955, van der Burg 1974). According to the latter author, *S. roseus* belongs to the so-called “sugar” fungi, which use honey-dew for growth.

106.13. *Sporobolomyces ruber* (Nakase, Okada & Sugiyama) Boekhout (1991a)

Synonym:

Ballistosporomyces ruber Nakase, Okada & Sugiyama (1989b)

Growth on 5% malt extract agar: After 5 days at 25°C, the cells are ellipsoidal to fusiform, (6.0–9.0) × (2.0–3.0) μm , and single or in short branched chains. Budding is polar and lateral, with the buds usually on short denticles or stalks, which generally proliferate sympodially. Colonies are butyrous or rather tough, somewhat pustulate, dull or somewhat shiny, pinkish-red, and with the margin entire.

Growth on the surface of assimilation media (glucose): Absent, but a sediment is formed.

Dalmu plate culture on morphology agar: After 7 days at 25°C, hyphae and pseudohyphae are absent. Aerobic growth is orange-cream, orange-pink (salmon) or brownish-orange, dull or somewhat shiny, moist or somewhat tough, somewhat pustulate or reticulate, convex, and with the margin entire and crenulate.

Formation of ballistoconidia: Ballistoconidia occur on malt extract agar and potato-dextrose agar. They are allantoid, and measure (6.0–12.5) × (1.5–5.0) μm (Fig. 424).

Fermentation: absent.

Fig. 424. *S. ruber*, CBS 7512. Ballistoconidia on malt extract agar. Bar = 5 μm .

Assimilation (17°C):

Glucose	+	<i>N</i> -Acetyl-D-glucosamine	n
Galactose	-	Methanol	-
L-Sorbose	-	Ethanol	-

Urease	-		

Co-Q: 10 (Nakase et al. 1989b).

Mol% G + C: 50.8, JCM 6884 (T_m : Nakase et al. 1989b); 48.3, JCM 6884 (HPLC: Nakase et al. 1989b).

Origin of the strain studied: CBS 7512 (JCM 6884, NB 258), dead leaf of *Vitis ficifolia* var. *lobata*, T. Nakase, Japan.

Type strain: JCM 6884.

Comments: *Sporobolomyces ruber* has a distinctive mode of conidiogenesis in which conidia are usually formed on sympodially or percurrently proliferating denticles and stalks. Besides typical ballistoconidia, morphologically similar, but not actively discharged cells are formed. These types of reproduction were also observed in some other species, e.g., *Bensingtonia ingoldii*, *B. miscanthi* and *S. lactophilus* (Boekhout 1991a). *Sporobolomyces ruber* is characterized by salmon-orange colonies, lack of growth on trehalose and by its mode of conidiogenesis.

106.14. *Sporobolomyces salicinus* (Johri & Bandoni) Nakase & M. Itoh (1988)

Synonym:

Bullera salicina Johri & Bandoni (1984)

Growth on 5% malt extract agar: After 5 days at 25°C, the cells are ellipsoidal, cylindrical or subglobose, (8.0–14.0) × (4.0–7.0) μm , and single. Budding is polar, with the buds sessile or on short denticles and showing percurrent or sympodial proliferation. Scars are present. Pseudohyphae and short hyphae occasionally occur. Colonies are butyrous, smooth or slightly warty, dull or shiny, orange or brownish-orange, and with the margin entire, straight or crenulate.

Growth on the surface of assimilation media (glucose): Absent, but a sediment is formed.

Dalmat plate culture on morphology agar: After 7 days at 25°C, poorly developed pseudohyphae occur. Aerobic growth is pinkish to brownish-orange, shiny or dull, butyrous, smooth or somewhat warty, flat, and with the margin entire and straight.

Formation of ballistoconidia: Ballistoconidia occur on corn meal agar. They are ellipsoidal to allantoid, and measure (12.0–23.0) × (5.0–8.0) μm (Fig. 425).

Fermentation: absent.

Assimilation:

Glucose	+	<i>N</i> -Acetyl-D-glucosamine	n
Galactose	+	Methanol	-
L-Sorbose	-	Ethanol	-
Sucrose	+	Glycerol	+
Maltose	-	Erythritol	-

Fig. 425. *S. salicinus*, CBS 6983. Ballistoconidia on corn meal agar. Bar = 5 μm .

Additional assimilation tests and other growth characteristics:

2-Keto-D-gluconate	–	Nitrite	+
50% (w/w) Glucose	–	Growth at 30°C	+
Starch formation	–	Growth at 37°C	–
Urease	+		

Co-Q: 10 (Nakase 1989).

Mol% G+C: 51.1, JCM 2959 (T_m : Nakase and Itoh 1988).

Origin of the strain studied: CBS 6983 (JCM 2959, UBC 8081), leaf of willow (*Salix* sp.), R.J. Bandoni, British Colombia, Canada.

Type strain: UBC 8081.

Comments: *Sporobolomyces salicinus* has orange colonies and large ballistoconidia. These characteristics also occur in *S. kluyveri-nielii* and *S. phyllomatis*. *Sporobolomyces salicinus* can be differentiated from these species by growth on salicin and raffinose, and lack of growth on 2-keto-D-gluconate and D-gluconate. According to Takematsu et al. (1990), partial 18S rRNA sequences of *S. salicinus* are similar to those of *S. phyllomatis* and *S. gracilis*. Enteroblastic conidiation, scars and a thickened cell wall are obvious in older cultures.

106.15. *Sporobolomyces salmonicolor* (Fischer & Brebeck) Kluyver & van Niel (1924)

See under teleomorph *Sporidiobolus johnsonii* Nyland, p. 694

106.16. *Sporobolomyces sasicola* Nakase & M. Suzuki (1987b)

Growth on 5% malt extract agar: After 5 days at 25°C, the cells are ellipsoidal or cylindrical, (7.0–15.0) × (2.0–3.5) μm, and single. Budding is usually polar and sessile. Colonies are butyrous, smooth or somewhat warty, shiny, yellowish-cream, and with the margin entire and straight.

Growth on the surface of assimilation media (glucose): Absent, but a sediment is formed.

Dalmu plate culture on morphology agar: After 7 days at 25°C, hyphae and pseudohyphae are absent. Aerobic growth is pale yellowish-brown, shiny or dull, butyrous, flat, ridged or somewhat reticulate, slightly inflated toward the margin, and with the margin entire, straight, undulate or crenulate.

Formation of ballistoconidia: Ballistoconidia occur on corn meal agar, malt extract agar and potato-dextrose agar. They are allantoid, (6.0–10.0) × (2.0–3.0) μm (Fig. 426).

Fig. 426. *S. sasicola*, CBS 7285. Ballistoconidia on malt extract agar. Bar = 5 μm.

Fermentation: absent.

Co-Q: 10 (Nakase and Suzuki 1987b).

Mol% G+C: 56.9, JCM 5979 (T_m : Nakase and Suzuki 1987b).

Origin of the strain studied: CBS 7285 (JCM 5979), dead leaf of *Sasa* sp., T. Nakase, Japan.

Type strain: JCM 5979.

Comments: *Sporobolomyces sasicola* is characterized by pale colonies and lack of growth with 2-keto-D-gluconate. It differs from other species with these characteristics, viz. *S. lactophilus*, *S. subbrunneus* and *S. xanthus*, by growth with L-arabinose, and lack of growth with citrate, nitrate and nitrite.

106.17. *Sporobolomyces shibatanus* (Okunuki) Verona & Ciferri (1938)

See under teleomorph *Sporidiobolus pararoseus* Fell & Tallman, p. 694

106.18. *Sporobolomyces singularis* Phaff & do Carmo-Sousa (1962)

Synonym:

Bullera singularis (Phaff & do Carmo-Sousa) Rodrigues de Miranda (1984c)

Growth on 5% malt extract agar: After 5 days at 25°C, the cells are ellipsoidal to subglobose, (6.0–12.0) × (2.5–6.0) μm, and single. Budding is polar, with the buds sessile or on short denticles and with percurrent or sympodial proliferation. Colonies are mucoid, smooth, shiny, pale yellowish-brown, and with the margin entire and straight.

Growth on the surface of assimilation media: Absent, but a sediment is formed.

Dalmu plate culture on morphology agar: After

7 days at 25°C, no hyphae or pseudohyphae are formed. Aerobic growth is whitish to cream, shiny, mucoid, smooth, somewhat raised, and with the margin entire.

Formation of ballistoconidia: Ballistoconidia were not observed. According to Phaff and do Carmo-Sousa (1962), they are bilaterally symmetrical, and kidney- to sickle-shaped.

Fermentation: absent.

Co-Q: 10 (Nakase 1989).

Mol% G+C: 58.0 (Nakase 1989).

Origin of the strain studied: CBS 5109 (ATCC 24193, JCM 5356, NCYC 900, NRRL Y-5852, UCD-FST 60-79), frass from *Scolytus tsugae* in dead specimen of *Tsuga heterophylla*, H.J. Phaff and L. do Carmo-Sousa, Oregon, USA.

Type strain: UCD-FST 60-79 (CBS 5109).

Comments: *Sporobolomyces singularis* belongs to a group of species with pale colonies and that assimilate 2-keto-D-gluconate. *S. singularis* can be differentiated from other species of this group by a combination of mucoid colonies and lack of assimilation of D-xylose, sucrose, maltose, nitrate and nitrite. *Rhodotorula foliorum* and *R. lignophila* do not form ballistoconidia but are physiologically and morphologically similar. *Rhodotorula foliorum* differs by assimilation of arbutin, nitrate and nitrite, while *R. lignophila* fails to grow with D-arabinose, salicin and ribitol.

106.19. *Sporobolomyces subbrunneus* Nakase & M. Suzuki (1985c)

Growth on 5% malt extract agar: After 5 days at 25°C, the cells are fusiform to ellipsoidal, (7.5–11.0) × (2.0–3.0) μ m, and single. Budding is polar with the

Fig. 427. *S. subbrunneus*, CBS 7196. Ballistoconidia on malt extract agar. Bar = 5 μ m.

buds usually sessile. After prolonged cultivation poorly developed pseudohyphae sometimes occur. Colonies are butyrous, smooth to slightly warty, dull, pale yellowish-brown, and with the margin entire and straight.

Growth on the surface of assimilation media (glucose): Absent, but a sediment is formed.

Dalmau plate culture on morphology agar: After 7 days at 25°C, no hyphae or pseudohyphae occur. Aerobic growth is pale yellowish-brown, dull, butyrous, smooth or slightly warty, flat, and with the margin entire.

Formation of ballistoconidia: Ballistoconidia occur on malt extract agar and yeast extract–malt extract agar. They are ellipsoidal or allantoid, (6.0–11.0) × (2.5–4.0) μ m (Fig. 427).

Fermentation: absent.

Assimilation:

Co-Q: 10 (Nakase and Suzuki 1985c).

Mol% G+C: 68, JCM 5278 (T_m : Nakase and Suzuki 1985c).

Origin of the strain studied: CBS 7196 (IFO 10168, JCM 5278), rice (*Oryza sativa*), T. Nakase, Japan.

Type strain: JCM 5278.

Comments: *Sporobolomyces subbrunneus* belongs to

a group of species with pale colonies and inability to assimilate 2-keto-D-gluconate. Among these species, *S. subbrunneus* can be characterized by its lack of growth with maltose, cellobiose, and by assimilation of lactate and D-gluconate.

106.20. *Sporobolomyces tsugae* (Phaff & do Carmo-Sousa) Nakase & M. Itoh (1988)

Synonym:

Bullera tsugae Phaff & do Carmo-Sousa (1962)

Growth on 5% malt extract agar: After 5 days at 25°C, the cells are globose to subglobose or ellipsoidal, (3.5–8.0)×(5.0–7.5) μm, and single. Short germ hyphae sometimes occur. Budding is polar, with percurrent or sympodial proliferation. Colonies are mucoid, smooth, shiny, cream to pale yellowish-brown, lack color near the margin, and with an entire, straight or undulate margin.

Growth on the surface of assimilation media (glucose): A ring, islets and a sediment are formed.

Dalmou plate culture on morphology agar: After 7 days at 25°C, no hyphae or pseudohyphae are formed. Aerobic growth is whitish to cream, lacking color near the margin, shiny, mucoid, smooth, convex, and with the margin entire, straight or undulate.

Formation of ballistoconidia: Ballistoconidia are formed on morphology agar. They are ellipsoid, (6.0–10.5)×(3.0–7.0) μm (Fig. 428).

Fermentation: absent.

Assimilation:

Co-Q: 10 (Nakase 1989).

Mol% G+C: 50.4–52.3, two strains, CBS 5038, CBS 7096 (T_m : Boekhout 1991a); 50.4 (Nakase 1989).

Origin of the strains studied: CBS 5038 (ATCC 18802, JCM 2960, UCD-FST 60-71), frass from an insect under the bark of *Tsuga heterophylla*, H.J. Phaff and L. do Carmo-Sousa, Oregon, USA; CBS 7096, polluted water, F. Hinzelin, France; ICG 4441, rotten trunk of a tree, A. Fonseca, Portugal.

Type strain: UCD-FST 60-71 (CBS 5038).

Comments: *Sporobolomyces tsugae* belongs to a group of species with pale colonies that assimilate 2-keto-D-gluconate. Among these species, *S. tsugae* can be differentiated by assimilation of L-sorbose and α-methyl-D-glucoside. According to Phaff and do Carmo-Sousa (1962), ballistoconidia are globose (UCD-FST 60-71). However, no ballistoconidia were observed in this strain by the present authors. CBS 7096 and ICG 4441 form distinct bilaterally symmetrical ballistoconidia.

106.21. *Sporobolomyces xanthus* (Nakase, Okada & Sugiyama) Boekhout (1991a)

Synonym:

Ballistosporomyces xanthus Nakase, Okada & Sugiyama (1989b)

Growth on 5% malt extract agar: After 5 days at 25°C, the cells are ellipsoidal or allantoid, (7.0–10.0)×(2.5–4.0) μm, and single. Budding is multipolar, usually on short denticles, and with the buds frequently allantoid. Colonies are butyrous, smooth, shiny, pale yellowish-brown, and with the margin entire and straight.

Growth on the surface of assimilation media:

Absent, but a sediment is formed.

Dalmou plate culture on morphology agar: After 7 days at 25°C, hyphae and pseudohyphae are absent, but yeast cells form undifferentiated chains. Aerobic growth is yellow-brown or orange-yellow, shiny, but towards the margin becoming dull, butyrous, flat, somewhat reticulate, near the margin slightly striate, and with the margin entire, straight or lobate.

Formation of ballistoconidia: Ballistoconidia occur on corn meal agar and malt extract agar. They are allantoid, (4.5–9.0)×(2.0–4.0) μm (Fig. 429).

Fermentation: absent.

Fig. 429. *S. xanthus*, CBS 7513. (A) Yeast cells on morphology agar. (B) Ballistoconidia on corn meal agar. (C) Formation of stalked conidia on yeast extract-malt extract agar. Bar = 10 μ m.

Co-Q: 10 (Nakase et al. 1989b).

Mol% G+C: 62.1, JCM 6885 (T_m : Nakase et al. 1989b); 56.8, JCM 6885 (HPLC: Nakase et al. 1989b).

Origin of the strains studied: CBS 7513 (JCM 6885, NB 206), dead leaf of *Acer rufinerve*, T. Nakase, Japan.

Type strain: JCM 6585.

Comments: *Sporobolomyces xanthus* belongs to a group of species with pale colonies and which do not grow with 2-keto-D-gluconate. Among the species with these

characteristics, *S. xanthus* can be differentiated by growth on D-galactose and from its morphology.

Comments on the genus

The genus *Sporobolomyces* is characterized by the formation of ballistoconidia, lack of xylose in whole-cell hydrolyzates, and, usually, Co-Q 10 as the major ubiquinone. Several species have red, orange or pink colonies due the presence of β -carotenoids, γ -carotenoids, torulene and torularhodine (Valadon 1966, Fiasson 1967, Fiasson et al. 1973). Recently, species with pale colonies have been described, which, presumably, do not form these pigments. The pale colored species can be divided into two groups based on the assimilation of 2-keto-D-gluconate (Nakase 1989). A considerable heterogeneity of the genus is indicated by rRNA sequences (Takematsu et al. 1990, Fell et al. 1992). The presence of Co-Q 10(H₂) in *S. elongatus* (Nakase and Suzuki 1986d) suggests a further heterogeneity within the genus. Subdivision of the genus based on the presence or absence of pseudohyphae (Ciferri and Redaelli 1929, Novák and Zsolt 1961) was rejected by Lodder and Kreger-van Rij (1952).

Two species, viz. *S. salmonicolor* and *S. shibatanus*, have their teleomorphs in the teliospore-forming genus *Sporidiobolus*. Differences in DNA contents among cells of a strain of *S. salmonicolor* were interpreted to represent haploid and diploid stages (van der Walt and Pitout 1969). A teleomorph genus, *Aessosporon* van der Walt, with *A. salmonicolor* van der Walt as type species was described based on this supposedly diploid stage (van der Walt 1970f). However, later authors observed mating, including formation of dikaryotic hyphae with clamp connections and teliospores, between the type strains of *A. salmonicolor* and *S. salmonicolor* (Fell and Statzell-Tallman 1980b). Therefore, the genus *Aessosporon* is not recognized as representing the teleomorph.

A close taxonomic relationship has been proposed between species of *Sporobolomyces* and the genus *Rhodotorula* (Janke 1954, Crook and Johnston 1962, Tsuchiya et al. 1969, Weijman and Rodrigues de Miranda 1988, Golubev 1989a,b, Dörfler 1990). This is supported by nucleotide sequences of the large subunit rRNAs of species belonging to both genera, which resulted in heterogeneous dendrograms (Fell et al. 1992). This may indicate that currently used generic concepts are not adequate from an evolutionary point of view. However, for practical reasons, we maintain the generic separation of ballistoconidia-forming and non-ballistoconidia-forming genera.

Conidiogenesis is usually polar, but sometimes may also be multipolar. Cells are usually formed on short denticles, but in some species elongate denticles or stalks occur (Boekhout 1991a). Scars may be distinct (de Hoog 1982, Boekhout 1991a), and proliferation is percurrent and/or sympodial.

The genus *Ballistosporomyces* was described for two species, which were reported to reproduce by formation

of ballistoconidia and inactively discharged conidia, but not by budding cells (Nakase et al. 1989b). The inactively discharged conidia are formed on denticles or stalks, which proliferate sympodially or percurrently. However, these types of conidiogenesis were observed in other species of *Sporobolomyces* as well, e.g., in *S. lactophilus*, and budding cells do occur in the genus *Ballistosporomyces* (Boekhout 1991a). Therefore, *Ballistosporomyces* is considered to be congeneric with *Sporobolomyces* (Boekhout 1991a). Conidium formation

on elongate denticles and stalks, as observed in some species of *Sporobolomyces* and *Bensingtonia* (Boekhout 1991a), and other characteristics, such as ubiquinone and carbohydrate composition, are similar to those characteristics in *Kurtzmanomyces* (Yamada et al. 1988a, Nakase et al. 1989b).

Several species of *Sporobolomyces*, e.g., *S. roseus*, widely occur in nature. An important habitat is the phyllosphere (Derx 1930). Air-borne propagules of *Sporobolomyces* can cause respiratory allergy (Evans 1965).

107. *Sterigmatomyces* Fell emend. Y. Yamada & Banno

I. Banno and Y. Yamada

Diagnosis of the genus

Cells are spherical to ovoidal and produce one or more short conidiogenous stalks (1.5–3.0 µm length). A conidium develops terminally on the stalk. When the new cell (conidium) is mature it may in turn produce stalks, often resulting in short branched chains of cells. Newly formed cells separate at a septum, in the mid-region of the stalk on the parent cell. True mycelium is not produced. Ballistoconidia are not produced.

Glucose is not fermented. Nitrate may or may not be assimilated. *myo*-Inositol is not assimilated. Diazonium blue B color reaction is positive. Xylose is absent in the cells. Coenzyme Q-9 is present.

Type species*Sterigmatomyces halophilus* Fell**Species accepted**

Key characters of the species in the genus *Sterigmatomyces*

Species	Assimilation				Growth at 37°C	Mol% G + C
	Sucrose	Lactose	Raffinose	Nitrate		
<i>Sterigmatomyces elviae</i>	+	+	+	–	+	52.0
<i>S. halophilus</i>	–	v	–	v	–	55.3

Systematic discussion of the species**107.1. *Sterigmatomyces elviae* Sonck & Yarrow (1969)**

Growth in malt extract: After 3 days at 24°C, the cells are spherical to ovoidal, (3–6) × (3–10) µm, and reproduce by the formation of conidia on one to five short (<2 µm) stalks on each cell. The conidia are separated at the mid-point of the stalks on the parent cell. Occasionally, the conidia form additional stalked conidia and appear as a chain of conidia. Conidiogenous stalks are often so short that cell propagation appears to be typical budding. A light ring and sediment are present. After one month the cells are within the same size range; a moderate ring and sediment are present.

Growth on malt agar: Two colony types are found; in one type the streak culture is smooth, dull, cream-colored, edges entire, with cells similar to those described in malt extract. The other type differs and forms a glistening and viscous colony. Cells are ellipsoidal and apiculate, (2–7) × (3–13) µm, with one, or rarely, more short stalks (0.5 µm) and the general appearance of a typically budding yeast cell.

Dalmau plate culture on corn meal agar: Pseudomycelium and true mycelium are absent.

Fermentation: absent.

107.2. *Sterigmatomyces halophilus* Fell (1966)**Synonyms:**

Sterigmatomyces halophilus Fell var. *indicus* Fell (1966)

Sterigmatomyces indicus (Fell) Fell (1970a)

Growth in malt extract: After 3 days at room temperature, the cells are spherical to ovoidal, (2–7) × (3–11) μm, with one to ten short conidiogenous stalks, 0.5 × (1–3) μm (Fig. 430). New cells (conidia) are formed on the stalks. The conidia can produce secondary stalked conidia with old cells, resulting in short branched chains. Cells are separated by septal formation in the mid-region of the stalks. A light film is produced which develops into powdery islets and after one month there is a heavy white pellicle. A sediment is present.

Growth on malt agar: The cell morphology is similar to that in malt extract. The cells are varied in size, (1–4) × (3–17) μm, and some are thin and long (127 μm). The stalks are generally short 0.5 × (1–3) μm; some are elongated to 26 μm. The width of the elongated stalk remains about 0.5 μm. The streak is chalky-white, pasty with a dry granular surface, and the border is irregular to

Fig. 430. *S. halophilus*, IFO 1488. After 48 hours at 25°C on malt extract. Scanning electron micrograph. Bar = 1 μm.

lobate. Colonies may develop that are smooth, glistening or dull and with an entire margin.

Dalmiau plate culture on corn meal agar: Pseudomycelium and true mycelium are absent. Short branched chains of cells may be produced.

Fermentation: absent.

Type strain: CBS 4609 (IFO 1488).

Comments on the genus

Vegetative cells produce short stalks terminally developing only one bud (conidium), which is separated at the mid-point of the stalk. The coenzyme Q system is mainly Co-Q 9. These characteristics clearly distinguish *Sterigmatomyces* from *Fellomyces* and *Kurtzmanomyces*. *S. indicus* was previously separated from *S. halophilus* on the basis of nitrate utilization. However, Kurtzman (in Fell et al. 1984a) and Kurtzman (1990a) considered that *S. indicus* is synonymous with *S. halophilus*, since the two species exhibited 100% DNA reassociation. Yamada et al. (1986a) supported this idea by a comparison of electrophoretic enzyme patterns.

108. *Sympodiomyopsis* Sugiyama, Tokuoka & Komagata

J. Sugiyama and S.-O. Suh

Diagnosis of the genus

Colonies on malt agar are dull cream-colored. Asexual reproduction is principally enteroblastic-annellidic and rarely holoblastic-sympodial. Vegetative cells are obclavate or obovoid and true mycelium is sometimes developed. Ascospores, teliospores, ballistospores, and sterigmatospores have not been observed.

Sugars are not fermented. The following tests are positive: extracellular DNase, urease and diazonium blue B. Xylose is present in trace amounts in the cells. The major ubiquinone system is Q-10.

Type species

Sympodiomyopsis paphiopedili Sugiyama, Tokuoka & Komagata

Species accepted

1. *Sympodiomyopsis paphiopedili* Sugiyama, Tokuoka & Komagata (1991)

Systematic discussion of the species

108.1. *Sympodiomyopsis paphiopedili* Sugiyama, Tokuoka & Komagata (1991)

Growth in 5% malt extract: After 3 days at 25°C, the cells vary from ovoid to elongate, sometimes subglobose, (4–11) × (2–6) μm, occurring singly, in pairs or in short chains, and reproducing principally by enteroblastic-annellidic, or rarely, by holoblastic-sympodial budding (Figs. 431, 432).

Growth on 5% malt extract agar: After 3 days at 25°C, the streak culture is dull and cream-colored; the surface is smooth, and colony texture is soft and slightly mucoid.

Dalmeu plate culture on corn meal agar: After 14 days at 25°C, true mycelium is sometimes formed. Mycelium is composed of hyphae which are

hyaline, smooth, thin-walled, septate, branched, 1–2 μm wide, rarely 5 μm wide, and often torulose. Ascospores, teliospores, ballistospores and sterigmatospores have not been observed.

Fermentation: absent.

Fig. 431. *S. paphiopedili*, IAM 13459. (A)–(B) In malt extract after 4–7 days. (C) On corn meal agar after 4–25 days. Undifferentiated hyphae with terminal, intercalary or scattered conidiogenous cells; some of these bear 3 or more conidia in sympodial order.

Fig. 432. *S. paphiopedili*, TEM micrographs. (A) Enteroblastic-annellidic conidiogenesis in young yeast cells. (B) Bud scars at the conidiogenous tip. Arrows indicate multilayered cell wall of the parent cell. (C) Successive conidiogenesis occurs at the newly developed apex. Bar = 1 μm.

Co-Q: 10 (Sugiyama et al. 1991).

Mol% G + C: 56.3 (T_m : Sugiyama et al. 1991).

Xylose in the cells: Present in trace amounts (Sugiyama et al. 1991).

Origin of the strain studied: Orchid (*Paphiopedilum primurinum*) nectar collected at the Koishikawa Botanic

Garden of the University of Tokyo, Japan (Sugiyama et al. 1991).

Type strain: IAM 13459 (CBS 7429).

Comments on the genus

Sympodiomyces paphiopedili is usually dominant as a yeast morph, although it is associated with a hyphal morph. Sugiyama et al. (1991) considered that *S. paphiopedili* is basidiomycetous because of the following characteristics: positive reaction for urease, DNase and diazonium blue B color tests, Q-10 ubiquinone system, relatively high G + C content, and a basidiomycetous type of cell wall ultrastructure (Fig. 432B).

Morphologically, *S. paphiopedili* is similar to *Sympodiomyces parvus* Fell & Statzell (1971), which is characterized by a yeast morph and inconspicuous hyphal morph. The mode of conidiogenesis of these two genera is superficially similar. However, *Sympodiomyces parvus* is considered to be an ascomycetous yeast by van der Walt and Hopsu-Havu (1976) and Fell (1984b) because of negative urease and diazonium blue B color reactions, and a cell wall ultrastructure typical of ascomycetous yeasts. The septal pore ultrastructure of *S. paphiopedili* resembles that found in members of the Ustilaginales (Suh et al. 1993a). The 18S rDNA sequence-based tree also shows *S. paphiopedili* to be phylogenetically close to *Tilletia caries*, a smut fungus (Suh and Sugiyama 1994).

109. *Tilletiopsis* Derx ex Derx

T. Boekhout

Diagnosis of the genus

Hyphae are regularly branched, narrow, septate, hyaline, monokaryotic, usually partly lysed, and with retraction septa; septal pores are micropore-like. Ballistoconidia are bilaterally symmetrical, allantoid, falcate or cylindrical, and formed on sterigmata. Chlamydoconidia are sometimes present and hyaline or pigmented. Clamp connections are absent. Colonies are cream-colored, pinkish-cream, pinkish-yellow, yellow-brown or brown.

Diazonium blue B and urease reactions are positive. Xylose is absent from whole-cell hydrolyzates. Major ubiquinone is Q-10. Starch-like compounds are not produced.

Type species*Tilletiopsis washingtonensis* Nyland**Species accepted**

1. *Tilletiopsis albescens* Gokhale (1972)
2. *Tilletiopsis flava* (Tubaki) Boekhout (1991)
3. *Tilletiopsis fulvescens* Gokhale (1972)
4. *Tilletiopsis minor* Nyland (1950)
5. *Tilletiopsis pallescens* Gokhale (1972)
6. *Tilletiopsis washingtonensis* Nyland (1950)

<i>T. washingtonensis</i>	v	–	–	+	+	–	–	66.5–70

Systematic discussion of the species**109.1. *Tilletiopsis albescens* Gokhale (1972)**

Growth on 5% malt extract agar: After 5 days at 17°C, hyphae are regularly branched, narrow, with cells measuring (10–55) × (1.5–3.5) μ m, and with retraction

septa (Fig. 433). Colonies are tough, flat, glabrous or pruinose, dull, whitish-cream, and with an eroded margin.

Growth on the surface of assimilation media: A ring and a thick film are formed.

Dalmau plate culture on morphology agar: After 7 days at 17°C, hyphae are abundantly formed. Inflated cells with refractive contents occur and measure (20–40)×(3.0–6.0) μm. Chlamydo-spores occur intercalarily or terminally, are subglobose, ellipsoidal or cylindrical, and are solitary or catenate, (13–20)×(5.0–15.0) μm. Aerobic growth is whitish to yellowish-cream, dull, flat, frequently somewhat raised in the center and the margin eroded.

Formation of ballistoconidia: Ballistoconidia form on sterigmata and are allantoid, falcate or cylindrical, (7.0–16.0)×(1.0–4.0) μm (Fig. 433).

Fermentation: absent.

Assimilation (17°C):

Glucose	+	<i>N</i> -Acetyl-D-glucosamine	n
Galactose	+	Methanol	–
L-Sorbose	+	Ethanol	v
Sucrose	+	Glycerol	+

Urease	+		

Co-Q: 10, CBS 608.83, CBS 370.85, (Boekhout et al. 1992a).

Mol% G + C: 55.0–58.5 (–63.5), 6 strains (T_m : Boekhout et al. 1992b).

Origin of the strains studied: CBS 608.83 (ATCC 24343, UBC 926, YK 801), sewage, W.B. Cooke, Cincinnati, Ohio, USA; CBS 370.85, barley powdery mildew culture, J.P. Skou, Denmark; CBS 361.86 (IFO 9015, YK 802), origin unknown, Japan; UAMH 5028, lesion of colostomy, I. Weitzman, New York, USA.

Type strain: UBC 926.

Comments: *Tilletiopsis albescens* is morphologically and physiologically similar to *T. pallescens*. It can be differentiated from this species by colonies that are whiter, and a higher mol% G + C of ca. 55–59. Yamazaki et al. (1985) observed low similarity between electrophoretic enzyme patterns of these species.

109.2. *Tilletiopsis flava* (Tubaki) Boekhout (1991a)

Synonym:

Tilletiopsis minor Nyland var. *flava* Tubaki (1952)

Growth on 5% malt extract agar: After 5 days at 17°C, hyphae are regularly branched, narrow, with cells measuring (15–100)×(1.5–2.0) μm, and with retraction septa (Fig. 434). Colonies are soft or somewhat tough, warty or reticulate, somewhat pruinose, dull, pale yellowish-brown, and with an entire margin.

Growth on the surface of assimilation media: A thin film is formed.

Dalmau plate culture on morphology agar: After 7 days at 17°C, hyphae are abundantly formed. Inflated cells with refractive contents occur and measure (9.0–15.0)×(3.0–6.0) μm. Aerobic growth is pale to dark brownish orange-yellow, dull, flat, and with the margin entire or somewhat eroded.

Formation of ballistoconidia: Ballistoconidia are allantoid, falcate or cylindrical, (8.0–20.0)×(1.5–2.5) μm (Fig. 434).

Fermentation: absent.

Fig. 434. *T. flava*, CBS 401.84. Hyphae and ballistoconidia on malt extract agar. Bar = 5 μ m.

Assimilation (17°C):

Co-Q: 10, CBS 401.84 (Boekhout et al. 1992a).

Mol% G+C: 63.2, one strain (T_m : Boekhout et al. 1992b).

Origin of the strain studied: CBS 401.84 (IFO 6833, UBC 917, YK 808), leaves of maple (*Acer* sp.), K. Tubaki, Japan.

Type strain: IFO 6833.

Comments: *Tilletiopsis flava* can be differentiated from both *T. fulvescens* and *T. minor* by its inability to grow on galactose, lactose, melezitose and erythritol (Boekhout

1991a). *Tilletiopsis flava* further differs from these species by electrophoretic enzyme patterns (Yamazaki et al. 1985), electrophoretic karyotypes and a mol% G+C of ca. 63 (Boekhout et al. 1992a,b).

109.3. *Tilletiopsis fulvescens* Gokhale (1972)

Growth on 5% malt extract agar: After 5 days at 17°C, hyphae are regularly branched, narrow, cylindrical, with cells measuring (15–60) × (1.0–2.5) μ m, and with retraction septa (Fig. 435). Colonies are soft to rather dry, flat, warty or reticulate, glabrous or pruinose, dull, yellow-brown, and with an entire or eroded margin. A brown pigment is exuded into the agar.

Growth on the surface of assimilation media (glucose): Islets, a thin film and a sediment are formed.

Dalmay plate culture on morphology agar: After 7 days at 17°C, abundant hyphae are formed. Chlamydospores are ellipsoidal, subglobose, cylindrical, and 4.0–8.0 μ m in diameter. Aerobic growth is yellow or yellow-brown, dull, flat, and with the margin entire or eroded.

Formation of ballistoconidia: Ballistoconidia are allantoid or falcate, (5.0–16.0) × (1.0–2.5) μ m (Fig. 435).

Fermentation: absent.

Assimilation (17°C):

Glucose	+	<i>N</i> -Acetyl-D-glucosamine	n

2-Keto-D-gluconate	+	Nitrite	+
50% (w/w) Glucose	-	Growth at 30°C	+
Starch formation	-	Growth at 35°C	-
Urease	+		

Co-Q: 10, CBS 321.71 (Boekhout et al. 1992b).

Mol% G+C: 66.3–68.0, 4 strains (T_m : Boekhout et al. 1992a).

Origin of the strains studied: CBS 321.71 (ATCC 36405), *Oxycoccus microcarpus*, Madison, USA; CBS 607.83 (ATCC 24344, UBC 8006, YK 809) leaf of *Forsythia*, S. Reid, British Columbia, Canada.

Type strain: UBC 8006.

Comments: *Tilletiopsis fulvescens* is similar to *T. minor* and can be differentiated from the latter species by

Fig. 435. *T. fulvescens*, CBS 607.83. Hyphae and ballistoconidia on malt extract agar. Bar = 5 μ m.

a higher mol% G+C of ca. 66–68 (Boekhout 1991a, Boekhout et al. 1992b), and softer colonies. Moreover, the electrophoretic enzyme patterns of these species are dissimilar (Yamazaki et al. 1985).

109.4. *Tilletiopsis minor* Nyland (1950)

Growth at 5% malt extract agar: After 5 days at 17°C, hyphae are regularly branched, narrow, cylindrical, with cells of (10–75) × (1.0–2.0) μ m, and with retraction septa. Chlamydospores occurring terminally or intercalarily, and are ellipsoidal, subglobose, fusiform, or cylindrical, (5.0–20.0) × (3.0–7.0) μ m (Fig. 436). Colonies are tough, glabrous, pruinose or covered with slender fascicles, shiny or dull, cream to yellow-brown, and with an entire or eroded margin. A red brown pigment is exuded into the agar.

Growth on the surface of assimilation media: Islets, a ring and a small sediment are formed.

Dalmu plate on morphology agar: After 7 days at 17°C, hyphae are abundantly formed. Chlamydospores are similar to those on malt extract agar. Aerobic growth is yellowish-brown, dull or somewhat shiny, flat, convex or pulvinate, somewhat irregular, and with an entire or somewhat eroded margin.

Fig. 436. *T. minor*, CBS 543.50. (A) Chlamydospores on malt extract agar. (B) Ballistoconidia on morphology agar. Bar = 5 μ m.

Formation of ballistoconidia: Ballistoconidia are allantoid or falcate, (6.0–16.0) × (1.0–2.5) μ m (Fig. 436).

Fermentation: absent.

Co-Q: 10, CBS 543.50, CBS 346.33 (Boekhout et al. 1992b).

Mol% G+C: 55.2–56.9, 12 strains (T_m : Boekhout et al. 1992a).

Origin of the strains studied: CBS 346.33 (ATCC 36406), origin unknown, H.G. Derx; CBS 543.50 (ATCC 10764, IMI 56590, YK 805), from leaves, G. Nyland, Washington, USA; CBS 440.61, leaves of *Taraxacum officinale*, Rothamsted, UK; CBS 264.82, powdery mildew, T. Hijwegen, Netherlands; CBS 604.83 (IFO 6904, UBC 915, YK 807), leaves, K. Tubaki, Tokyo, Japan; UAMH 2678, origin unknown, D. Westlake.

Type strain: CBS 543.50.

Comments: *Tilletiopsis minor* is an inhabitant of the phyllosphere. It has also been isolated from such diverse sources as air, industrial plants and medical specimen (see Boekhout 1991a). Reduction of growth of mildew by *T. minor* was observed under certain environmental conditions (Hijwegen 1986).

Tilletiopsis minor is characterized by dull, brownish, and somewhat pruinose colonies, which show limited expansion growth. *Tilletiopsis fulvescens*, another species with these characteristics, differs by a higher mol% G+C of ca. 66–68.

CBS 604.83 differs from other strains of *T. minor* by assimilation of erythritol (Boekhout 1991a), electrophoretic enzyme patterns (Yamazaki et al. 1985) and somewhat different karyotypes (Boekhout et al. 1992a).

109.5. *Tilletiopsis pallescens* Gokhale (1972)

Growth on 5% malt extract agar: After 5 days at 17°C, hyphae are regularly branched, narrow, cylindrical,

with cells of $(20-80) \times (1.5-3.0) \mu\text{m}$, and with retraction septa. Chlamydo-spores occur terminally or intercalarily and are catenate or single, subglobose, ellipsoidal or cylindrical, $(10-50) \times (3.0-15.0) \mu\text{m}$. Colonies are tough, flat, somewhat ridged or pustulate in the center, covered with slender fascicles, pale yellowish-brown or cream, and with an eroded margin.

Growth on the surface of assimilation media (glucose): A ring, islets and a film are formed.

Dalmay plate culture on morphology agar: After 7 days at 17°C , hyphae are abundantly formed. Chlamydo-spores are similar to those formed on malt extract agar. Aerobic growth is whitish, dull, flat, frequently with the center somewhat wrinkled or pustulate, pruinose, and with slender tapering fascicles, and an eroded margin.

Formation of ballistoconidia: Ballistoconidia are allantoid, falcate to cylindrical, $(6.5-30.0) \times (1.5-4.0) \mu\text{m}$ (Fig. 437).

Fermentation: absent.

Urease	+	Growth at 35°C	-

Co-Q: 10, CBS 606.83, CBS 369.85 (Boekhout et al. 1992b).

Mol% G+C: 42-45.5, 16 strains (T_m : Boekhout et al. 1992a).

Origin of the strains studied: CBS 606.83 (ATCC 24345, UBC 8007, YK 810), fruit-body of *Sirobasidium*, Shamoda, Japan; CBS 162.85, gall of *Clitocybe odorata*, H.A. van der Aa, Netherlands; CBS 364.85, CBS 367.85, CBS 368.85, all from powdery mildew cultures, J.P. Skou, Denmark; CBS 365.85 (ATCC 36535), powdery mildew, H.C. Hoch and R. Provvidenti, USA; CBS 438.90 (ATCC 66528), powdery mildew, A.L. Klecan, S. Hippe and S.C. Somerville, Michigan, USA.

Type strain: UBC 8007.

Comments: *Tilletiopsis pallescens* is similar in many aspects to *T. albescens*, but it can be differentiated from this species by colony appearance and a lower mol% G+C of ca. 42-45.5. *Tilletiopsis pallescens* is frequently isolated from other fungi, and has been reported to antagonize powdery mildews (Hoch and Provvidenti 1979, Hijwegen 1988, Klecan et al. 1990). Karyotypes of European strains, isolated from powdery mildew, were found to be similar, whereas the remaining strains showed considerable variation (Boekhout et al. 1992a).

109.6. *Tilletiopsis washingtonensis* Nyland (1950)

Synonyms:

Tilletiopsis cremea Tubaki (1952)

Tilletiopsis lilacina Tubaki (1952)

Growth on 5% malt extract agar: After 5 days at 17°C , hyphae are regularly branched, narrow, with cells of $(20-100) \times (1.0-3.0) \mu\text{m}$, and with retraction septa (Fig. 438). Chlamydo-spores occur terminally or intercalarily and are subglobose, ellipsoid or cylindrical, and frequently catenate, $(6.0-35.0) \times (2.5-10.0) \mu\text{m}$. Colonies are soft, butyrous flat, usually glabrous, shiny or dull, yellowish-cream or pale pinkish yellow-brown, and with the margin eroded.

Growth on the surface of assimilation media (glucose): A ring, film and a sediment are formed.

Dalmay plate on morphology agar: After 7 days at 17°C , hyphae are abundantly formed. Chlamydo-spores are similar to those formed on malt extract agar. Aerobic growth is pale pinkish-cream, dull or shiny flat, pustulate, ridged or reticulate, and with the margin entire, straight or lobate.

Formation of ballistoconidia: Ballistoconidia are formed singly or in small groups, and are allantoid, falcate or cylindrical, $(8.0-24.0) \times (1.0-3.5) \mu\text{m}$ (Fig. 438).

Fermentation: absent.

Co-Q: 10, CBS 544.50, CBS 605.83 (Boekhout et al. 1992b).

Mol% G + C: 66.5–70.0, 18 strains (T_m : Boekhout et al. 1992a).

Origin of the strains studied: CBS 544.50 (ATCC 36489, YK 803), leaves of *Rubus idaeus*, G. Nyland, Washington, USA; CBS 603.83 (IFO 6832, UBC 925, YK 811), leaves, K. Tubaki, Japan; CBS 605.83 (IFO 6831, NI 3113, UBC 912, YK 809), leaves, K. Tubaki, Japan; UAMH 1738, authentic strain from G. Nyland, Washington, USA.

Type strain: CBS 544.50.

Comments: *Tilletiopsis washingtonensis* seems to be a common inhabitant of the phyllosphere (Brady 1960, Pady 1974, Tubaki 1952). Nyland (1950) considered *T. washingtonensis* to be identical with Derx's (1948) *Tilletiopsis* species 4. *Tilletiopsis washingtonensis*, *T. cremaea* and *T. lilacina* are considered conspecific because of morphological, physiological, and biochemical similarities (Boekhout 1991a). The consistency of the colonies, considered an important taxonomic criterion by Tubaki (1952), seems of insignificant value. Considerable heterogeneity was observed with respect to electrophoretic

Fig. 438. *T. washingtonensis*, CBS 544.50. Hyphae and ballistoconidia on morphology agar. Bar = 5 μ m.

enzyme (Yamazaki et al. 1985) and karyotype patterns (Boekhout et al. 1992a).

Comments on the genus

The name *Tilletiopsis* was published by Derx (1930). This author failed to publish a generic definition or to correctly describe the species (Derx 1930, 1948). Nyland circumscribed the genus by designating *T. washingtonensis* Nyland as neotype.

Anamorphs of Tilletiales, e.g., *Entyloma*, *Melanotaenium* and *Tilletia*, and probably species belonging to other genera as well, are morphologically similar to *Tilletiopsis* (Boekhout 1991a). Therefore, *Tilletiopsis* was regarded to be phylogenetically related to the Tilletiales (Boekhout et al. 1992b).

110. *Trichosporon* Behrend

E. Guého, M.Th. Smith and G.S. de Hoog

Diagnosis of the genus

Colonies are cream-colored, moist or dry, and with or without a white, farinose covering. True mycelium is present; pseudomycelium is absent. Arthroconidia are usually abundant; lateral, clavate conidia also may be present. Appressoria, sarcinae, fusiform giant cells and endoconidia are occasionally present. Hyphal septa are mostly with dolipores which may be with or without vesicular or tubular parenthesomes. Sexual reproduction is absent.

Fermentation is negative. The Diazonium blue B reaction is positive. Urea is hydrolyzed. Coenzyme Q-9 or Q-10 are formed. Xylose is present in whole-cell hydrolyzates.

Type species

Trichosporon ovoides Behrend

Species accepted

1. *Trichosporon aquatile* Hedrick & Dupont (1968)
2. *Trichosporon asahii* Akagi ex Sugita, Nishikawa & Shinoda (1994)
3. *Trichosporon asteroides* (Rischin) Ota (1926)
4. *Trichosporon brassicae* Nakase (1971)
5. *Trichosporon coremiiforme* (M. Moore) Guého & M.Th. Smith (1992)
6. *Trichosporon cutaneum* (de Beurmann, Gougerot & Vaucher) Ota (1926)
7. *Trichosporon dulcitum* (Berkhout) Weijman (1979)
8. *Trichosporon faecale* (Batista & Silveira) Guého & M.Th. Smith (1992)
9. *Trichosporon gracile* (Weigmann & Wolff) Guého & M.Th. Smith (1992)
10. *Trichosporon inkin* (Oho ex Ota) do Carmo-Sousa & van Uden (1967)
11. *Trichosporon jirovecii* Frágner (1969)
12. *Trichosporon laibachii* (Windisch) Guého & M.Th. Smith (1992)
13. *Trichosporon loubieri* (Morenz) Weijman (1979)
14. *Trichosporon moniliiforme* (Weigmann & Wolff) Guého & M.Th. Smith (1992)
15. *Trichosporon montevidense* (Acirole de Queiroz) Guého & M.Th. Smith (1992)
16. *Trichosporon mucoides* Guého & M.Th. Smith (1992)
17. *Trichosporon ovoides* Behrend (1890)
18. *Trichosporon pullulans* (Lindner) Diddens & Lodder (1942)
19. *Trichosporon sporotrichoides* (van Oorschot) van Oorschot & de Hoog (1981)

Systematic discussion of the species

110.1. *Trichosporon aquatile* Hedrick & Dupont (1968)

Growth on Sabouraud's glucose agar: After 10 days at 20–22°C, the colonies are pale cream-colored, mat, smoothly cerebriform or volcano-shaped, odorless, and 6–8 mm in diameter. Hyphae are flexuose, frequently branched at wide angles and finally disarticulating into narrow arthroconidia of variable length; terminal conidia are often clavate, $3 \times (6-14) \mu\text{m}$ (Fig. 439).

Fermentation: absent.

Fig. 439. *T. aquatile*, CBS 5988. Flexuose hyphal cells with clavate conidia. Slide culture with 2% malt extract agar, after 1–2 days at room temperature. Bar = 10 μm .

Co-Q: 9, CBS 5973 and 5988 (Hara et al. 1989, Guého et al. 1992b).

Mol% G + C: 62.9–62.4, CBS 5973 and 5988 (T_m : Guého et al. 1992b); 64.2, CBS 5973 (BD: Guého et al. 1984).

Origin of the strains studied: CBS 5973, water, ex NRRL; CBS 5988, water, Hedrick.

Type strain: CBS 5973.

Comments: The species is morphologically characterized by flexuose hyphae which are often branched at right angles. With the exception of erythritol, most higher

alcohols are not assimilated. The species shows no growth with L-sorbose and inositol.

110.2. *Trichosporon asahii* Akagi ex Sugita, Nishikawa & Shinoda (1994)

Synonyms:

- Trichosporon asahii* Akagi (1929) nom. inval.

Trichosporon figueirae Batista & Silveira (1960)
Trichosporon loboii Batista, Campos & Oliveira (1963)

Growth on Sabouraud's glucose agar: After 10 days at 20–22°C, the colonies are 16–24 mm in diameter, white, farinose at the center, with a wide, dry, often finely zonate margin with deep transverse fissures. Odor is lacking or faintly cheese-like. Arthroconidia are abundant, rectangular, mostly 2–3 µm wide, and with rounded ends, (3–4) × (4–7) µm (Fig. 440). Lateral conidia are absent. Appressoria are absent.

Fermentation: absent.

Assimilation:

Co-Q: 9, CBS 2479, CBS 2530, CBS 4829 and 6 additional strains (Hara et al. 1989, Guého et al. 1992b, Sugita et al. 1994).

Mol% G + C: 57.8–58.7, CBS 2479, CBS 2497, CBS 2530, CBS 4829,

CBS 5286 and 20 additional strains (T_m : Guého et al. 1992b); 59.9, CBS 2530 (BD: Guého et al. 1984); 59.8, CBS 2479, CBS 2939, CBS 4829 (HPLC: Sugita et al. 1994).

Origin of the strains studied: CBS 2479, nail of patient with psoriasis, Ota, type strain of *T. asahii*; CBS 2497, shrimp, Phaff, type strain of *T. cutaneum* var. *peneaus*; CBS 2530, mouse inoculated with pus, Ciferri, type strain of *T. infestans*; CBS 4829, human feces, Batista, type strain of *T. figueirae*; CBS 5286, skin lesion, Batista, type strain of *T. loboii*; blood (6), urine (2), lymphoma (2), mare uterus (1), animal white piedra (2), inflamed gland (1), tofu cake (1); TIMM 1318, SHP patient's environment, Ando.

Type strain: CBS 2479.

Fig. 440. *T. asahii*, CBS 561. Disarticulating hyphae with liberated, cubic arthroconidia. Slide culture with 2% malt extract agar, after 1–2 days at room temperature. Bar = 10 µm.

Comments: Fresh isolates may be creamy, attaining their characteristic dry colony appearance only after repeated transfers. The species grows with D-glucosamine and L-arabinitol but not with raffinose. Physiologically it cannot be distinguished from *T. asteroides*. *Trichosporon asahii* is close to *T. ovoides* and *T. inkin*, but differs by the absence of appressoria and by its ecological preferences. Physiologically it can be recognized from its growth with L-rhamnose and L-arabinitol.

The type strain of *Trichosporon infestans*, CBS 2530, differs by its absence of growth with D-xylose, trehalose and erythritol. However, it proved to be identical to *T. asahii* on the basis of DNA homology and partial rRNA sequences (Guého et al. 1992b) and is therefore listed as a doubtful synonym. Hara et al. (1989) reported Co-Q 10 for CBS 2530, while Guého et al. (1992b) found Co-Q 9.

Trichosporon asahii is mostly found as a causative agent of disseminated mycoses in patients with impaired

natural immunity. Occasionally it causes human or animal white piedra. Only a very few strains are known from non-vertebrate sources.

The species in the above sense comprises agents of human mycoses which in the literature are mostly referred to as *Trichosporon beigelii*. This name was abandoned because the identity of the type specimen could not be established (Guého et al. 1992a). Causative agents of capital white piedra are now known as *Trichosporon ovooides*. Guého et al. (1992a) stressed that *T. cutaneum*, which has widely been regarded as a synonym of *T. beigelii*, is in fact another species, having coenzyme Q-10 rather than Q-9. *T. cutaneum* can be distinguished from *T. asahii* by the absence of growth at 37°C, but it grows with melibiose and raffinose. Strain TIMM 1318 was designated as the standard for serotype II recognized within the genus (Nishiura et al. 1996).

110.3. *Trichosporon asteroides* (Rischin) Ota (1926)

Synonyms:

Parendomyces asteroides Rischin (1921)

Geotrichoides asteroides (Rischin) Langeron & Talice (1932)

Proteomyces asteroides (Rischin) Dodge (1935)

[nec *Monilia asteroides* (Castellani) Castellani & Chalmers (1919) =

Co-Q: 9, CBS 2481, CBS 6183 and CBS 7623 (Hara et al. 1989, Guého et al. 1992b).

Mol% G + C: 61.5–62.0, CBS 2481, CBS 6183 and 4 additional strains (T_m : Guého et al. 1992b).

Origin of the strains studied: CBS 2481, human skin, Beintema; CBS 6183, bovine mastitis, van der Walt; CBS 7623 (ATCC 22432), skin, Ahearn, type strain of *P. filamenta*; blood (1); skin (2); unknown source (1).

Type strain: CBS 2481.

Comments: The species can be recognized physiologically by growth with D-galactose, L-rhamnose, erythritol and L-arabinitol but not with glucono-δ-lactone. It cannot be distinguished physiologically from *T. asahii*, but in contrast, cultures are filamentous with the mycelium locally disarticulating into continuous or septate hyphal elements of variable size.

Two strains of *Fissuricella filamenta*, isolated from human skin, showed DNA homology values around 85% with *T. asteroides* strains (Guého et al. 1992b). The groups of strains are consequently genetically close, despite the

fact that the *F. filamenta* strains were entirely composed of meristematic cells, while such cells were absent from the strains of *T. asteroides*. Colonies of *F. filamenta* are dry, finely cerebriform without a differentiated marginal zone, 5–6 mm diameter, finally become brownish, and crack the agar medium. Possibly *F. filamenta* is a meristematic mutant of *T. asteroides*. The meristematic growth of *F. filamenta* was reminiscent of the sarcinae known in *Trichosporon inkin* *in vivo* or obtained after cultivation on media rich in sugar. For this reason, synonymy of the two species was proposed by Pore et al. (1977). However, *T. inkin* forms appressoria and is unable to grow with L-rhamnose, xylitol and L-arabinitol.

110.4. *Trichosporon brassicae* Nakase (1971a)

Growth on Sabouraud's glucose agar: After 10 days at 20–22°C, the colonies are whitish, shiny, slightly moist, flat, pustular to cerebriform, and 19 mm in diameter. Hyphae are present and easily fall apart into elements of variable length which are rectangular, (4–8) × (10–30) μm (Fig. 442).

Fermentation: absent.

Assimilation:

Origin of the strain studied: CBS 6382, cabbage, Nakase.

Type strain: CBS 6382.

Fig. 442. *T. brassicae*, CBS 6382. Disarticulating hyphae and liberated, partly inflated, hyphal elements. Slide culture with 2% malt extract agar, after 1–2 days at room temperature. Bar = 10 μm.

Comments: *T. brassicae* differs from all other *Trichosporon* species by its inability to assimilate cellobiose. With TEM, no septal pores were found, but septa were often swollen and of spongy texture (Guého et al. 1992b).

110.5. *Trichosporon coremiiforme* (M. Moore) Guého & M.Th. Smith (Guého et al. 1992b)

Synonym:

Hemispora coremiiformis M. Moore (1935)

Growth on Sabouraud's glucose agar: After 10 days at 20–22°C, the colonies are cream-colored, dry, mat, nearly flat, odorless, and 11 mm in diameter, with a finely fimbriate margin. Hyphae are often present in fine tufts and branchlets; hyphae mainly disarticulate into arthroconidia, 3 × (6–10) μm (Fig. 443).

Fermentation: absent.

Assimilation:

Ethylamine	+	Growth at 42°C	–

Co-Q: 9, CBS 2482 (Hara et al. 1989, Guého et al. 1992b, Sugita et al. 1994).

Mol% G+C: 59.3, CBS 2482 (T_m : Guého et al. 1992b); 60.3, CBS 2482 (HPLC: Sugita et al. 1994).

Origin of the strains studied: CBS 2482, head lesion, Moore, type strain of *H. coremiiformis*.

Type strain: CBS 2482.

Comments: *T. coremiiforme* has the following unique combination of physiological characters: growth with L-rhamnose, α -methyl-D-glucoside, L-arabinitol and glucono- δ -lactone; absence of growth with D-glucosamine and melibiose. Sugita et al. (1994) proposed *T. coremiiforme* as a variety of *T. asahii* on the basis of 56% DNA relatedness of respective type cultures (CBS 2482 and CBS 2479).

110.6. *Trichosporon cutaneum* (de Beurmann, Gougerot & Vaucher) Ota (1926)

Synonyms:

Oidium cutaneum de Beurmann, Gougerot & Vaucher (de Beurmann and Gougerot 1909)

Monilia cutanea (de Beurmann, Gougerot & Vaucher) Castellani & Chalmers (1913)

Mycoderma cutaneum (de Beurmann, Gougerot & Vaucher) Brumpt (1913)

Geotrichoides cutaneus (de Beurmann, Gougerot & Vaucher) Langeron & Talice (1932)

Geotrichum cutaneum (de Beurmann, Gougerot & Vaucher) de Almeida (1933)

Proteomyces cutaneus (de Beurmann, Gougerot & Vaucher) Dodge (1935)

Basidiotrichosporon cutaneum (de Beurmann, Gougerot & Vaucher)

Kocková-Kratochvílová, Sláviková & Zemek (1977b) nom. nud.

Geotrichoides paludosus Smit (1934)

Trichosporon minor de Arêa Leão (1940) nom. nud.

Growth on Sabouraud's glucose agar: After 10 days at 20–22°C, the colonies are cream-colored, cerebriform, with broad, moist, glistening marginal zones, and 15–17 mm in diameter; the odor is cheese-like. Cultures generally consist of disarticulating hyphae, but may revert to yeast growth with subspheroidal budding cells. Arthroconidia are regular, (3–4) \times (4–8) μ m, with lateral, clavate blastoconidia (Fig. 444).

Fermentation: absent.

Assimilation:

Co-Q: 10, CBS 2466, CBS 2480 and CBS 2545 (Hara et al. 1989, Guého et al. 1992b); 10, CBS 2466 (Yamada et al. 1982).

Mol% G+C: 60.7–61.2, CBS 2466, CBS 2480, CBS 2545 (T_m : Guého et al. 1992b); 63.5, CBS 2466 (BD: Guého et al. 1984).

Origin of the strains studied: CBS 2466, skin lesion, Langeron; CBS 2480, axillary white piedra, de Arêa Leão, type strain of *T. minor*; CBS 2545, activated sludge, Smit, type strain of *G. paludosus*.

Type strain: CBS 2466.

Fig. 444. *T. cutaneum*, CBS 2466. Disarticulating, branched hyphae. Slide culture with 2% malt extract agar, after 1–2 days at room temperature. Bar = 10 μ m.

Fig. 445. *T. dulcitum*, CBS 7608. Hyphae disarticulating into arthroconidia; hyphae with cymose branching. Slide culture with 2% malt extract agar, after 1–2 days at room temperature. Bar = 10 μ m.

Comments: Key characters are the absence of growth with galactitol and glucono- δ -lactone; however, the species cannot be distinguished easily from *T. moniliiforme* by differences in growth reactions. *T. moniliiforme* shows variable growth reactions with glucono- δ -lactone. *Trichosporon cutaneum* is more sensitive to cycloheximide, not growing after two days of incubation with 0.01%, and to elevated temperature, not being able to grow at 35°C. The two species differ in their ecology; *T. moniliiforme* is restricted to natural sources such as soil. In contrast to the opinion held in the older literature, *T. cutaneum sensu stricto* appears to be a rare species (Guého et al. 1992b) and mostly occurs as an agent of superficial mycoses of warm-blooded animals.

110.7. *Trichosporon dulcitum* (Berkhout) Weijman (1979b)

Synonyms:

- Oospora dulcita* Berkhout (1923)
Geotrichum dulcitum (Berkhout) Windisch (1952)
Protendomyces domschii Windisch (1965)
Schizosaccharomyces zambettakesii Ramírez Gómez (1957)
Geotrichum zambettakesii Ramírez Gómez (1959)
Endomyces zambettakesii (Ramírez Gómez) Novák & Zsolt (1961)

Growth on Sabouraud's glucose agar: After 10 days at 20–22°C, the colonies are cream-colored, moist, flat, with shallow central depressions, and 25–28 mm in diameter. The growth has a strong smell of rotten cauliflower. Large hyphae with cymose branching are often present. Arthroconidia are formed and become subspheroidal to cylindroidal, (5–8) × (10–40) μ m (Fig. 445).

Fermentation: absent.

Co-Q: 9, CBS 8257, CBS 5785 and CBS 5786 (Hara et al. 1989, Guého et al. 1992b).

Mol% G+C: 54.9–55.4, CBS 8247, CBS 5786 and 2 additional strains (T_m : Guého et al. 1992b); 57.5, CBS 8257 (BD: Guého et al. 1984).

Origin of the strains studied: CBS 8257, soil, Den Dooren de Jong; CBS 5785, toadstool, Ramírez, type strain of *S. zambettakesii*; CBS 5786, soil, Windisch, type strain of *P. domschii*; CBS 7608, loess soil, Nirenberg.

Type strain: CBS 8257.

Comments: The species is an inhabitant of soil. It is mesophilic with optimum growth at 18°C. *Schizosaccharomyces zambettakesii* was found to be a synonym on the basis of DNA reassociation (Guého et al. 1992b), but in contrast to other strains of the species, it does not grow with citrate as sole carbon source.

110.8. *Trichosporon faecale* (Batista & Silveira) Guého & M.Th. Smith (Guého et al. 1992b)

Synonym:

Endomyces mali (Lewis) Dekker var. *faecalis* Batista & Silveira (1959b)

Growth on Sabouraud's glucose agar: After 10 days at 20–22°C, the colonies are cream-colored, moist, irregularly cerebriform at the center, flat or with radial fissures at the margin, and with some areas having a whitish, hispid covering. True hyphae are present, and disarticulate into separate cells measuring 2.5×(3.5–9.0)µm (Fig. 446).

Fermentation: absent.

Fig. 446. *T. faecale*, CBS 4828. Hyphae disarticulating into arthroconidia. Slide culture with 2% malt extract agar, after 1–2 days at room temperature. Bar = 10µm.

Co-Q: 9, CBS 4828 (Hara et al. 1989, Guého et al. 1992b, Sugita et al. 1994).

Mol% G+C: 58.7, CBS 4828 (T_m : Guého et al. 1992b); 60.0, CBS 4828 (HPLC: Sugita et al. 1994).

Origin of the strain studied: CBS 4828, human feces, Batista, type strain of *E. mali* var. *faecalis*.

Type strain: CBS 4828.

Comments: The species is close to *T. ovoides*, *T. inkin* and *T. aquatile* on the basis of DNA reassociation data (Guého et al. 1992b), but can be distinguished by its unique combination of physiological characters: assimilation of D-glucosamine, D-arabinose, L-rhamnose, ribitol and glucono-δ-lactone but lack of growth with L-sorbose and melibiose. As for *T. coremiiforme*, Sugita et al. (1994) proposed *T. faecale* as a variety of *T. asahii* on the basis of 53% DNA relatedness of respective type cultures (CBS 4828 and CBS 2479).

110.9. *Trichosporon gracile* (Weigmann & Wolff) Guého & M.Th. Smith (Guého et al. 1992b)

Synonyms:

Oidium gracile Weigmann & Wolff (1909)

Oospora gracile (Weigmann & Wolff) Berkhout (1923)

Geotrichum gracile (Weigmann & Wolff) Windisch (1952)

Geotrichum vanrijiae Saëz (1964)

Trichosporon lutetiae Saëz (1977)

Growth on Sabouraud's glucose agar: After 10 days at 20–22°C, the colonies are glassy-whitish, mat and smooth, nearly flat, with slight, shallow depressions at

Fig. 447. *T. gracile*, CBS 8189. Hyphae disarticulating into arthroconidia. Slide culture with 2% malt extract agar, after 1–2 days at room temperature. Bar = 10 μ m.

the center, and measure 29–30 μ m in diameter. The odor is cheese-like. True hyphae are present and easily disarticulate into regularly rectangular arthroconidia that measure $3 \times (4–12) \mu$ m (Fig. 447).

Fermentation: absent.

Co-Q: 9, CBS 8189, CBS 8193, CBS 6861 and CBS 7609 (Hara et al. 1989, Guého et al. 1992b); 9, CBS 6861, CBS 8193 (Sugita et al. 1994).

Mol% G+C: 57.6–58.0, CBS 6861, CBS 8189, CBS 8193 and 3 additional strains (T_m : Guého et al. 1992b); 59.7–60.0, CBS 6861, CBS 8189, CBS 8193 (BD: Guého et al. 1984); 58.6–58.9, CBS 6861, CBS 8193 (HPLC: Sugita et al. 1994).

Origin of the strains studied: CBS 8189, sour milk, Bierberg, type strain of *Oidium gracile*; CBS 5066, frozen chicken, Barnett; CBS 6861, gut of deer (*Cervus eldisiamensis*), Saëz, type strain of *T. lutetiae*; CBS 8193, from duck (*Anas querquedula*), Saëz, type strain of *Geotrichum vanrijiae*; from swan (*Cygnus olor*) (1); from crab-eating raccoon (*Procyon cancrivorus*) (1).

Type strain: CBS 8189.

Comments: The species is mostly isolated from animal sources; the type strain of *Geotrichum gracile* came from sour milk. The species is physiologically characterized by absence of growth with D-galactose, L-rhamnose and α -methyl-D-glucoside (Guého et al. 1992b). Most strains of *T. gracile* are dry, while others are usually slimy.

110.10. *Trichosporon inkin* (Oho ex Ota) do Carmo-Sousa & van Uden (1967)

Synonyms:

Microsporium brachytonum Oho (1919) nom. prov.

Sarcinomyces inkin (Oho ex Ota) Ota (1926)

Sarcinosporon inkin (Oho ex Ota) King & Jong (1975)

Growth on Sabouraud's glucose agar: After 10 days at 20–22°C, colonies are finely cerebriform, often cracking the agar medium, and 9–12 mm in diameter, with a white, farinose covering; a marginal zone is absent. Appressoria are present. Hyphae disarticulate into rectangular arthroconidia, $4 \times (12–20) \mu$ m (Fig. 448). Sarcinae are produced on media rich in sugar. A faint odor is produced.

Fermentation: absent.

Assimilation:

Fig. 448. *T. inkin*, CBS 5585. Disarticulating hyphae with appressoria; cylindrical arthroconidia. Slide culture with 2% malt extract agar, after 5–10 days at room temperature. Sarcinae. After 4–5 days on 50% GYA at room temperature. Bar = 10 μ m.

Co-Q: 9, CBS 5585 and 4 additional strains (Guého et al. 1992b).

Mol% G+C: 58.3–59.5, CBS 5585 and 19 additional strains (T_m : Guého et al. 1992b); 61.5, CBS 5585 (BD: Guého et al. 1984).

Origin of the strains studied: CBS 5585, tinea cruris, do Carmo-Sousa; CBS 7613, anus, Stenderup; CBS 7628, endocarditis; CBS 7629, urine; pubic white piedra (8), peritonitis (1); skin lesion (1).

Type strain: CBS 5585.

Comments: On media with high sugar contents, the species produces sarcinae, and King and Jong (1975) used this property to define the genus *Sarcinosporon*. However, close molecular similarity was found between *T. inkin*, *T. ovoides* and *T. asahii* (Guého et al. 1992b). A diagnostic set of physiological criteria of *T. inkin* is formed from growth with α -methyl-D-glucoside, erythritol and inositol and absence of growth with L-rhamnose and melibiose. The species is ecologically remarkable because it is restricted to humans and it frequently causes cruric white piedra.

110.11. *Trichosporon jirovecii* Frágner (1969)

Synonyms:

Trichosporon cutaneum (de Beurmann, Gougerot & Vaucher) Ota var.

jirovecii (Frágner) Frágner (1970)

Trichosporon beemeri Kuttin & Müller (1981)

Growth on Sabouraud's glucose agar: After 10 days at 20–22°C, the colonies are whitish, mat, cerebriform at the center with broad, flat margins with narrow but deep radial fissures, and measure 15–16 mm in diameter. Cultures have a faint odor. Hyphae are sterile or disarticulate into irregular arthroconidia, (3–5) \times (6–20) μ m. Endoconidia and chlamydospores (5 \times 6 μ m) are occasionally present (Fig. 449). Groups of obovoidal, sometimes catenulate conidia form in small clusters laterally at disarticulating hyphae.

Fermentation: absent.

Co-Q: 10, CBS 6864 and CBS 6950 (Guého et al. 1992b).

Mol% G+C: 61.0–61.7, CBS 6864 and CBS 6950 (T_m : Guého et al. 1992b).

Origin of the strains studied: CBS 6864, human nail, Frágner, type strain of *T. jirovecii*; CBS 6950, Nile crocodile, Kuttin, type strain of *T. beemerii*.

Type strain: CBS 6864.

Comments: The species differs from *T. mucoides* by the absence of growth with glucono- δ -lactone and from *T. moniliiforme* and *T. cutaneum* by growth with galactitol.

110.12. *Trichosporon laibachii* (Windisch) Guého & M.Th. Smith (Guého et al. 1992b)**Synonyms:**

?*Trichosporon multisporum* Cochet (1940) nom. nud.

?*Trichosporon cutaneum* (de Beurmann, Gougerot & Vaucher) Ota var. *multisporum* (Cochet) Lodder & Kreger-van Rij (1952)

Endomyces laibachii Windisch (1965)

Growth on Sabouraud's glucose agar: After 10 days at 20–22°C, the colonies are white, mat, dry, finely farinose, and with sharp radial fissures that cause lifting of the agar; colonies are 42–46 mm in diameter. Hyphae form lateral, spheroidal conidia that are 4 μ m in diameter (Fig. 450).

Fermentation: absent.

Assimilation:

Co-Q: 9, CBS 5790 and 3 additional strains (Hara et al. 1989, Guého et al. 1992b, Sugita et al. 1994).

Mol% G+C: 57.0–57.5, CBS 5790, CBS 2495 and 2 additional strains (T_m : Guého et al. 1992b); 58.8, CBS 2495 (T_m : Guého et al. 1992b); 58.3, CBS 5790 (HPLC: Sugita et al. 1994).

Origin of the strains studied: CBS 5790, soil, Windisch, type of *Endomyces laibachii*; CBS 2495, rat droppings, Cochet, authentic strain of *T. multisporum*; water (1), soil (2).

Type strain: CBS 5790.

Comments: Judging from DNA reassociation values between 53 and 73%, *T. laibachii* and *T. loubieri* are closely related, possibly at the level of varieties (Guého et al. 1992b, Sugita et al. 1994). The taxa can readily be distinguished on the basis of micromorphology and physiology. Fusiform macroconidia are absent from *T. laibachii*, while small, lateral, ellipsoidal to spheroidal

blastoconidia are present. In addition, *T. laibachii* is able to grow with galactitol, but it fails to grow at 42°C.

The authentic strain of *T. multisporum*, CBS 2495 is close to *T. laibachii* from molecular comparisons (Guého et al. 1992b). The taxa nevertheless differ by growth responses to ribitol and creatinine and by the presence of a strong, cauliflower-like scent in cultures of *T. multisporum*.

110.13. *Trichosporon loubieri* (Morenz) Weijman (1979b)

Synonym:

Geotrichum loubieri Morenz (1963)

Growth on Sabouraud's glucose agar: After 10 days at 20–22°C, the colonies are white, mat, dry, finely farinose, and with sharp radial fissures that cause lifting of the agar. Colonies are 42–46 mm in diameter. Arthroconidia are present and measure (3–4) × (6–15) µm. In addition to arthroconidia, lateral or intercalary fusiform cells with granular contents are present and measure about 80 × 15 µm (Fig. 451).

Fermentation: absent.

Origin of the strains studied: CBS 7065, cow mastitis, Morenz; CBS 7132, mushroom (*Entyloma* sp.), de Hoog.

Type strain: CBS 7065.

Comments: The taxon is characterized by growth at 42°C and assimilation of L-rhamnose. In addition, large, fusiform cells with granular contents are present.

110.14. *Trichosporon moniliiforme* (Weigmann & Wolff) Guého & M.Th. Smith (Guého et al. 1992b)

Synonyms:

Oidium moniliiforme Weigmann & Wolff (1909)

Oospora moniliiformis (Weigmann & Wolff) Berkhout (1923)

Trichosporon cutaneum (de Beurmann, Gougerot & Vaucher) Ota var. *antarcticum* Goto, Sugiyama & Iizuka (1969)

Growth on Sabouraud's glucose agar: After 10 days at 20–22°C, the colonies are cream-colored, slimy at first, but later often dry, tough and with deep but narrow, radial folds. A faint odor is exuded. Arthroconidia are 2 µm wide and ellipsoidal; lateral conidia are present and measure 2.5 × 4 µm (Fig. 452).

Fermentation: absent.

Fig. 452. *T. moniliiforme*, CBS 2467. Hyphae in small fascicles, with lateral, clavate conidia. Slide culture with 2% malt extract agar, after 1–2 days at room temperature. Bar = 10 μ m.

Co-Q: 10, CBS 2467, CBS 5959 and 5 additional strains (Hara et al. 1989, Guého et al. 1992b).

Mol% G + C: 57.8–59.0, CBS 2467, CBS 5959 and 7 additional strains (T_m : Guého et al. 1992b); 60.2, CBS 5959 (BD: Guého et al. 1984).

Origin of the strains studied: CBS 2467, butter, Bierberg; CBS 5959, Lake Vanda, Sugiyama, type strain

of *T. cutaneum* var. *antarcticum*; from water (1), soil (3), pigeon guano (1), chicken run (1), flour (1).

Type strain: CBS 2467.

Comments: Physiologically the species cannot be distinguished from *T. cutaneum* on standard growth tests. However, most strains of *T. moniliiforme* were isolated from soil or water, sometimes in association with bird manure, while *T. cutaneum* is particularly known from superficial infections in humans.

110.15. *Trichosporon montevidense* (Aciole de Queiroz) Guého & M.Th. Smith (Guého et al. 1992b)

Synonyms:

Endomycopsis montevidensis Aciole de Queiroz (1973)

Geotrichum robustum Fang, Yen & Yue (1966)

Growth on Sabouraud's glucose agar: After 10 days at 20–22°C, the colonies are whitish, mat, somewhat hispid, strongly transversely folded, centrally coarsely cerebriform, have a citron yellow reverse and measure 22–23 mm in diameter. Cultures consist of sterile hyphae or hyphae may disarticulate into irregular arthroconidia, (3–5) \times (6–20) μ m (Fig. 453). Endoconidia are occasionally present.

Fermentation: absent.

Assimilation:

Glucose	+	<i>N</i> -Acetyl-D-glucosamine	+

L-Lysine	+	Growth at 37°C	–

Co-Q: 9, CBS 6721 (Guého et al. 1992b, Sugita et al. 1994).

Mol% G + C: 55.1–55.3, CBS 6721, CBS 8261, M9456 (T_m : Guého et al. 1992b); 57.0, CBS 6721, M9456 (HPLC: Sugita et al. 1994, Nishiura et al. 1996).

Fig. 453. *T. montevidense*, CBS 8261. Hyphae, disarticulating into arthroconidia. Slide culture with 2% malt extract agar, after 1–2 days at room temperature. Bar = 10 μ m.

Origin of the strains studied: CBS 6721, water, Aciole de Queiroz; CBS 8261, human feces, Fang. M9456, SHP patient's environment, Ando.

Type strain: CBS 6721.

Comments: The strains available are rather filamentous. The species was originally described as having ascospores (Aciole de Queiroz 1973), but endoconidia may have been misinterpreted as ascospores. *Trichosporon montevidense* is physiologically recognizable by its assimilation of galactose and inability to grow with L-sorbose, L-rhamnose, melibiose and erythritol. Strain M9456 was designated as the standard for serotype II recognized within the genus (Nishiura et al. 1996).

110.16. *Trichosporon mucoides* Guého & M.Th. Smith (Guého et al. 1992b)

Growth on Sabouraud's glucose agar: After 10 days at 20–22°C, the colonies are cream-colored, moist and glistening, strongly elevated and become cerebriform

Fig. 454. *T. mucoides*, CBS 7625. Hyphae with swollen terminal cells; liberated arthroconidia. Slide culture with 2% malt extract agar, after 1–2 days at room temperature. Bar = 10 μ m.

with smooth margins, which later show narrow radial fissures. The agar adjacent to colonies often becomes cracked. Colonies measure 13–17 mm in diameter. Growth is odorless. Arthroconidia are present; shorter lateral branches often terminate with clavate conidia measuring 4 × 8 μ m (Fig. 454).

Fermentation: absent.

Assimilation:

Glucose	+	<i>N</i> -Acetyl-D-glucosamine	+

Cadaverine	+	Growth at 30°C	+
Creatinine	–	Growth at 37°C	+
L-Lysine	+	Growth at 42°C	–

Co-Q: 10, CBS 7625, CBS 7616 and CBS 7626 (Guého et al. 1992b).

Mol% G+C: 58.3–58.8, CBS 7625, TIMM 1573 and 4 additional strains (T_m : Guého et al. 1992b, Nishiura et al. 1996).

Origin of the strains studied: CBS 7625, meningitis, Surmont; CBS 7616, spinal fluid of human patient, Ahearn; CBS 7626, pubic white piedra (AIDS), Fischerman; CBS 7653, sputum (1); skin lesion (1); TIMM 1573, SHP patient's environment, Ando.

Type strain: CBS 7625.

Comments: The species is characterized by the combination of growth with galactitol and at 37°C. Strains of *T. faecale* may have the same combination of characters, but they are recognized by the absence of growth with L-sorbose. Most isolates are of human origin (Surmont et al. 1990). Strain TIMM 1573 was designated as the standard for serotype II recognized within the genus (Nishiura et al. 1996).

110.17. *Trichosporon ovoides* Behrend (1890)**Synonyms:**

- ?*Pleurococcus beigelii* Küchenmeister & Rabenhorst (Rabenhorst 1867)
 ?*Zooglea beigeliana* Eberth 1873, cited by Redaelli & Ciferri (1941)
 ?*Hyalococcus beigelii* (Küchenmeister & Rabenhorst) Schroeter (1889)
 ?*Chlamydatomus beigelii* (Küchenmeister & Rabenhorst) Trevisan (Saccardo 1889)
 ?*Micrococcus beigelii* (Küchenmeister & Rabenhorst) Migula (1900)
 ?*Trichosporon beigelii* (Küchenmeister & Rabenhorst) Vuillemin (1902)

Geotrichum amycelicum Redaelli & Ciferri (1935)

Growth on Sabouraud's glucose agar: After 10 days at 20–22°C, the colonies are white, dry, farinose, irregularly folded with transverse fissures in the margins and reach 10–13 mm in diameter. Rectangular arthroconidia, (3–5) × (4–15) µm, are present (Fig. 455). Appressoria are sparingly present. No odor is detected.

Fermentation: absent.

Assimilation:

Co-Q: 9, CBS 7556, CBS 5585 (Guého et al. 1992b, Sugita et al. 1994).

Mol% G+C: 58.3–58.5, CBS 7556, CBS 5585 and 2 additional strains (T_m : Guého et al. 1992b); 61.7, CBS 5580 (BD: Guého et al. 1984); 60.1, CBS 7556 (HPLC: Sugita et al. 1994).

Origin of the strains studied: CBS 7556, hair white piedra, Lasagni; CBS 4098, hair, white piedra, de Arêa Leão; CBS 5580, skin lesion, Pollacci; CBS 7612 (ATCC 10266), white piedra, Miguens.

Neotype strain CBS 7556.

Comments: Two of the strains studied originated from

Fig. 455. *T. ovoides*, CBS 7556. Hyphae disarticulating into arthroconidia; terminal appressoria. Slide culture with 2% malt extract agar, after 1–2 days at room temperature. Bar = 10 µm.

human capital white piedra. This clinical picture corresponds well with the original description of *T. ovoides* (Behrend 1890) of which no material is known to be preserved. CBS 7556 was designated as the neotype strain of this species (Guého et al. 1992a). This name replaces the widely used but ambiguous name *T. beigelii*, for which no material nor adequate description is available.

T. ovoides is characterized by growth with erythritol and D-mannitol but not with melibiose. It shows close relationships to *T. asahii* and *T. inkin*, other *Trichosporon* species from humans that have the coenzyme Q-9 system. The three species have colonies which, when old, develop a white, farinose covering. *T. ovoides* cannot be differentiated physiologically from *T. inkin*, but DNA reassociations between the two species proved to be low (Guého et al. 1992b). *T. ovoides* develops appressoria as does *T. inkin* but has the same marginate colony as *T. asahii*.

110.18. *Trichosporon pullulans* (Lindner) Diddens & Lodder (1942)**Synonyms:**

- Oidium pullulans* Lindner (1895)
Oospora pullulans (Lindner) Lindau (1907)
Oosporidium fuscans Stautz (1931)
Monilia pullulans (Lindner) Langeron & Talice (1932)
Trichosporon fuscans (Stautz) Buchwald (1939)
Basidiotrichosporon pullulans (Lindner) Kocková-Kratochvílová, Sláviková & Zemek (1977b)

Growth on Sabouraud's glucose agar: After 10 days at 20–22°C, the colonies are flat, soft, regularly zonate with a fringed margin, initially smooth and cream-colored, later with a whitish, farinose to velutinous covering which becomes tan to somewhat orange colored. Colonies are 19–21 mm in diameter. The odor is faint. Initial budding is enteroblastic, but in older cultures disarticulating hyphae are prevalent, and become ovoidal, or spheroidal to ellipsoidal and measure $9 \times (9-20) \mu\text{m}$ (Fig. 456).

Fermentation: absent.

Co-Q: 9, CBS 2532, CBS 2535 and CBS 2540 (Hara et al. 1989, Guého et al. 1992b); CBS 2532, CBS 2533 (Yamada et al. 1982).

Mol% G + C: 56.6–57.3, CBS 2532, CBS 2535 and 4 additional strains (T_m : Guého et al. 1992b); 58.9–59.0, CBS 2540, CBS 2542 (BD: Guého et al. 1984).

Origin of the strains studied: CBS 2532, air, Lindner; CBS 2535, slime flux of chestnut (*Castanea* sp.), Stautz, type of *Oidium fuscans*; beer pipe, (1); sawdust (1); frozen beef (1); butter (1); slime flux of maple (*Acer* sp.) (1); Antarctic soil (3); nail (1).

Type strain: CBS 2532.

Fig. 456. *T. pullulans*, CBS 2532. Hyphae with lateral, spherical conidia. Slide culture with 2% malt extract agar, after 1–2 days at room temperature. Bar = 10 μm .

Comments: *T. pullulans* is easily recognized by its low optimum temperature for growth (17°C), assimilation of nitrate and absence of growth with lactate. Septal pores seem to be absent (Guého et al. 1992b). Another character uncommon in the genus *Trichosporon* is enteroblastic budding. *T. pullulans* is phylogenetically distinct from the remaining *Trichosporon* species (Guého et al. 1992b).

110.19. *Trichosporon sporotrichoides* (van Oorschot) van Oorschot & de Hoog (1981)¹

Synonym:

Trichosporiella sporotrichoides van Oorschot (1980)

Growth on Sabouraud's glucose agar: After 10 days at 20–22°C, the colonies are cream-colored, dry, mat, finely folded at the center, with a broad, flat outer zone with a fimbriate margin and are 10 mm in diameter. Cultures exude a strong, cheese-like smell. Hyphae disarticulate into elongated arthroconidia and form spheroidal lateral conidia that measure 3.5 μm in diameter (Fig. 457).

¹ Editors' Comment: Guého et al. (1992b) incorrectly listed CBS 8245 as the type strain of *Trichosporiella sporotrichoides* and subsequently followed that listing in the above treatment. According to van Oorschot and de Hoog (1981), the type strain is CBS 671.74 (CBS 8246) collected by J.H. van Emden from soil in Surinam. However, CBS 8245 (CBS 577.77) is an additional strain studied by van Oorschot and de Hoog (1981). Based on nDNA reassociation values, Guého et al. (1992b) found that CBS 8246 (the type strain of *Trichosporiella sporotrichoides*) is a synonym of *Trichosporon laibachii*. They also reported, based on LSU rRNA sequence analysis, that CBS 8245 is a distinct species within the genus, a result confirmed by Fell and Scorzettii (unpublished). Consequently it is the editors' opinion that the above description of CBS 8245 represents a new species and not *T. sporotrichoides*, which is a synonym of *T. laibachii*. This observation came to the attention of the editors late in the editing process, therefore the required revisions were not made.

Fermentation: absent.

Co-Q: 9, CBS 8245 (Guého et al. 1992b).

Mol% G + C: 61.5, CBS 8245 (T_m : Guého et al. 1992b).

Origin of the strain studied: CBS 8245, soil, Colombia.

Type strain: CBS 8245.

Comments: CBS 8245 has characteristic lateral conidia and is physiologically recognized by growth with creatinine but not with raffinose. It is similar to *T. laibachii* but distinguishable by absence of growth with raffinose and galactitol.

Comments on the genus

In the older literature, *Trichosporon* was defined largely on the basis of morphological criteria, but the genus has been redefined to comprise only arthroconidial species with a basidiomycetous affinity. rRNA sequencing studies have shown, that the genus is relatively close to *Cryptococcus* (Guého et al. 1993). The two genera probably belong to the Tremellales. In addition to a positive diazonium blue B staining reaction, presence of urease and absence of fermentation, the species have variously shaped septal dolipores. In *Trichosporon*, budding cells are sparse or absent. Some species are filamentous and produce lateral blastoconidia in addition to or occasionally instead of arthroconidia. Such strains have frequently been identified as hyphomycetes. The hyphomycete genus *Hyalodendron* is probably a synonym of *Trichosporon*, as it clustered amidst *Trichosporon* species when compared from partial 26S rRNA sequences (Guého et al. 1993).

Species of ascomycetous affinity are no longer maintained in *Trichosporon* but have been transferred to *Geotrichum*. The following three species were described by Lu and Li (1991) as members of *Trichosporon* but are excluded from the genus due to their ascomycetous affinity:

Trichosporon bacangense Lu & Li (reidentified as *Saccharomycopsis fibuliger*);

Trichosporon beijingense Lu & Li (reidentified as *Candida fennica*);

Trichosporon sinense Lu & Li (reidentified as *Candida* species).

The genus *Trichosporon* was recently revised using a combination of physiological and molecular criteria (Guého et al. 1992a,b); a review of the clinically significant species was given by Guého et al. (1994). The genus was found to consist of a large number of closely

Fig. 457. *T. sporotrichoides*, CBS 8245. Hyphae disarticulating into arthroconidia which swell and may bud further. Slide culture with 2% malt extract agar, after 1–2 days at room temperature. Bar = 10 μ m.

related species, each with rather specialized ecological requirements. The concept of a limited number of extremely variable species, as maintained in the previous edition of "The Yeasts", was thus refuted. In contrast, the genus *Trichosporon* now represents a natural grouping of arthrosporous anamorphs of heterobasidiomycetes, among which are likely to be many new species that will require characterization (Sugita et al. 1995).

Older taxa for which no type material is known to exist could not be compared in this treatment and are listed below as doubtful taxa:

Endomyces rotundus Castellani (1912b)

Monilia rotunda (Castellani) Castellani & Chalmers (1913)

Oidium rotundatum (Castellani) Castellani & Chalmers (1919)

Trichosporon ribeiroi Gomes de Moraes (1941) nom. nud.

Trichosporon undulatum Windisch (1952) nom. nud.

Species received too late for inclusion in this treatment:

Trichosporon rugosum (Castellani) Ota (1926);

Trichosporon pararugosum (Castellani, Douglas & Thompson) Nannizzi (1934);

Trichosporon rotundatum (Castellani) Puntoni (1935).

The preceding three taxa (see above for synonyms) were obtained by the courtesy of W.I. Golubev (Russian Collection of Microorganisms, Pushchino, Russia). They have the same rRNA sequence giving the priority to the specific epithet *rugosum*. Phylogenetically, the species *T. rugosum* is related to *T. ovoides* and *T. asahii*.

Recent species not available for inclusion in this treatment: *Trichosporon domesticum* Sugita, Nishikawa & Shinoda (1995)

111. *Trichosporonoides* Haskins & Spencer

G.S. de Hoog and M.Th. Smith

Diagnosis of the genus

Colonies are smooth or cerebriform, cream-colored turning to olivaceous brown. Budding is multilateral. When budding cells are formed on true hyphae or are loose, they frequently cohere in pseudomycelial chains. Chlamydo spores are absent. Cell walls are multilamellar. Septal dolipore is present.

Glucose is fermented. Nitrate is assimilated. Coenzyme Q-9. Xylose and fucose are absent from cell walls. Diazonium blue B is positive. Urease is positive.

Type species

Trichosporonoides oedocephalis Haskins & Spencer

Species accepted

1. *Trichosporonoides madida* de Hoog (1979)
2. *Trichosporonoides megachiliensis* Inglis & Sigler (1992)

Systematic discussion of the species

111.1. *Trichosporonoides madida* de Hoog (1979a)

Growth on 4% malt extract/0.5% yeast extract

agar: After 10 days at 20–22°C, colonies are 4–6 mm in diameter, cerebriform, initially mucoid, soft, with a sharp, irregular margin, cream-colored, and finally grayish-brown. Budding cells are subhyaline, ellipsoidal,

(2.8–4.5) × (4.5–8.0) μm, with multilateral budding, and may cohere in short pseudomycelial chains; hyphae are mostly absent (Fig. 458).

Fermentation:

Glucose	+	Maltose	+
Galactose	–	Lactose	–
Sucrose	+	Raffinose	–

Fig. 458. *T. madida*. CBS 240.79. Yeast phase and pseudomycelium with blasto- and arthroconidia. ChA, 22°C, 5 days.

Assimilation:

Glucose	+	<i>N</i> -Acetyl-D-glucosamine	n
Galactose	-	Methanol	n
L-Sorbose	-	Ethanol	n
Sucrose	+	Glycerol	+
Maltose	+	Erythritol	+

Additional assimilation tests and other growth characteristics:

Urease + Growth at 37°C +

Co-Q: 9, CBS 240.79.

Mol% G+C: 50.2, CBS 240.79 (T_m : de Hoog and Guého 1984).

Origin of the strain studied: CBS 240.79, isolated at a margarine factory.

Type strain: CBS 240.79.

Comments: Although the source of isolation is not

exactly known, *T. madida* may be regarded as a lipophilic species, as are *Moniliella suaveolens* and *Trichosporonoides spathulata*. It differs by a considerably lower mol% G+C content of DNA (de Hoog and Guého 1984). It can be differentiated from *M. suaveolens* by growth at 37°C and from *T. spathulata* by a large number of growth characteristics.

111.2. *Trichosporonoides megachiliensis* Inglis & Sigler (Inglis et al. 1992)

Growth on 4% malt extract/0.5% yeast extract agar: After 10 days at 20–22°C, colonies are 14–16 mm in diameter, finely cerebriform, initially mucoid, soft, with a sharp, irregular margin, and a yellowish-brown center. Budding cells are subhyaline, ovoidal or subspherical, (4–7.5) × (4–7) µm, with multilateral budding; cells cohere in short pseudomycelial chains which separate into arthroconidia (Fig. 459). Hyphae are mostly scant.

Fermentation:

Glucose	+	Maltose	+
Galactose	-	Lactose	-
Sucrose	+	Raffinose	-

Assimilation:

Glucose	+	<i>N</i> -Acetyl-D-glucosamine	n

Co-Q: 9, CBS 191.92.

Mol% G+C: Not determined.

Origin of the strains studied: CBS 190.92 (ATCC 76718), from *Ascosphaera*-infected larva of the alfalfa leafcutting bee (*Megachile rotundata*), Canada, Goettel, and two further strains from the same source.

Type strain: CBS 190.92, ex type.

Fig. 459. *T. megachiliensis*, CBS 190.92. Mycelium with blastoconidia. PCA, 22°C, 5 days.

111.3. *Trichosporonoides nigrescens* Hocking & Pitt (1981)

Growth on 4% malt extract/0.5% yeast extract agar: After 10 days at 20–22°C, colonies are 3 mm in diameter, dry, hemispherical, mustard yellow, and later cerebriform and blackish-brown. Hyphae, when present, are subhyaline and disarticulate into arthroconidia; terminally they change into pseudomycelium and produce chains of blastoconidia. Conidia are subhyaline, but become dark olivaceous, (4.0–6.5) × (5.0–8.0) μm (Fig. 460).

Fermentation:

Glucose	+	Maltose	+
Galactose	+	Lactose	–
Sucrose	–	Raffinose	–

Assimilation:

Glucose	+	<i>N</i> -Acetyl-D-glucosamine	n
Galactose	+	Methanol	n

D-Glucosamine	n	Vitamin-free	+

Fig. 460. *T. nigrescens*, CBS 269.81. Pseudomycelium of yeastlike phase. MEYA, 22°C, 10 days.

Additional assimilation tests and other growth characteristics:

Growth at 37°C	–
Co-Q: 9, CBS 269.81.	
Mol% G + C: 57, 2 strains (BD: Hocking and Pitt 1981).	

Origin of the strains studied: CBS 269.81, from spoiled melon jam, Pitt, Australia; from marmalade (1).

Type strain: CBS 269.81.

Comments: The black and mustard yellow pigments rapidly disappear from cultures maintained on malt agar. Cultures are then strongly reminiscent of several *Moniliella* species. *T. nigrescens* may be a yeastlike form of the osmophilic species *Moniliella mellis* (Fabian & Quinet) V. Rao & de Hoog, which also is unable to grow with sucrose. *T. nigrescens* differs by growth with D-ribose and without vitamins.

111.4. *Trichosporonoides oedocephalis* Haskins & Spencer (1967)

Growth on 4% malt extract/0.5% yeast extract agar: After 10 days at 20–22°C, colonies are 4 mm in diameter, slimy, slightly wrinkled, initially white, but soon becoming olivaceous-brown with an ochraceous reverse. Odor is strongly yeastlike. Hyphae are submerged, hyaline, (2.0–3.5) μm wide, and disarticulate into rectangular arthroconidia. Blastoconidia, which are formed in chains on hyphae, are ellipsoidal, (2.0–3.5) × (4–8) μm, and reproduce further by budding. Inflated hyphal heads that bear spherical, thick-walled, golden brown, synchronously produced conidia may also be present (Fig. 461).

Fermentation:

Glucose	+	Maltose	+
Galactose	+	Lactose	–
Sucrose	+	Raffinose	–

Fig. 461. *T. oedocephalis*, CBS 649.66. Pseudomycelium with blasto- and arthroconidia; swollen capitate cells with synchronous conidia. MEYA, 22°C, 30 days.

Assimilation:

Glucose	+	<i>N</i> -Acetyl-D-glucosamine	n
Galactose	+	Methanol	n
L-Sorbose	-	Ethanol	n
Sucrose	+	Glycerol	+
Maltose	+	Erythritol	+
Cellobiose	+	Ribitol	-
Trehalose	-	Galactitol	-
Lactose	-	D-Mannitol	+
Melibiose	-	D-Glucitol	+
Raffinose	-	α -Methyl-D-glucoside	-
Melezitose	-	Salicin	-
Inulin	-	D-Gluconate	-
Soluble starch	-	DL-Lactate	-
D-Xylose	-	Succinate	v
L-Arabinose	v	Citrate	v
D-Arabinose	-	Inositol	-
D-Ribose	+	Hexadecane	n
L-Rhamnose	-	Nitrate	+
D-Glucosamine	n	Vitamin-free	-

Additional assimilation tests and other growth characteristics:

Urease + Growth at 37°C +

Co-Q: 9, CBS 649.66.

Mol% G+C: 45.8, CBS 649.66 (T_m : de Hoog and Guého 1984).

Origin of the strain studied: CBS 649.66 (ATCC 16958), from the brood of a honey bee, Haskins, California.

Type strain: CBS 649.66.

Comments: The species is close to *Moniliella mellis* (Fabian & Quinet) V. Rao & de Hoog and *M. pollinis* (Hennebert & Verachtert) de Hoog & Guého, all of which are associated with honey bees. However, the mol% G+C contents of DNA of all three species are markedly different (de Hoog and Guého 1984). *M. mellis* is recognized by its absence of growth with sucrose, while *M. pollinis* is unable to grow with galactose. The equally osmophilic species *Trichosporonoides nigrescens* differs by inability to ferment sucrose.

111.5. *Trichosporonoides spathulata* de Hoog (1979a)

Growth on 4% malt extract/0.5% yeast extract agar: After 10 days at 20–22°C, colonies are 4 mm in diameter, smooth to wrinkled, cream-colored to oliveaceous, and with a vague marginal zone of submerged

Fig. 462. *T. spathulata*, CBS 241.79. Yeastlike phase with blasto- and arthroconidia. PCA, 22°C, 5 days.

hyphae. Pseudomycelium is present. Hyphae are (2–3) μ m wide, hyaline, and bear lateral and terminal chains of blastoconidia; hyphae soon disintegrate into rectangular arthroconidia (Fig. 462).

Fermentation:

Glucose	+	Maltose	+
Galactose	+	Lactose	v
Sucrose	+	Raffinose	-

Assimilation:

Glucose	+	<i>N</i> -Acetyl-D-glucosamine	n
Galactose	v	Methanol	n
L-Sorbose	-	Ethanol	n
Sucrose	+	Glycerol	+
Maltose	+	Erythritol	+

D-Xylose	v	Succinate	+
L-Arabinose	-	Citrate	+
D-Arabinose	-	Inositol	-
D-Ribose	+	Hexadecane	n
L-Rhamnose	-	Nitrate	+
D-Glucosamine	n	Vitamin-free	+

Additional assimilation tests and other growth characteristics:

Urease + Growth at 37°C +

Co-Q: Not determined.**Mol% G+C:** 61.5–62.5, CBS 241.79, CBS 242.79 (T_m : de Hoog and Guého 1984).**Origin of the strains studied:** CBS 241.79 and two additional cultures, all from ghee (buffalo milk), India.**Type strain:** CBS 241.79.

Comments: The species is thus far only known from a few strains isolated from Indian buffalo milk. Its mol% G+C content is in the range of that of *Moniliella suaveolens* rather than of the remaining *Trichosporonoides* species; it differs consistently from *M. suaveolens* by its ability to grow at 37°C.

Comments on the genus

The genus is very similar to *Moniliella* Stolk & Dakin. Both genera are supposed to be of heterobasidiomycetous affinity (de Hoog 1979b), as concluded from ability to hydrolyze urea, a positive diazonium blue B staining reaction, the presence of multilamellar cell walls, dolipore septal ultrastructure (Martínez 1979), and 5S rRNA sequences (Walker 1984). Both genera are peculiar by their xerophily (Hocking and Pitt 1981) and fermentative abilities (Martínez et al. 1979), and lack xylose as well as fucose from their cell walls (Weijman 1979a). The cellular dimensions in *Moniliella* are generally larger than in *Trichosporonoides* (de Hoog 1979a, Inglis et al. 1992).

Ramírez (1989) described a *Trichosporonoides* species, *T. australiensis* Ramírez, from orange-mango drink in Australia. No culture is available for study. Inglis et al. (1992) considered *T. australiensis* to be synonymous with *Brettanomyces anomalus*.

112. *Tsuchiyaea* Y. Yamada, Kawasaki, M. Itoh, Banno & Nakase

Y. Yamada and I. Banno

Diagnosis of the genus

Cells are globose, ovoid to cylindrical, and reproduce by the formation of enteroblastic buds or of conidia on stalks. A single conidium is formed at the top of the stalks and liberated at a septum in the mid-region of the stalks without projection. Ballistoconidia are absent.

Glucose is not fermented. D-Glucuronate and *myo*-inositol are assimilated. Diazonium blue B color reaction is positive. Xylose is present in the cells. Nitrate is not assimilated. Urease is produced. Coenzyme Q-9 is present.

Type species

Tsuchiyaea wingfieldii (van der Walt, Y. Yamada & Ferreira) Y. Yamada, Kawasaki, M. Itoh, Banno & Nakase

Species accepted

1. *Tsuchiyaea wingfieldii* (van der Walt, Y. Yamada & Ferreira) Y. Yamada, Kawasaki, M. Itoh, Banno & Nakase (1988)

Systematic discussion of the species

112.1. *Tsuchiyaea wingfieldii* (van der Walt, Y. Yamada & Ferreira) Y. Yamada, Kawasaki, M. Itoh, Banno & Nakase (1988b)

Synonym:

Sterigmatomyces wingfieldii van der Walt, Y. Yamada & Ferreira (1987d)

Growth in malt extract: After 3 days at 25°C, the cells are globose to ellipsoidal, (4.0–10.0) × (3.0–9.0) μm, reproduce by enteroblastic budding, and occur singly, in pairs or short chains. Giant cells, 8.0 × 14.0 μm, may be present. A sediment, ring and islets are formed. After 4 weeks at ambient temperature, a sediment and a thick, wrinkled creeping pellicle are present.

Growth on malt agar: After 3 days at 25°C, the cells are globose, ellipsoidal, ovoid, occasionally apiculate, (3.0–11.0) × (3.0–10.0) μm, occur singly, in pairs or short chains, and reproduce either by enteroblastic budding or by the formation of stalks which delimit conidia terminally. The conidia are detached by disjunction at a septum in the mid-region of the stalks. The mature, detached conidia, (9.5–14.0) × (5.5–6.5) μm, are clavate to spathulate, with truncate bases. Stalk-forming cells are, as a rule, lipid-rich, and form 1–3 stalks, which measure (2.0–10.0) × (1.5–2.0) μm. The streak culture is butyrous, creamy-white, and faintly crispulate with an entire margin. After 4 weeks at ambient temperature, the culture is crispulate, cream-colored and dull with a lobate margin.

Dalmau plate culture on corn meal agar: Neither pseudomycelium nor mycelium is formed.

Fermentation: absent.

Co-Q: 9.

Mol% G + C: 55.37, type strain (CBS 7118); 53.3 (HPLC).

Xylose in cells: Present.

Origin of the strain studied: IFO 10204 (CBS 7118), frass of a Scolytid beetle in *Olea europae* subsp. *africana*, J.P. van der Walt, South Africa.

Type strain: CBS 7118 (IFO 10204).

Comments: *T. wingfieldii* is morphologically unique in reproducing either by enteroblastic budding or by the formation of conidia on the apex of stalks, and in containing xylose in the cells. The presence or absence of xylose in

cells has been utilized as an important criterion for classifying basidiomycetous yeasts at the generic level. By these characteristics *Tsuchiyaea* is distinguished from *Sterigmatomyces*. *T. wingfeldii* conidia are separated at the midpoint of the short stalks and the species have coenzyme Q-9. In contrast, *Fellomyces* and *Kurtzmanomyces* have

conidia that are disjointed at the distal end of the stalks and have coenzyme Q-10. The latter two genera therefore are clearly discriminated from *Tsuchiyaea*. The characteristic of the type culture is that its propagation by stalked conidia appears to be limited to growth on solid media, a characteristic that is not observed in malt extract.

Part VII

***Prototheca*, a yeastlike alga**

This Page Intentionally Left Blank

113. *Prototheca* Krüger

R.S. Pore

Diagnosis of the genus

Colonies are yeastlike, but budding is absent. Reproduction is by the formation of a variable number of sporangiospores (2–16 or more) within a sporangium. The sporangiospores are released through a split in the sporangial wall and usually disperse (Fig. 463). The reproductive morphology is similar to that of *Chlorella* and is the basis for a presumptive phylogenetic relationship to the algae, however, *Prototheca* lacks plastids or vestigial plastids (referred to in the literature, but not confirmed by this author). The sporangium is nearly spherical, or an enlarged version of the sporangiospore. The sporangiospores are usually spherical or ellipsoidal, but reniform and falcate strains occur. A dauer cell stage resists staining in Rose Bengal stain¹. No sexual stage occurs (Pore 1985).

Fig. 463. Schematic life cycle of *Prototheca*. A sporangiospore (A) enlarges to form a dauer cell (B), undergoes further development to a sporangium (C), which releases more sporangiospores (D).

Ammonium chloride is assimilated as a sole nitrogen source, but nitrate is not (Pore 1972). Glucose is assimilated and the assimilation of a few other carbon substrates has taxonomic significance (Pore 1985). Lactic acid is produced from glucose by *P. zopfii* and some species produce acid, but not gas from glucose. Glycogen is the storage carbohydrate; starch is absent. Neither chlorophylls nor carotenoids are produced. Thiamine and oxygen are required for growth. The cell wall resists acid and alkaline hydrolysis (Conte and Pore 1973).

Type species

Prototheca zopfii Krüger

Species accepted

1. *Prototheca moriformis* Krüger (1894)
2. *Prototheca stagnora* (Cooke) Pore (1985)
3. *Prototheca ulmea* Pore (1986)
4. *Prototheca wickerhamii* Tubaki & Soneda (1959)
5. *Prototheca zopfii* Krüger (1894)
 - a. *Prototheca zopfii* Krüger var. *zopfii* (1985)

<i>P. wickerhamii</i>	+	+	-	+	+	-	+	-
<i>P. zopfii</i>	+	-	+	-	-	+	v	-

^a Dauer cell less than 8.5 µm in diameter, sporangiospores less than 4.3 µm.

^b Dauer cell greater than 8.5 µm in diameter, sporangiospores greater than 5.7 µm.

^c All cell stages obviously nearly spherical.

^d Cell surrounded by clear zone when negatively stained upon primary isolation. All tests were done in *Prototheca* isolation medium at 25°C with 1% wt./vol. carbon sources (Pore 1985).

Systematic discussion of the species

113.1. *Prototheca moriformis* Krüger (1894a)

Synonym:

Prototheca moriformis Krüger var. *betulinus* Chodat (1913)

Growth on *Prototheca* isolation medium (PIM): The *Prototheca* isolation medium is described in Table 98. After 5–10 days, cells are encapsulated, resulting in a slimy, glistening, mucoid to viscoelastic, translucent to white colony. Newly released sporangiospores are spherical, or more frequently ellipsoidal, (3–5×4–6, ave. 4×5 µm). Dauer spores are usually ellipsoidal (7–9×9–11, ave. 8×10 µm). The sporangium is spheroidal or ellipsoidal, (8–15×10–20, ave. 12×14 µm). Sporangiospores rapidly developed a 1–5 µm (ave. 3 µm) thick capsule that is retained as the cell develops.

Growth on glucose-peptone based media, eg., Sabouraud's medium: The colony type remains the same, but a tan pigment accumulates with age. Cell morphology and size varies slightly depending on the substrate. Temperature optima vary between 22–30°C, but some strains grow at 37°C. *P. moriformis* grows over a wide pH range.

Fermentation: absent.

Table 98
Prototheca Isolation Medium (PIM)

Distilled water	1 L
Potassium hydrogen phthalate	10 g
Sodium hydroxide	0.9 g
Magnesium sulfate	0.1 g
Potassium phosphate, monobasic	0.2 g
Ammonium chloride	0.3 g
Thiamine	0.001 g
Purified agar	15 g
Carbon source ^a	10 g
pH	5.1±0.1
Autoclave	15 min.

^a For assimilation test media, substitute carbon source 1% wt./vol. For isolation medium, add glucose and 5-fluorocytosine (0.25 g/L) (Pore 1973).

Assimilation (48 hours):

Glucose	+	<i>N</i> -Acetyl-D-glucosamine	n

L-Rhamnose	-	Nitrate	-
D-Glucosamine	n	Vitamin-free	-

Additional assimilation tests and other growth characteristics:

1-Propanol	+/w	Acetate (pH 5.1)	+/w
D(-)Fructose	+	Clotrimazole	v
D(+)Mannose	-		

Origin of the strains studied: Thirty-five strains were examined for morphological and major nutritional traits. Strains excluded from the species *P. moriformis* were NRRL Y-6865, Y-6867, Y-6869, and Y-6871; CDC B-1444 and B-1692; ATCC 16522, 16523 and 16524; UTEX 1434. *P. moriformis* has been isolated from plant, animal, soil, aqueous and sewage habitats (Pore 1985).

Type strain: ATCC 50081, cheese factory waste water, via R.S. Pore (1985); neotype (Pore 1985).

Comments: Krüger's (1894a,b) original description of slimy *Prototheca* sp. was confirmed by Pringsheim (1963) and Pore (1985). It was acknowledged by Pore (1985) that the main difference between *P. moriformis* and *P. zopfii* is the presence of the distinctive capsule that also causes the slimy or mucoid colony characteristic of *P. moriformis*. It was also acknowledged that a few strains of *P. moriformis* lost their capsule forming capacity in long-term culture, making them indistinguishable from *P. zopfii* by current

methods. This is a reversible phenomenon, the cause of which is unknown. The major justification for maintaining *P. moriformis* as a separate species is that typical isolates, which are stable for the capsule trait, are readily obtained from nature. The capsular polymer is a polyglycan composed primarily of galactose and rhamnose. *P. moriformis* was shown to have a DNA base composition similar to *P. zopfii*, but the DNA homology was only about 25% (Huss et al. 1988).

113.2. *Prototheca stagnora* (Cooke) Pore (1985)

Synonym:

Prototheca viscosa Pringsheim 1963 nom. nud.

Growth on PIM: After 5–10 days, cells are encapsulated, resulting in a slimy, glistening, translucent to whitish colony. Newly released sporangiospores are spherical, (2.5–4.5, ave. 3.5 µm). Dauer cells are spherical, (5.5–8, ave. 6.5 µm), as are sporangia (7–14, ave. 9.5 µm). Rarely, sporangiospores are spheroidal or ellipsoidal. All stages are encapsulated, capsules are 1–5 (ave. 3 µm) in thickness. In a few strains, the capsule characteristic was lost upon serial subculture.

In addition to PIM, *P. stagnora* grows on other media, including Sabouraud's medium. No significant differences (an exception was the development of a variable tan colony pigment in old cultures) in the colony type or cell morphology on other media were noted. Neither temperature optima nor pH is critical for growth, but 25±5°C and pH 5–8 are usually suitable.

Fermentation: absent.

Assimilation (72 hours):

Glucose	+	<i>N</i> -Acetyl-D-glucosamine	n
Galactose	+	Methanol	n
L-Sorbose	n	Ethanol	n
Sucrose	–	Glycerol	v
Maltose	w	Erythritol	n
Cellulose	n	Ribitol	n
Trehalose	–	Galactitol	n
Lactose	v	D-Mannitol	–
Melibiose	–	D-Glucitol	n
Raffinose	–	α-Methyl-D-glucoside	n
Melezitose	–	Salicin	n
Inulin	n	D-Gluconate	n
Soluble starch	–	DL-Lactate	n
D-Xylose	–	Succinate	+
L-Arabinose	–	Citrate	n
D-Arabinose	n	Inositol	–
D-Ribose	n	Hexadecane	–
L-Rhamnose	–	Nitrate	–
D-Glucosamine	n	Vitamin-free	–

Additional assimilation tests and other growth characteristics:

1-Propanol	+/w	Acetate (pH 5.1)	w/–
D(–)Fructose	+	Clotrimazole	v
D(+)Mannose	v		

Origin of the strains studied: Twenty-five strains were examined for morphological and major nutritional traits; of these 19 were directly isolated from nature. Strains from culture collections included NRRL Y-6872, ATCC 16528

and CDC B-1277. A strain excluded from the species was UTEX 1442 (ATCC 16527).

Type strain: ATCC 16528, from sludge, via W.B. Cooke.

Comments: *P. stagnora* was emended by Pore (1985) to include only the smaller of the two sizes originally described by Cooke (1968). Also, the capsule characteristic was added to the emended description, but the originally reported assimilation of sucrose was not substantiated in the emended description. Subsequently, strains of *P. stagnora* which were unable to assimilate fructose were transferred to *P. ulmea* (Pore 1986). *P. stagnora*, in order of frequency, was isolated from sewage and plant material.

113.3. *Prototheca ulmea* Pore (1986)

Growth on PIM: After 5–10 days, cells are encapsulated resulting in a nonpigmented mucoid colony. Sporangiospores are ellipsoidal to subglobose, (2.8–3.0×3.0–3.5 µm, ave. 2.9×3.3 µm). Sporangia are spheroidal, (7.2–10 µm, ave. 8.6 µm). Dauer cells are ellipsoidal, (4.5–5.8×5.5–8.0 µm, ave. 5.3×6.7 µm). Capsule thickness is 2–5 µm, ave. (3.5 µm).

P. ulmea grows on additional laboratory media such as Sabouraud's medium and the colony and morphology is similar to that produced on PIM. Temperature optima (approx. 25°C) and pH are not critical for growth, but *P. ulmea* is the slowest growing and least robust *Prototheca* species.

Fermentation: absent.

Assimilation (72 hours):

Glucose	+	<i>N</i> -Acetyl-D-glucosamine	n
Galactose	–	Methanol	n
L-Sorbose	n	Ethanol	n
Sucrose	–	Glycerol	n
Maltose	–	Erythritol	n

D-Ribose	n	Hexadecane	–
L-Rhamnose	–	Nitrate	–
D-Glucosamine	n	Vitamin-free	–

Additional assimilation tests and other growth characteristics:

1-Propanol	–	Acetate (pH 5.1)	–
D(–)Fructose	–	Clotrimazole	v
D(+)Mannose	–		

Origin of the strains studied: Eighteen strains isolated from nature were examined for morphological and major nutritional traits.

Type strain: ATCC 50112, from slime flux of elm, via R.S. Pore.

Comments: Some strains of *P. ulmea* were originally included with *P. stagnora* Pore (1985), but based upon several distinctive features, a separate species was later described (Pore 1986). *P. ulmea* was ellipsoidal and did not assimilate fructose nor any known carbohydrate other than glucose. Many strains were isolated from the slime flux of various elm species, including the American elm (*Ulmus americana*).

113.4. *Prototheca wickerhamii* Tubaki & Soneda (1959)

Growth on PIM: A white or off-white yeastlike colony forms after 5 days. All cell stages are spherical. Sporangiospores are 2.5–4.5 µm (ave. 3.2 µm), sporangia are 7–13 µm (ave. 9.4 µm), and dauer cells are 5.5–8.5 µm (ave. 6.5 µm) in diameter.

Temperature optima are usually above 25°C and some strains grow at 37°C. The pH range is wide. A wide range of media support growth. On Sabouraud's medium, for example, the colony characteristically develops a tan pigmentation with age.

Fermentation: absent.

Assimilation (48 hours):

Glucose	+	<i>N</i> -Acetyl-D-glucosamine	–
Galactose	+	Methanol	–
L-Sorbose	–	Ethanol	+
Sucrose	–	Glycerol	+

Additional assimilation tests and other growth characteristics:

1-Propanol	–	Acetate (pH 5.1)	–
D(–)Fructose	+	Clotrimazole	w/–
D(+)Mannose	v		

Origin of the strains studied: Eighty-five strains were examined for morphological and major nutritional traits. Representatives from culture collections included UTEX 1440; NRRL Y-2348, Y-6865, Y-6867, Y-6869, Y-6871, Y-7029 and Y-7045; CDC 45-1029-70, 43-1068-70, B-1280, B-1281, B-1282, B-1418, B-1444, B-1694, and B-2224; ATCC 16522, 16523, 16529 and 16531.

Type strain: ATCC 16529, from household plumbing, via W.B. Cooke.

Comments: *P. wickerhamii* is the only species for which there is a corresponding species of *Chlorella* with shared properties. *Chlorella protothecoides* Krüger (1894a,b) and

P. wickerhamii both require thiamine and use ammonium (but not nitrate) nitrogen for growth, while most species of *Chlorella* are otherwise (Pore 1972). In addition, both species assimilate trehalose (Kessler 1982), exhibit acetate (pH 5.1) inhibition, and grow well on PIM, a selective medium. Like *Prototheca* spp., but unlike many other *Chlorella* spp., *C. protothecoides* stores glycogen and has a similar cell wall (Conte and Pore 1973).

The DNA base composition of *P. wickerhamii* was closer to that of *C. protothecoides* than were those of other *Prototheca* spp. tested, but DNA binding homologies showed great heterogeneity between the two, as well as between the *Prototheca* spp. themselves (Huss et al. 1988). Confirmation of the relationship between *P. wickerhamii* and *C. protothecoides* comes from 16S-like rRNA gene DNA sequence similarities that place these two species apart from other *Chlorella* spp. tested (Huss and Sogin 1990). Further sequence and structural analysis of the conserved SSU rRNA mitochondrial gene inferred a close phylogenetic relationship between *P. wickerhamii* and plants (Wolff and Kück 1990).

P. wickerhamii was found in high numbers in all domestic and municipal sewage where it is numerically the most common *Prototheca* sp. (Pore et al. 1986). It has been isolated from many aquatic sources, food, plants, and animals. It may be infrequently isolated from human feces, but a causative effect has not been determined. It was weakly pathogenic for mice and was the principal cause of protothecosis in man (Pore et al. 1983, Pore 1997).

113.5. *Prototheca zopfii* Krüger (1894a)

This species has three varieties:

Prototheca zopfii Krüger var. *zopfii* (1885)

Synonyms:

- Prototheca zopfii* Krüger (1894a)
- Prototheca chlorelloides* Beijerinck (1904)
- Prototheca ciferrii* Negroni & Blaisten (1941)
- Prototheca salmonis* Gentles & Bond (1977)
- Prototheca segbwema* Davis, Spencer & Wakelin (1964)
- Prototheca trispora* Ciferri, Montemartini & Ciferri (1957)
- Prototheca ubrizsyi* Zsolt & Novák (1968)

Prototheca zopfii var. *hydrocarbonea* (Kocková-Kratochvílová & Havelkova) Pore (1985)

Synonym:

- Prototheca hydrocarbonea* Kocková-Kratochvílová & Havelkova (1974)

Prototheca zopfii var. *portoricensis* (Ashford, Ciferri & Dalmau) Pore (1985)

Synonym:

- Prototheca portoricensis* Ashford, Ciferri & Dalmau (1930)

Growth on PIM: After 5 days, colonies are white or off-white, creamy to distinctly roughened or wrinkled. Cells are commonly spheroidal to ellipsoidal, but a few strains

are reniform. Cells are waxy and hydrophobic. Newly released sporangiospores are spheroidal, (4.5–7.5 μm , ave. 6.5 μm), or ellipsoidal (3–7 \times 5–8 μm , ave. 5.5 \times 6.5 μm). Dauer cells are spheroidal, (8.5–14 μm , ave. 11 μm), or ellipsoidal (6–11 \times 8.5–13 μm , ave. 9.5 \times 11.5 μm), and sporangia are spheroidal, (14–25 μm , ave. 17.3 μm), or ellipsoidal (11–20 \times 14–23 μm , ave. 14.5 \times 16.5 μm) Fig. 464).

Cell morphology and colony type vary depending on substrate and environmental conditions. Temperature and pH variation are tolerated. Some strains grow at 37°C. *P. zopfii* grows more vigorously than other species in culture.

Fermentation: absent.

*Assimilation (w/+) on suitable basal medium in published reports, but not confirmed.

Origin of the strains belonging to the variety *zopfii*: ATCC 16524, 16532, 16533; UTEX 289, 328, 1434; NRRL Y-6868, Y-7056, Y-7059, YB-2462, YB-4121; CDC B-1268, B-1271, B-1272, B-1285, B-1692, all of unknown origin. UTEX 1442 (sewage), NRRL YB-990 and YB-4825 (plants), ATCC 16527 (sewage); CDC B1270 (animal).

Type strain: ATCC 16533.

Origin of the strains belonging to the variety *hydrocarbonea*: ATCC 30253 (marine sediment), NRRL Y-7676 (origin unknown).

Type strain: ATCC 30253.

Origin of the strains belonging to the variety *portoricensis*: NRRL YB-4826 (human intestine), UTEX 178 (unknown).

Type strain: NRRL YB-4826.

Comments: Negroni and Blaisten (1941), and later Cooke (1968) designated *P. zopfii* as the lectotype for

Fig. 464. *P. zopfii*. Phase contrast microscopy: (A) s, sporangiospore; d, dauer cell; m, mature sporangium. (B)–(C) Sporangium and sporangiospores by scanning electron microscopy.

Prototheca. Krüger (1894a,b) described *P. zopfii* as spheroidal, but Pore (1985) concluded that 75% of the strains were ellipsoidal, 25% were spheroidal, and a few strains were reniform. Reniform strains have been referred to as *P. zopfii* var. *portoricensis* Pore (1985), but there are no nutritional traits to otherwise distinguish this taxon. Hexadecane-assimilating strains (Walker and Pore 1978) have been referred to as *P. zopfii* var. *hydrocarbonea* Pore (1985), but there are no other nutritional or morphological traits to otherwise distinguish this taxon.

Blaschke-Hellmessen et al. (1985) reported that three unnamed varieties of *P. zopfii* differed from one another morphologically and nutritionally. Two varieties were reported to assimilate galactose but, this could not be confirmed when PIM was used as the basal medium (Pore 1985). Hence, assimilation of galactose varied depending on the basal medium used. Additional synonyms used in the literature, but for which no authorities were found are *P. creiana*, *P. krugeri*, *P. pastoriensis*, *P. portoricensis* var. *ciferrii*, *P. portoricensis* var. *trisporea*, and *P. tropicalis*.

In long term culture some strains spontaneously, but reversibly, develop an extracellular polysaccharide capsule, making them morphologically and physiologically indistinguishable from *P. moriformis* (Pore 1985). *P. zopfii* is common in sewage and has been isolated from many plant and animal sources. It caused mastitis in dairy cattle (Pore et al. 1987, Pore 1997).

Chapter 114

Key to species

R.W. Payne, C.P. Kurtzman and J.W. Fell

1. Introduction

Species given in this key are those that readily grow in the standard media used for fermentation and assimilation tests. Consequently, *Coccidiascus*, *Endomyces*, Endomycete-like species and *Malassezia* are excluded here, but are given in the keys to genera. Some species occur more than once in the key, depending on variability of fermentation and growth reactions.

Data for *Lalaria* species are limited and members of this genus are omitted from the key. However, *Lalaria* is given in the Key to the genera of ascomycetous yeasts. *Fellomyces horovitziae* is characterized in the treatment of the genus *Fellomyces*, but the data were received too late for inclusion in this key.

When sexual states are known for common anamorphic species, the taxon is given in the key under the teleomorphic name. For example, *Candida lipolytica* is given under *Yarrowia lipolytica* and *Phaffia rhodozyma* is given as *Xanthophyllomyces dendrorhous*. Known anamorph-teleomorph connections can be made by consulting the indexes.

Species separations in this key are often made from the reaction on a single test. Consequently, species descriptions need to be consulted to verify the identification.

#	Test	Positive	Negative
1	Diazonium Blue B reaction	→ 2	→ 318
2	Glucose fermentation	→ 3	→ 18
3	Erythritol growth	→ 4	→ 12

Introductory remarks

Taxa are given in alphabetical order regardless of their phylogenetic relationships. The species listed are those that readily grow in standard media used for fermentation and assimilation tests. Consequently, *Coccidiascus*, *Endomyces*, Endomycete-like species and *Malassezia* are excluded. Data for *Lalaria* species are limited and members of this genus are omitted from the summary. *Fellomyces horovitziae* is characterized in the treatment of the genus *Fellomyces*, but the data were received too late for inclusion here. Assimilation reactions for *Aureobasidium pullulans* are given here but not elsewhere in the book.

When sexual states are known for common anamorphic species, the taxon is listed in the summary under the teleomorphic name. For example, *Candida lipolytica* is given under *Yarrowia lipolytica* and *Phaffia rhodozyma* is given as *Xanthophyllomyces dendrorhous*. Known anamorph–teleomorph connections can be made by consulting the indexes.

Species	Fermentation					Assimilation reactions and other characteristics																													
	Glucose	Galactose	Sucrose	Maltose	Trehalose	Glucose	Galactose	L-Sorbose	Sucrose	Maltose	Cellobiose	Trehalose	Lactose	Melibiose	Raffinose	Melezitose	Inulin	Soluble starch	D-Xylose	L-Arabinose	D-Arabinose	D-Ribose	L-Rhamnose	D-Glucosamine	N-Acetyl-D-glucosamine	Methanol	Ethanol	Glycerol	Erythritol	Ribitol	Galactitol	D-Mannitol	D-Glucitol

Glossary of terms used in this book

- abstricted:** formation of spores by the cutting off of successive portions of the sporophore through growth of the septa
- acerose:** needle-shaped
- acicular:** needle-shaped, see acerose
- acropetal:** produced successively in the direction of the apex; the apical part is youngest
- aerobic:** free oxygen is required for growth; an atmosphere with free oxygen
- agglutinate:** clump or bind together
- allantoid:** curved with rounded ends, sausage-shaped
- allele:** any of the alternative expressions of a gene
- allotype:** paratype of the opposite sex to the holotype
- amphigenous hymenium:** spore layer of fruit body formed on two sides
- amphidiploidy (allopolyploidy):** production of a fertile species by the fusion of the genomes of two separate but usually related species with different chromosome numbers; the new species is reproductively isolated from the parent species
- ampulliform:** flask-like form; shaped like a Florence flask
- anamorph (anamorphic state):** asexual part of life cycle, mitotic state
- anastomosis:** fusion between hyphae
- annellation:** formation of ring-like protrusions near the apex of a cell resulting from successive formation of conidia at the same site
- annellidic:** having annellations
- apex:** end of a cell farthest from base or point of attachment
- apical:** referring to apex
- apiculate:** cell with a short projection (**apiculum**) at one or both ends of a cell
- arthroconidium (arthrospore):** an asexual spore resulting from the division of a hypha or a single cell by fission, for example, *Trichosporon*
- ascophore:** ascus-bearing hypha
- ascus:** the sac-like cell in which ascospores are produced
- autogamy:** fusion of nuclei within a cell in the absence of cell fusion
- axenic culture:** a pure culture of a single organism
- ballistoconidium:** an asexual ballistospore
- ballistospore:** spore that is forcibly projected from a basidium
- base composition of DNA:** molar ratio of guanine + cytosine (G+C) or adenine + thymine (A+T) expressed as the percent that the particular base pair comprises of a DNA molecule
- basidiocarp:** the teleomorphic reproductive structure of a basidiomycete
- basidiophore:** basidium-bearing hypha
- basidiospore:** a spore produced by a basidium
- basidium:** organ of the teleomorphic (sexual) state of a basidiomycete that produces basidiospores
- basipetal:** produced successively in the direction of the base; the apical part is oldest
- biallelic incompatibility:** two alleles per mating locus, for example, A_1 and A_2 or a and α , ascomycetes and basidiomycetes
- bifactorial mating system:** see tetrapolar incompatibility system
- bilaterally symmetrical:** with one plane of symmetry
- bipolar incompatibility (unifactorial):** a system with a single incompatibility locus; bipolar, because of the two incompatibility groups found among the progeny of a cross; may be biallelic or multiallelic
- bisexual:** two opposite mating types in the genome of a single cell, a heterothallic diploid
- blastese:** non-septate cells that resemble true mycelium, found in the genera *Brettanomyces* and *Dekkera*
- blastoconidium:** a vegetative spore formed by enlargement of the bud initial that precedes septal formation
- blastospore:** see blastoconidium
- botuliform:** cylindrical with rounded ends
- bud:** formation of a new cell from an outgrowth on the parent cell on a broad or narrow base
- budding:**
monopolar: forming buds at only one pole of the cell, usually on a broad base
bipolar: forming buds at both poles of the cell, usually on a broad base
polar: forming buds at one or both poles of the cell, usually on a narrow base or on a denticle
multipolar (multilateral): forming buds, usually on a narrow base, over nearly the entire surface of the cell
- bud-fission:** bud formation on a broad base with cross-wall development at the constriction between bud and parent cell; typical yeasts with bipolar budding are *Nadsonia*, *Saccharomyces*, *Hanseniaspora* (*Kloeckera*) and *Wickerhamia*
- bullate:** spores with a rounded projection
- capitate:** with a spherical tip
- capsule:** a hyaline sheath of polysaccharide surrounding the yeast cell
- catenulate:** in a chain
- cerebriform:** brain-like appearance

- chlamydo-spore:** a thick-walled, intercalary or terminal asexual spore
- clamp connection:** a hyphal outgrowth formed during cell division of dikaryotic hyphae in basidiomycetes that makes a connection between the two cells by anastomosis. The function is to separate dividing nuclei during cell division; one of the daughter nuclei passes through the clamp.
- clavate:** club-shaped, broadest at the apex
- clone:** the asexual offspring from a single cell
- closure line:** the site in the center of the septum where, during growth, the septum has closed; there is a double layer of plasmalemma visible in a longitudinal section through the center of the hypha
- coenzyme Q number:** the number of isoprene units in the side chain of coenzyme Q (ubiquinone)
- collarlette:** cup-shaped structure found at the apex of certain conidiogenous cells such as on the conidiophore of *Phialophora* or after successive budding at the same site on the cells of certain yeasts
- compatible mating types:** see complementary mating types
- complementary mating types:** strains (mating types) capable of mating to initiate a fertile dikaryotic or diploid state
- congeneric:** belonging to the same genus
- conidiophore:** a specialized hypha on which conidia are produced
- conidium (conidiospore):** an anamorphic spore
- conjugated ascus:** ascus developed from the fusion of two cells
- conjugation:** fusion of two cells during the mating process
- conspecific:** belonging to the same species
- coralloid:** made up of erect, branched or unbranched structures, coral-like
- coremium:** a fascicle of conidiophores; synnema
- cornute:** horned, horn-shaped
- crenate:** see lunate
- crenate-shaped:** see lunate
- crispulate:** with a wavy margin
- cross:** to bring together genetic material from different individuals
- cross wall:** see septum
- cupulate:** cup-shaped
- cystidium:** a sterile cell situated among the basidia and usually projecting beyond them in the hymenium in basidiomycetes
- dacryoid:** teardrop, tear-shaped; one end rounded and the other more or less pointed
- dactyloid:** finger-like
- dangeardien:** a structure (asci or basidia) in which karyogamy and meiosis take place
- degree Balling:** the gravity of wort that indicates sugar content by weight. The measurement is made with a saccharometer graduated with a scale that was constructed in 1843 by Carl Joseph Napoleon Balling. Degree Balling is similar to degree Brix, except that Brix was determined at 15°C whereas Balling was determined at 17.5°C. A saccharometer is a hydrometer consisting of a long graduated stem attached to an elongated bulb, which is weighted at the bottom. The hydrometer is placed in the wort and the gravity can be read on the graduated stem; the lower the content of sugar the deeper the meter sinks into the liquid.
- dehiscent, dehiscing:** opening when mature by pores or by becoming broken in parts
- deliquescent ascus:** see evanescent ascus
- dentate:** with tooth-like projections
- denticle:** a small tooth-like projection
- diclavate:** club-shaped at both ends
- dikaryon:** cells containing two genetically distinct nuclei
- dikaryotic:** see dikaryon
- dimorphic:** having two forms, e.g., budding cells and hyphae
- diobovate:** ovate at both ends with a central narrowing
- diplo-haplontic life cycle:** the cells reproducing vegetatively may be haploid or diploid, e.g., *Saccharomyces cerevisiae*
- diploid:** nucleus with a double set (2n) of chromosomes
- diplontic life cycle:** the vegetative cells are diploid, e.g., *Saccharomyces ludwigii*
- diplophase:** the part of the life cycle in which the cells are diploid
- distal:** terminal, away from the point of origin
- DNA:** deoxyribonucleic acid
- DNA reassociation:** the pairing or reannealing of complementary single strands of DNA to form a double-stranded molecule (duplex)
- DNA sequence homology:** the extent of homology or relatedness between the sequences of nucleotides on complementary DNA molecules
- DNA sequence relatedness:** see DNA sequence homology
- dolipore/parenthosome septum:** a septal pore complex in the basidiomycetes in which the pore margin is enlarged into a barrel-like morphology (dolipore) and the paraseptal cytoplasm on either side is delimited by endoplasmic-reticulum-derived membrane domes (parenthesomes)
- dormant:** in state of rest
- echinulate:** with more or less pointed projections
- effuse:** growing flat
- ellipsoidal:** elliptical in optical section
- ellipsoidopedunculate:** stalk-like and ellipsoidal
- endospore:** an anamorphic spore formed within a vegetative cell or with a basidium
- enteroblastic:** involvement of the inner part of the cell wall of the parent cell in the formation of the bud
- epibasidium:** a structure located between a probasidium and basidiospores

epithet: the second (specific) part of a Latin binomial
erose: having delicate tooth-like projections from the edge
evanescent ascus: an ascus that breaks down when mature and liberates the ascospores
exosporium: the outer layer of the spore wall

falcate: sickle-shaped
farinose: with a powdery appearance
fascicle: bundle
fasciculate: growth in fascicles
filament (filamentous): thread-like hyphal or pseudohyphal cell
fimbriate: with a torn or minutely fringed margin
foliaceous: with a leaf-like appearance
fusiform: spindle-like
fusoid: spindle-like

G + C content: mol percent guanine + cytosine (G+C) of DNA; see also base composition of DNA

galeate: hat-shaped
gametangiogamy: fusion of gametangia
gametangium: gamete producing cell; alternatively, when gametes are not formed, copulation or conjugation of gametangia occurs
gelatinous: jelly-like
genotype: the genetic constitution of an individual taxon or cell
glabrous: smooth, not hairy or roughened

haploid: having a single set (n) of chromosomes
haplontic life cycle: the vegetative cells are haploid
haustorium: a special hyphal branch, some portion of which penetrates a host cell and absorbs nutrients
heterogamous conjugation: conjugation of two cells of different form or size
heterothallic: sexual reproduction requires the interaction of different mating types
hirsute: having long hairs
holoblastic: involvement of the entire cell wall of the parent cell in the formation of the bud
holometabasidium: non-septate metabasidium
holomorph: all stages of a fungus comprising the teleomorph and anamorph
holotype: material or strain indicated as nomenclatural type by the original author
homokaryon: a strain in which all nuclei are of the same genotype
homokaryotic fruiting: formation of a basidiomycete "teleomorph" in the absence of a dikaryophase; the mycelial cells are uninucleate and lack clamp connections
homonym: the same name given to two or more different taxa of the same rank based on different nomenclatural types
homothallic: sexual reproduction without the preceding interaction of complementary mating types

hyaline: transparent or colorless
hybrid: progeny of a cross involving genetically different parents
hymenium: spore bearing layer of an ascomycete or basidiomycete fruit body
hypha: one of the filaments of a mycelium

ICBM: International Code of Botanical Nomenclature
imperfect state: see anamorph
incompatibility: inability of two sexual strains to sexually reproduce
intercalary cell: a cell between two other cells
interfertility: mating of two organisms with production of fertile offspring
intramatrical: living in the matrix or substratum
isogamous: conjugating cells of the same shape and size
isotype: a duplicate of the holotype from the same, single collection as the holotype

karyogamy: the fusion of the two sex nuclei after plasmogamy

lateral: at the side
lectotype: a specimen designated as the nomenclatural type when no holotype was indicated at the time of publication, if the holotype is missing, or if the holotype is found to belong to more than one taxon
lenticular: shape of a double convex lens
life cycle: series of stages or events between the zygote of one generation and the subsequent zygote of the next generation
lobate: lobed
lobiform: in the shape of a lobe
locus: the site of a gene on a chromosome
lunate: like a crescent moon
lyophilization: a method of preserving viable, metabolically inactive cultures by freeze drying

mating: fusion of two cells that are sexually reactive
mating types: cells of opposite types, which are able to conjugate
meiosis: reduction division associated with sexual reproduction
meiosis bud: a bud attached to the parent cell which serves as the site of meiosis after fusion of the bud and parent cell nuclei
mesophilic: optimum temperature of growth is 20-40°C
metabasidium: the part of the basidium in which meiosis occurs
micropore: narrow pore-like structure in a septum
mitosis: nuclear division with retention of the original number of chromosomes in each daughter nucleus
multiallelic incompatibility: more than two alleles per incompatibility locus; more than two alleles for control of a particular function, for example, A_1 , A_2 , A_3 and $A_1 B_1$, $A_2 B_3$, basidiomycetes

- mycelium:** a mass of hyphae of an individual fungus; see also true- and pseudomycelium
- neotype:** strain or material designated as type when the material or strain on which the original description was based no longer exists
- new combination, combinatio novo, comb. nov.:** name of a taxon, which has been transferred in rank or position such as from one genus to another; term used by authors when new combination is made
- nomen conservandum, nom. cons.:** conservation of the name of a genus or species, although technically not acceptable, which has been approved by an International Botanical Congress
- nomen invalidum, nom. inval. invalid name:** a name, which has not been validly published, i.e., in accordance with the ICBN
- nomen nudum, nom. nud.:** a name published without an adequate description or diagnosis, i.e., in accordance with the ICBN
- nuclear segregation:** the segregation of genetically different nuclei contained in a heterokaryotic multikaryon
- numerical analysis, numerical taxonomy:** taxonomic arrangement based upon quantitation of phenotypic similarities and differences
- obclavate:** club-shaped with the broadest part at the base
- oblate:** flattened at the poles
- oblong:** twice as long as wide and having somewhat truncate ends
- obovate:** inversely ovate, narrowest at the base
- obovoid:** see obovate
- obpyriform:** pear-shaped but attached at the broad end
- obtuse:** rounded or blunt
- ogival:** pointed like a Gothic arch
- orbicular:** spherical
- osmophilic:** able to grow in a medium with elevated, i.e., greater than usual, sugar- or salt concentration
- osmotic medium:** medium with elevated sugar or salt concentration
- osmotolerance:** resistance to osmotic pressure
- ovoid:** egg-like, i.e., with narrowest end near tip
- paraphysis:** sterile filaments in the hymenium of ascomycetes and basidiomycetes; in the latter they are dikaryotic and allied to basidia, cystidia or hyphae
- parasexuality:** recombination of hereditary properties based not on sexual reproduction (meiosis) but on mitotic non-disjunction
- paratype:** strain other than the holotype on which the original description of a species is based
- parenthosome:** in basidiomycetes a curved, double membrane-derived structure differentiated from the endoplasmic reticulum that occurs on either side of the septal dolipore
- pedicel:** a small stalk-like structure
- peduncle:** stalk
- perfect state:** see teleomorph
- persistent ascus:** ascus not deliquescing (dissolving) at maturity
- phenotype:** the totality of characteristics of an individual as a result of the interaction between expressed genotype and environment
- phragmometabasidium:** a metabasidium divided by septa
- pileus:** the cap or hymenium-supporting part of the complex basidiomata or ascomata, e.g., agarics or morels
- plasmodesmata:** isthmus-like strands of protoplasm connecting adjacent cells; in hyphal septa also designated as micropores
- plasmogamy:** fusion of the cytoplasm of two compatible cells
- plicate:** folded into pleats
- probasidium:** the morphological part or developmental stage of the basidium in which karyogamy occurs
- promycelium:** see metabasidium
- protosterigma:** basal, filamentous or inflated part of the sterigma
- prototrophic:** growth factor-independent
- pseudohyphae:** see pseudomycelium
- pseudomycelium:** a linear arrangement of budding cells that remain attached to each other
- psychrophilic:** optimum temperature for growth is below 20°C
- pulcherrima cells:** round cells containing a large oil drop as with *Metschnikowia (Candida) pulcherrima*
- pulcherrimin:** a red iron-containing compound produced by some strains of *Metschnikowia*, *Kluyveromyces*, and certain other yeasts
- pulvinate:** cushion-like
- pyriform:** pear-shaped
- reannealing experiments:** see DNA reassociation
- reniform:** kidney-like shape
- reticulate:** net-like
- rotational symmetry:** with all planes of symmetry through the length axis
- rugose:** wrinkled
- saccate:** like a sack or bag
- Saturn-shaped:** spherical with a ledge around the middle, i.e., like the planet Saturn
- self-fertile:** see homothallic
- septum:** a cross wall in a hypha
- sessile:** lacking a stem or stalk
- seta:** a stiff hair or bristle
- sib mating:** mating or crossing of siblings
- simple pore:** central pore with the septum tapering
- somatogamous conjugation:** fusion of two whole cells
- sphaeropedunculate (capitate):** spheroidal end on an elongated cell

- sporidium**: see basidiospore
- sporophore**: a spore-producing or supporting structure
- stalagmoid**: like a long tear or drop
- stemonitoid**: with capitate synnema
- sterigma**: an extension (process) of a cell that supports a basidiospore
- sterigmate**: originating on sterigma
- stilbelloid**: with coremia
- stipitate capitate**: see sphaeropedunculate, but stipe may be long
- sympodial proliferation**: see sympodium
- sympodium**: a conidiophore that extends in growth by a succession of apices; a spore is produced at each apex and the growth continues to the side of the apex; the result is a zigzag appearance
- syngamy**: fusion of sexual cells resulting in karyogamy and zygote formation
- synnema**: see coremium
- teleomorph, teleomorphic state**: the state of the life cycle in which asco- or basidiospores are formed after nuclear fusion; meiotic state
- teliospore**: a thick-walled spore, which is a probasidium
- tetrapolar incompatibility system (bifactorial mating system)**: a system with two incompatibility loci, *A* and *B*, which control mating competence; tetrapolar, because of the four incompatibility groups found among the progeny of a cross, usually multiallelic basidiomycetes
- tremelloid**: gelatinous, jelly-like
- tremelloid basidium**: cruciately septate phragmobasidium, i.e., having longitudinal and/or oblique septa
- true hyphae**: see true mycelium
- true mycelium**: a body of hyphal cells with apical growth and usually, cross walls
- truncate**: ending abruptly as though the end was cut off
- tubercle**: small wart-like structure; tuberculate with tubercles
- turbinate**: top-like in form
- type material**: specimen material on which the name of a taxonomic group, i.e., a species is based; may be dried herbarium material or a viable, metabolically inactive culture preserved by lyophilization or liquid nitrogen freezing
- type species**: the species which was designated as the nomenclatural type of a genus
- type strain**: the preserved, original specimen designated as the nomenclatural type
- unifactorial mating system**: see bipolar incompatibility system
- unisexual**: vegetative cells of a single mating type
- velvety**: having a velutinous appearance, i.e., densely covered with fine hairs
- ventricose**: swelling out in the middle or at one side; inflated
- verrucose**: having small rounded processes or warts
- verticil**: whorl
- vesicle**: a bladder-like sac, cell or cavity; a thin-walled body
- vesiculate**: with many vesicles
- wale-like**: ascospore ornamentation comprised of short ridges, which may be irregularly placed
- Woronin bodies**: membrane bound refractive spherical bodies occurring on either side of the pore of an ascomycete septum
- zygote**: a diploid cell that is the result of the fusion of two sexual cells or nuclei

Index to species and varietal names

Recurrent use of species and variety names, as well as new combinations from taxonomic changes, result in placement of the same name with different genera. Combinations accepted by authors of the present edition are given in bold type. Page numbers to each combination are given following the genus name.

- aaseri**
 – *Azymocandida* 476
 – ***Candida* 476**
abadieae, *Pichia* 172, 345
abstinens
 – *Brettanomyces* 175
 – *Dekkera* 175, 177
abuliensis, *Saccharomyces* 360, 362
acaciae
 – *Pichia* 282
 – *Yamadazyma* 282
accraensis
 – *Castellania* 564
 – *Monilia* 563
acellobiosus, *Saccharomyces drosophilaram* var. 234
aceris-sacchari, *Saccharomyces* 287
acetaethylicus, *Saccharomyces* 287
aceti, *Saccharomyces* 362
***acetoabutens*, *Moniliella* 785**
acheniorum
 – ***Rhodotorula* 805**
 – *Sterigmatomyces* 805
acidi-lactici
 – *Torulopsis* 526
 – *Torulopsis holmii* var. 526
acidifaciens
 – *Saccharomyces* 424
 – *Zygosaccharomyces* 424
acidificans, *Pichia membranaefaciens* var. 319
acidodevoratus
 – *Schizosaccharomyces* 393
 – *Schizosaccharomyces pombe* var. 393
acidosaccharophilii, *Saccharomyces* 362
acidothermophilum, *Candida* 223
aclotiana
 – *Rhodotorula* 821
 – *Torula* 821
actoni
 – *Endomyces* 477
 – *Monilia* 477
aculeatum
 – ***Aciculoconidium* 439**
 – *Trichosporon* 439, 440
***acuta*, *Rhodotorula* 805**
acutus, *Candida* 805
***adeninivorans*, *Arxula* 441**
adeninovorans, *Trichosporon* 441, 442
adzetii, *Pichia* 162
aegyptiaca
 – *Castellania* 564
 – *Monilia* 564
aeria
 – *Paratorulopsis* 747
 – *Torula* 747
 – *Torulopsis* 747
aerius

 – *Debaryomyces vanrijiae* var. 170
 – *Geotrichum* 862
 – *Pichia* 170
vanudenii
 – *Kluyveromyces* 234
 – *Kluyveromyces marxianus* var. 234
 – *Saccharomyces* 234
vanzylui, *Torulopsis* 532
variabile, *Trichosporon* 293
variabilis
 – *Bullera* 740
 – *Candida* 293
 – *Monilia* 293
 – *Oospora* 293
 – *Proteomyces* 872
 – *Torulopsis pulcherrima* var. 264
 – *Trigonopsis* 399, 605
 – *Zygosaccharomyces* 431
vartiovaarae
 – *Candida* 567
 – *Torulopsis* 567
vartiovaarae, *Torulopsis* 567
verticillatus, *Saccharomyces* 537
veronae
 – *Candida* 322
 – *Kluyveromyces* 240
 – *Pichia* 348
 – *Saccharomyces* 240
 – *Sporidiobolus* 697
 – *Trichosporon* 322
versatilis
 – *Brettanomyces* 567
 – *Candida* 172, 567
 – *Hasegawaea japonica* var. 391
 – *Schizosaccharomyces* 391
 – *Schizosaccharomyces japonicus* var. 391
 – *Torulopsis* 567
versicolor, *Zygosaccharomyces* 234
versiforme, *Geotrichum* 211
verticillata, *Mycotorula* 477
vesica, *Mycotorula* 536
vinacea, *Torulopsis* 492
vinaria, *Candida* 568
vineae
 – *Hanseniaspora* 219
 – *Kloeckeraspora* 219
 – *Vanderwaltia* 219
vini
 – *Brettanomyces* 175
 – *Brettanomyces bruxellensis* var. 175
 – *Candida* 569
 – *Debaryomyces* 158
 – *Endomycopsella* 383
 – *Endomycopsis* 383
