Preface

The importance of yeasts is underscored by our often daily consumption of bread as well as fermented beverages. Recent advances in biotechnology have increased reliance on yeasts for pharmaceuticals and for bulk biochemicals such as citric acid. Furthermore, clinically important yeasts are commonplace, especially with increasing numbers of immune-suppressed patients, and biologists are continuing to discover the importance of yeasts in the ecosystem. All of these areas of science and technology have a common need, the rapid and accurate identification of yeasts. The goal of this book is to provide that information.

This book, the fourth edition of *The Yeasts, A Taxonomic Study*, represents a continuation of the monographic series begun by J. Lodder and N.J.W. Kreger-van Rij (1st edn., 1952), J. Lodder (2nd edn., 1970) and N.J.W. Kreger-van Rij (3rd edn., 1984). As with each successive edition, the number of taxa treated has increased. In the third edition (1984), 60 genera and 500 species were described, whereas in the fourth edition, there are 100 genera representing over 700 species. Numbers alone do not fully reflect the increased coverage of the present treatment. Besides newly described species, the current edition includes additional genera of yeastlike taxa, some of which, such as *Ascoidea* and *Dipodascus*, are now recognized as members of the ascomycetous yeast clade, whereas others, such as *Trichosporonoides* and *Prototheca*, are not considered to be yeasts but are included because they are morphologically similar to yeasts and sometimes confused with them. Similarly, we broadened the discussion of the basidiomycetes to acquaint the reader with some of the dimorphic species whose yeast phases are often found on isolation plates. Molecular studies have shown many of these dimorphic species have close phylogenetic relationships with the commonly recognized basidiomycetous yeasts.

Not surprisingly, molecular sequence analyses have contributed prominently to the classification system used in the fourth edition. However, because sequence data are not yet available for all known species, a phylogenetically-based classification system is not fully developed. As a consequence, the placement of many species in genera and families is uncertain. Despite these limitations, the system of classification presented in the current edition is more predictive of natural relationships than was possible in earlier treatments.

The current edition features an expanded list of assimilation tests over that of earlier editions. Besides providing increased diagnostic resolution of taxa, the additional physiological data will aid biotechnologists searching for species that are capable of unique biochemical transformations.

This edition includes chapters on the importance of yeasts and on current methods used for their classification. We hope readers will find these chapters useful, and that they will provide a start for more extensive study with a fascinating group of fungi that we know as the yeasts.

Acknowledgements

R.J. Bandoni thanks T.W. Flegel for providing illustrations of basidiomata of *Tremella fuciformis* and *Holtermannia* sp. The helpful suggestions of Mary Berbee, concerning the introductory chapters on the Heterobasidiomycetes and Tremellales, are also acknowledged with thanks.

I. Banno and Y. Yamada thank Kozaburo Mikata, Research Head of the Yeast Section, Institute for Fermentation, Osaka, for his cooperation in laboratory work.

P.A. Blanz acknowledges Michael Gottschalk for his cooperation in analyzing 5S rRNAs.

J.W. Fell acknowledges research support by the U.S. National Science Foundation, Ocean Sciences Division, Biological Oceanography. Technical assistance by Rebecca Roemig and the photographic expertise by Don Heuer, RSMAS, University of Miami is greatly appreciated.

C.P. Kurtzman thanks Christie J. Robnett, Eleanor Basehoar-Powers and Millie Jo Smiley for technical assistance, Georgetta Stonewall and June Kestner for manuscript processing and the preparation of tables and indexes, and Kerry O'Donnell for helpful discussions.

M.-A. Lachance gratefully acknowledges research funding by the Natural Science and Engineering Council of Canada. Thanks are given to Ming Zhan for his assistance with the photomicrography of *Kluyveromyces* species, and J.R. Nicoli for bringing attention to the recent literature on probiotics, discussed in the yeast ecology chapter.

Sally A. Meyer thanks Eric B. O'Neill for his laboratory assistance and support in the preparation of the *Candida* manuscript, the graduate and undergraduate students whose projects on *Candida* species provided much useful information, and Robert B. Simmons for the excellent photography.

T. Nakase thanks Masako Takashima for assistance.

R.W. Payne gratefully acknowledges the grant-aided support that IACR receives from the Biotechnology & Biological Sciences Research Council of the United Kingdom.

H. Prillinger thanks the Österreichische Nationalbank for research sponsorship.

M.Th. Smith thanks G.A. Poot for assistance.

William T. Starmer acknowledges the U.S. National Science Foundation for support of research on the ecology of yeasts.

A. Vaughan-Martini and A. Martini gratefully acknowledge the technical assistance of Stefania Barcaccia and Fausto Macarelli.

The Editors are indebted to the Staff at the Centraalbureau voor Schimmelcultures, Delft and Baarn, The Netherlands, for generously supplying many of the yeast cultures examined during the preparation of this book.

Special thanks are extended to Walter Gams, Centraalbureau voor Schimmelcultures, Baarn, The Netherlands, who kindly checked names of taxa for correctness, and who generously provided taxonomic advice.

This Page Intentionally Left Blank

Use of this book

1. Introductory chapters

The first four sections of this book provide an overall introduction to the yeasts. Section I discusses the current definition of yeasts, their classification, and the rules for their nomenclature. Section II focuses on the importance of yeasts as human, animal, and plant pathogens, their role in biotechnology, and their ecological importance. Section III provides chapters on the ultrastructural, biochemical and molecular biological properties that are currently being used to recognize yeasts and to develop a framework for their classification. Methods for isolation and identification of yeasts are given in Section IV along with protocols for various biochemical analyses that are used for characterization of species.

2. Chapters on the genera and species

The arrangement of taxa in the fourth edition is somewhat different from that of previous editions. Because it is possible to determine whether isolates are ascomycetes or basidiomycetes from the diazonium blue B (DBB) test and from ultrastructure of cell walls, anamorphs can now be placed in their appropriate taxonomic class. Consequently, the taxonomic descriptions start with ascomycetous yeasts that have known sexual states, followed by the anamorphic ascomycetous genera. In turn, the teleomorphic basidiomycetes are described followed by their anamorphs. In previous editions, anamorphs from both classes were placed in the same section. The introductory chapters for both the ascomycetes and the basidiomycetes include brief diagnostic descriptions of each genus followed by a key to genera. A key to the anamorphic genera of yeastlike archi- and euascomycetes also has been provided.

3. Descriptions of species

Each species description begins with a designation of the anamorph or teleomorph, where known, followed by a listing of synonyms. The characterization proceeds to morphological and physiological descriptions. Noteworthy information for the species is given in the section entitled "Comments". Each genus description concludes with the section entitled "Comments on the genus", where the history of the genus is given along with a discussion of its classification. Many of the comments sections also provide information of interest to biotechnologists, clinicians and ecologists.

The following symbols are used for the fermentation and assimilation reactions given with species descriptions:

Symbol	Meaning
+	positive
l	latent (rapidly developing a positive reaction after a lag)
+/l	positive or latent
s	positive but slow
w	weak
ws	weak and slow
+/w	positive or weak
w/-	weak or negative
lw	latent but weak (rapidly developing a weak reaction after a lag)
-/l	negative or latent
v	variable
-	negative
n	no data

Representative species have been illustrated for each genus. The illustrations, which may be either drawings or photographs, included a scale marker bar and growth conditions.

A summary table of fermentation and assimilation reactions and certain key biochemical characteristics has been compiled. For easy access, taxa are listed alphabetically, first by genus and then by species. The following abbreviated symbols are used in this table:

+	+, s, l, +/l	×	+/w
–	–	v	v, w/–, –/l
w	w, ws, lw	n	no data or not applicable

4. Keys to taxa

Keys to genera are given in the introductory chapters to the ascomycetes and the basidiomycetes, and keys to the species assigned to a particular genus are given in the chapter discussing that genus. A key has also been constructed that includes all species of ascomycetes and basidiomycetes for which there are available data. In addition to the preceding, the following specialized keys have been developed: key to selected human- and animal-associated yeasts (see chapter 2: yeasts pathogenic for humans); key to anamorphic genera of yeastlike archi- and euascomycetes (chapter 16); key to yeasts forming ballistospores (chapter 76).

5. Yeastlike taxa

Some of the yeastlike taxa likely to be mistaken as yeasts are briefly discussed in this book. For example, species of the genus *Aureobasidium* are commonly isolated dimorphic euascomycetes that often appear white to light pink in color and yeastlike on isolation plates. Similarly, the achlorophyllic algal genus *Prototheca* is often misidentified as a yeast, and for this reason a chapter on the genus is included.

6. Indexes to taxa

The fourth edition contains two indexes to taxa. The first of these is a standard index that lists genera followed by assigned species and their synonyms. Validly accepted combinations are given in bold type. The second index alphabetically lists all species and variety names followed by all genera to which the species and varieties were ever assigned. Validly accepted genera are given in bold type.

7. Glossary

A glossary has been provided that includes morphological, genetic, and molecular biological terms.

8. References

The references for all chapters have been consolidated into a single list. By using a consolidated list, sufficient space was saved that titles could be included, whereas this would not have been possible if each chapter had a reference list.

Part I

Classification of yeasts

This Page Intentionally Left Blank

Chapter 1

Definition, Classification and Nomenclature of the Yeasts

C.P. Kurtzman and J.W. Fell

Contents

1. Definition and classification of the yeasts	3
2. Taxonomy	3

International Botanical Congress, Yokohama, Japan, in 1993, and has been published by Koeltz Scientific Books, D-61453 Königstein, Germany. The following is a brief discussion of the Botanical Code as it applies to yeasts.

1. Definition and classification of the yeasts

The English word yeast and its equivalents in many other languages are based on words meaning foam and to rise, direct references to the fermentation processes giving beer and bread. For this reason yeasts are often thought of as fermentative ascomycetous fungi similar to *Saccharomyces cerevisiae*. In fact, it is not uncommon in some areas of molecular biology to treat the words “yeast” and “*Saccharomyces*” as synonyms. The discovery that some taxa are basidiomycetes has broadened our perception of the nature of yeasts. As a consequence, we have come to view yeasts as fungi with vegetative states that predominantly reproduce by budding or fission, resulting in growth that is comprised mainly of single cells.

An imprecise distinction has been made between yeasts and those dimorphic filamentous fungi that oftentimes produce abundant yeastlike growth. Yeasts can be defined as those fungi whose vegetative growth predominantly results from budding or fission and which do not form their sexual states within or upon a fruiting body. For ascomycetous yeasts, this distinction has been substantiated by molecular comparisons, which demonstrate the budding and fission yeasts to be phylogenetically distinct from one another and from the euascomycetes (see chapter 15). One exception is the genus *Eremascus*, which has unenclosed asci, but budding cells are not formed. A similar distinction can be made for basidiomycetous yeasts, which appear phylogenetically separate from the mushrooms and other taxa that form complex fruiting bodies (see chapter 74). In summary, yeasts, whether ascomycetes or basidiomycetes, are generally characterized by budding or fission as the primary means of vegetative reproduction and have sexual states that are not enclosed in fruiting bodies.

2. Taxonomy

Rules for taxonomy of the yeasts and other fungi fall under the authority of the International Code of Botanical Nomenclature. The most recent version of this Code (Greuter et al. 1994) was adopted at the Fifteenth

2.1. Description of new taxa

2.1.1. Species: Publication of new species must include a description of essential characters as well as a diagnosis that distinguishes the taxon from previously described species. Since January 1, 1935, the description and/or diagnosis must be given in Latin. Failure to comply with this requirement results in an invalidly described species termed a “nomen invalidum” (nom. inval.). A nomen invalidum also results if publication is not in a recognized scientific journal, e.g., as in a patent or a trade magazine. If the new species is designated without a description or a diagnosis, it is invalid and termed a “nomen nudum” (nom. nud.). Names of taxa must be given in Latin or modified in such a way that they follow the rules of Latin derivation including appropriate gender designations. If a name has been incorrectly crafted, it may be treated as an “orthographic error” and corrected. An example is *Pichia membranifaciens* for which the 1888 spelling “*membranaefaciens*” has been corrected in this book. The authority name does not change due to the spelling correction. Other requirements for valid publication include deposition of type material in a publicly accessible herbarium. This material must be an original specimen of the organism, and it is to be dead and dried. The 1994 Code now allows lyophilized specimens to be valid type material (holotype) and that living cultures derived from the lyophilized material are considered *ex typo*, i.e., from the type. It seems that once the original material is exhausted, there is no longer type material available. A possible solution to this problem would be to lyophilize new material and designate it as a neotype, a convention permitted when the original type material is lost or destroyed and the species can be otherwise recognized. This discussion leads to the recognition that a majority of presently accepted yeast species are technically invalid because legitimate type material has not been preserved. A portion of presently lyophilized stocks in culture collections should be held from distribution and designated as neotypes. Consequently, the designation of “Type strain” given for each cultivatable species described in this book

can, at best, represent a neotype. The 1994 Code does recognize the need for living cultures in the practice of modern taxonomy and states in Recommendation 8B.1: "Whenever practicable a living culture should be prepared from the holotype material of the name of a newly described taxon of fungi or algae and deposited in at least two institutional culture or genetic resource collections. (Such action does not obviate the requirement for a holotype specimen under Art 8.2)." The 1994 Code further states in Recommendation 8B.2: "In cases where the nomenclatural type is a culture permanently preserved in a metabolically inactive state (see Art. 8 Ex. 1), any living isolates obtained from that should be referred to as "ex-type" (*ex typo*), "ex-holotype" (*ex holotypo*), "ex-isotype" (*ex isotypo*), etc., in order to make it clear they are derived from the type but are not themselves the nomenclatural type." From these recommendations, it is clear that the Code strongly encourages scientific cooperation and communication through active sharing of published taxonomic specimens. A listing of commonly used yeast culture collections is given in Table 1.

2.1.2. Genera, families, orders: The rules for describing new genera, families and orders are similar to those for describing new species. These taxa must be based on a validly described species and provided with a Latin

description and diagnosis. The rules of priority are briefly described below, but one exception is that orders are exempt from priority usage.

2.2. Basionyms, synonyms, priority of usage

Because of the inexact art of species characterization, as well as the occasional situation in which two independent investigators describe the same new species, the Botanical Code has provided a set of rules to reconcile resulting problems. The following example should prove helpful to the reader, but the Code needs to be consulted for full details.

- 1 *Saccharomycopsis fibuligera* (Lindner) Klöcker (1924)

Synonyms

- 2 *Endomyces fibuligera* Lindner (1907)
- 3 *Endomycopsis fibuligera* (Lindner) Dekker (Stelling-Dekker 1931)
- 4 *Pichia fibuligera* (Lindner) Boidin, Pignal, Lehodey, Vey & Abadie (1964)
- 5 *Endomyces lindneri* Saito (1913)
- 6 *Saccharomycopsis lindneri* (Saito) Klöcker (1924)
- 7 *Endomycopsis fibuligera* (Lindner) Dekker var. *lindneri* Dekker (Stelling-Dekker 1931)
- 8 *Endomyces hordei* Saito (1914)
- 9 *Saccharomycopsis hordei* (Saito) Klöcker (1924)

- 10 *Endomycopsis fibuligera* (Lindner) Dekker var. *hordei* (Saito) Dekker (Stelling-Dekker 1931)
 11 *Candida lactosa* Dwidjoseputro & Wolf (1970)

In the example, *Saccharomycopsis fibuligera* (1) is the currently accepted name. The species was originally described by Lindner in 1907 as *Endomyces fibuligera* (2) and transferred to *Saccharomycopsis* by Klöcker in 1924. Other authors transferred the species to *Endomycopsis* (3) and to *Pichia* (4), but in all cases, the original author, Lindner, is listed in parentheses. The other species listed (5–11) are misidentified strains of *S. fibuligera*. The genus assignments for some of these “species” were also changed before it was recognized that they were conspecific with *S. fibuligera*. In the context of the Code, *Endomyces fibuligera* (2) is the basionym or basal name for the species. Synonyms 2, 3 and 4 are nomenclatural or obligate synonyms of *S. fibuligera* because they are all based on the same type strain. Synonyms 5–11 are termed taxonomic or facultative synonyms because they are based on different type strains. Species 6 and 7 represent obligate synonyms of *Endomyces lindneri*, hence the listing of synonyms is ordered by priority of publication date of obligate synonyms followed by publication date of facultative synonyms and their own obligate synonyms. The Code requires, with few exceptions, that the first described name has priority of usage. Thus, *Endomyces fibuligera* Lindner (1907) is the basionym, and personal preference for another name to serve as basionym, e.g., *Endomyces lindneri* Saito (1913), is generally not allowed. Arguments for exceptions might include uncertain names

and the substitution of economically or medically important names for an older but obscure basionym.

The following citations provide examples of descriptions of new taxa and the conservation of older names, but the most recent edition of the Botanical Code should be consulted as well.

New species and genera

Fell, J.W., A.C. Statzell, I.L. Hunter and H.J. Phaff. 1969. *Leucosporidium* gen. n., the heterobasidiomycetous stage of several yeasts of the genus *Candida*. *Antonie van Leeuwenhoek* 35, 433–462.

New combinations

Kurtzman, C.P. 1995. Relationships among the genera *Ashbya*, *Eremothecium*, *Holleya* and *Nematospora* determined from rDNA sequence divergence. *J. Ind. Microbiol.* 14, 523–530.

Conservation of taxa

Fell, J.W., C.P. Kurtzman and K.J. Kwon-Chung. 1989. Proposal to conserve *Cryptococcus* (fungi). *Taxon* 38, 151–156.

Because the Botanical Code requires an accounting of names previously used, taxonomy sometimes appears fickle. A more positive view is that lists of synonyms document the clarification of species relationships over time. If we are to accept this latter view, we are also obligated not to make name changes in haste as our science progresses.

Chapter 2

Yeasts pathogenic for humans

D.G. Ahearn

Contents

1. Description	9
2. Key to selected human- and animal-associated yeasts	11

1. Description

The principal yeasts pathogenic for humans are *Candida albicans* and *Cryptococcus neoformans*. *Candida albicans* is an asexual, diploid (possibly aneuploid), pleomorphic fungus with an ascomycetous-type cell wall. This species is endogenous in the oral-, gastrointestinal-, or urogenital tracts of humans and other warm blooded animals. *Candida albicans* may be categorized as an obligate commensal because its host-free occurrence is relatively rare. Probably 40 to 60% of the adult population harbors *C. albicans*. Infections are usually of endogenous origin, but patient to patient spread can occur (Ahearn 1988, Jones 1990).

The syndromes produced by *Candida albicans* are highly diversified including vulvovaginitis, dermatitis, cystitis, fever, myositis, hepatic dysfunction, and mental confusion. These may occur singly or in combinations dependent upon the superficial, locally invasive, or deep nature of the infection. *Candida albicans* is involved in millions of superficial infections per year (mainly vulvovaginitis) and in over 90% of the systemic or deep yeast infections (estimated in the USA for the 1980's to range from 5000 to 8000 per year). Strains of *C. albicans* vary in their virulence, but as with all yeast infections, the balance between transient or commensal colonization or parasitism is dependent upon the physiological status of the host. Chronic superficial candidiasis is often associated with malnutrition, pregnancy, and diseases with impaired immune systems such as diabetes and malignant neoplasms. Oral candidiasis and localized esophagitis show a particularly high frequency among patients infected with the human immunodeficiency virus (Phelan et al. 1987). Recently, a yeast phenotypically similar to *C. albicans*, but apparently genetically distinct, *C. dubliniensis*, has been associated with AIDS (Sullivan et al. 1995). Candidiema may be indicative of deep or systemic yeast infections involving two or more organs. Such grave infections are frequently iatrogenic resulting from hyperalimentation, broad spectrum antibiotics, and immunosuppressive or antineoplastic therapies.

In contrast to *C. albicans*, *Cryptococcus neoformans*,

the anamorph of *Filobasidiella neoformans*, is not usually a commensal of humans. *Cryptococcus neoformans*, a basidiomycetous yeast, includes two varieties that are often haploid when isolated from nature. *Cryptococcus neoformans* var. *neoformans* includes serotypes A, D, and AD, and *C. neoformans* var. *gatti* includes serotypes B and C. Serotypes A and D are usually associated with soil enriched with pigeon droppings. Serotype A is most common in the U.S.A. and serotype D is reported mostly from Europe. Serotypes B and C seem confined to warm regions (Kwon-Chung and Bennett 1984); in particular serotype B has been associated with the flowering of *Eucalyptus camaldulensis* (Ellis and Pfeiffer 1990). *Cryptococcus neoformans* most often primarily infects the lungs with mild symptoms. In stressed patients, a pneumococcal-type pneumonia is not uncommon. This species has a predilection for the central nervous system and may produce, if untreated, a fatal meningoencephalitis, particularly among the immunocompromised. Reporting of cryptococcosis is not mandatory, therefore its incidence is unknown. In Georgia, U.S.A. in 1978, Bowman and Ahearn noted 76 cases of cryptococcosis. Kaufman and Blumer (1978) estimated that there were about 300 cases of cryptococcal meningitis throughout the U.S.A. for that same year. In 1987, in Georgia, U.S.A. at least 146 infections occurred (Ahearn, unpublished). Throughout the U.S.A., there has been a notable increase in reported cryptococcosis. The Centers for Disease Control, Atlanta, Georgia, U.S.A., has documented cryptococcosis as the primary presenting syndrome for the acquired immune deficiency syndrome (AIDS) in 135 cases for 1983, 279 cases for 1984, 514 cases for 1985, and 704 cases for 1986 (R.M. Selik, personal communication). This steep increase involves fatal cryptococcal meningitis in 7–17% of patients with AIDS (Gal et al. 1986, Zuger et al. 1986). By 1990, cryptococcosis had become the fourth to fifth most important secondary infection complicating AIDS in the U.S.A. (R.M. Selik, personal communication). At least 2000 cases of extrapulmonary cryptococcosis (an incidence of about 7%) occurred among AIDS patients in the U.S.A. in 1990 (Centers for Disease Control 1991). Probably 450 more cases of cryptococcosis occurred among non-AIDS patients for this same year. The actual rate of increase of cryptococcosis over the past decade cannot be determined because not only is

reporting of the disease not mandatory, but the basis for defining AIDS, which is receiving intensive monitoring, has become less stringent during the past few years. Nevertheless, the worldwide increase in the incidence of life threatening cryptococcosis is alarming. Although oral candidiasis, and to some degree esophagitis, are prognostic of HIV infection (Phelan et al. 1987), systemic candidiasis has not shown the same relative increase among AIDS patients as has cryptococcosis.

Candida tropicalis is probably the third most important yeast pathogen of humans. This species does not normally produce germ tubes or chlamydoconidia, but elongated pseudohyphal cells may develop commonly in some strains in serum at 37°C. *Candida tropicalis*, like *C. albicans*, is a diploid ascomycetous-type yeast, but it is commonly isolated from host-free habitats. Both species have overlapping antigenic properties; *C. tropicalis* and *C. albicans* serotype A bear the mannan specific epitopes 1, 4, 5, 6, whereas *C. albicans* serotype B has 1, 4, 5, 13b (Tsuchiya et al. 1965). Hamajima et al. (1988) detected a cell wall antigen (t) in *C. tropicalis* that permits its serological distinction from *C. albicans* ser. A. DNAs from the holotype strains of these species show insignificant DNA relatedness, but rare strains with phenotypic properties intermediate between those of the holotypes show intermediate (40–50%) relatedness with the separate species (Hamajima et al. 1988; Ahearn and Meyer, unpublished). Deep or systemic infections by *C. tropicalis* appear to be increasing and there is some suggestion that the prognosis for a disseminated infection with *C. tropicalis* is more grave than that for *C. albicans* (Ahearn and Lawrence 1984).

Because host factors in general are preeminent in yeast infections, it is difficult to determine specific virulence factors for many yeasts. Nevertheless, there appears to be an association of specific species with certain syndromes. In part, this may reflect a natural habitat association. For example, the usually commensal or mildly pathogenic, lipophilic *Malassezia* spp. may cause fungemia and fatal pulmonary infections of neonates receiving lipid supplementation via broviac catheters (Guého et al. 1987b, Danker et al. 1987, Larocco et al. 1988). Even the important industrial yeast, *Saccharomyces cerevisiae*, which can be expected to be ingested in normal diets, may produce fatal complications in immune deficient patients (Ossama et al. 1989; Aucott et al. 1990). Funguria or fungemia by skin mycota or commensals of mucus membranes (e.g., *Candida parapsilosis*, *Candida glabrata*, respectively) frequently follow combinations of extensive antibacterial therapy and catheterization (Solomon et al. 1984, Van Cutsem et al. 1986). In other instances, such as with the emerging pathogens *Trichosporon* spp., *Candida lusitanae* and *Candida norvegensis*, the selective effect of antifungal therapies may be an additional factor (Ahearn and McGlohn 1984; Gargeya et al. 1990, Nielsen et al. 1990, Walsh et al. 1990).

Selected yeasts implicated as pathogens of humans and

their common habitats are listed in Table 2. This list is restricted in comparison to general lists of medically important (or human- and animal-associated) yeasts because it includes only those species that fit the criteria of McGinnis et al. (1980):

- the fungus must be isolated;
- the fungus must be properly identified;
- the clinical disease must be compatible with a mycosis;
- the fungus must be seen in clinical and pathological specimens.

Species such as *Rhodotorula rubra*, *Candida famata*, *C. haemulonii*, *C. krusei*, *C. lipolytica*, and *C. rugosa*, which have been associated mainly with transient fungemia, have not been included. Undoubtedly, specific case histories in the future will indicate these species and others can produce a broader syndrome. For example, *C. haemulonii*, a genetically heterogenous form species complex, is more frequently becoming associated with lower limb ulcers and fungemia (Gargeya et al. 1991, Lehmann et al. 1991).

The increasing incidence of yeast infections has stimulated the development of commercial yeast identification systems (Land et al. 1991). Some of these systems provide for accurate identification of most strains of the common medically important yeasts, but generally the data bases for these systems include information for less than 50 species. Also, given strains may deviate from the norm in key characters. For example, *C. albicans* may not readily produce germ tubes, chlamydoconidia, or even pseudohyphae (Ahearn and Schlitzer 1984). Some strains of *Cryptococcus neoformans*, particularly a mating types, may produce melanin only under certain conditions (Nurudeen and Ahearn 1979); other rare strains may not demonstrate urease activity or assimilate inositol. Rhamnose may not be assimilated by rare strains of *C. lusitanae* (Gargeya et al. 1990). An increasing number of auxotrophs of *C. albicans* and *C. glabrata* have been observed among yeasts submitted for identification to the Centers for Disease Control, Atlanta, GA. Such isolates, probably induced by the administration of antineoplastic drugs, do not grow on the generally used synthetic media, but often grow in the complex fermentation broths.

A selective phenotypic key for the identification of the more common adventitious yeast pathogens and some of the common animal-associated yeasts is presented below. Steps in the key include multiple characters, so that the key permits a presumptive species identification, i.e., a distinction of the adventitious species from most species presented as animal-associated in this monograph. For definitive identification, however, additional diagnostic tests must be performed. The key does not distinguish the genotypic species present in the form species *C. albicans*, *C. haemulonii*, *C. parapsilosis*, *C. tropicalis* and *Malassezia furfur*.

Table 2
Syndromes and habitats of yeasts causing infections in humans

Species	Representative infections		Habitats	
	Superficial	Deep	Association with humans	Host-free
<i>Candida albicans</i>	vaginitis	disseminated	mucus membranes	soil, air, water, plants (rare)
<i>Candida glabrata</i>	vaginitis (rare)	pyelonephritis, osteomyelitis	urine, sputa, feces	soil, water (rare)
<i>Candida guilliermondii</i>	otitis (rare)	endocarditis, joint infection	sputa, feces	soil, water
<i>Candida kefyr</i> (= <i>Kluyveromyces marxianus</i>)	unknown	disseminated	sputa	dairy products
<i>Candida krusei</i>	unknown	disseminated	sputa	water, soil
<i>Candida lusitanae</i>	unknown	disseminated	sputa, feces	animal manure
<i>Candida norvegensis</i> (= <i>Pichia norvegensis</i>)	unknown	disseminated	sputa, urine	water, soil
<i>Candida parapsilosis</i>	onchomycosis (rare)	endocarditis, endophthalmitis	skin, sputa	soil, water, plants
<i>Candida tropicalis</i>	vaginitis (rare)	peritonitis, endocarditis	sputa, urine, feces	organically enriched soil and aquatic habitats
<i>Candida viswanathii</i>	unknown	meningitis	unknown	unknown
<i>Cryptococcus neoformans</i>	skin (rare) ^a	pulmonary, CNS	sputa (rare)	aged pigeon droppings, eucalyptus flowers
<i>Malassezia furfur</i> (<i>M. pachydermatis</i>)	dermatitis	pulmonary	skin	unknown
<i>Pichia angusta</i>	unknown	lymph nodes	unknown	insects, soil
<i>Saccharomyces cerevisiae</i>	unknown	disseminated	sputa	food (fruits), soil
<i>Trichosporon</i> spp.	white piedra	disseminated	skin, hair	soil, water

^a Secondary manifestation of deep infection.

2. Key to selected human- and animal-associated yeasts

1.
 - a Growth on Sabouraud's, malt agars, or yeast nitrogen base with glucose agar → 2
 - b No growth on the above media without addition of olive oil *Malassezia furfur*: p. 782
M. sympodialis: p. 783
 - c No growth on yeast nitrogen base with glucose agar without olive oil, growth present on Sabouraud's or malt agars *Malassezia pachydermatis*: p. 782
- 2(1a).
 - a Germ tubes produced *Candida albicans*: p. 476
C. dubliniensis: p. 479
 - b No germ tubes produced → 3
- 3(2b).
 - a Hyphae or pseudohyphae absent or scarce → 4
 - b Hyphae or pseudohyphae well developed → 16
- 4(3a).
 - a Inositol assimilated (rarely negative), starch synthesized → 5
 - b Inositol not assimilated, starch not synthesized → 9
- 5(4a).
 - a Nitrate assimilated → 6
 - b Nitrate not assimilated → 7
- 6(5a).
 - a Sucrose assimilated *Cryptococcus albidus*: p. 748

Chapter 3

The industrial and agricultural significance of yeasts

A.L. Demain, H.J. Phaff and C.P. Kurtzman

Our ability to harness the activities of yeasts has given us not only food and drink but deeper insights into the chemical basis of our own existence. These microscopic organisms surely rank among the most fruitful and versatile of the domesticated plants.

(Paraphrased from Anthony N. Rose, 1960)

1. Introduction

Yeasts are used in many industrial processes, such as the production of alcoholic beverages, biomass (baker's, food, and fodder yeasts), and various metabolic products. The last category includes enzymes, vitamins, capsular polysaccharides, carotenoids, polyhydric alcohols, lipids, glycolipids, citric acid, ethanol, carbon dioxide, and compounds synthesized by the introduction of recombinant DNA into yeasts. Some of these products are produced commercially while others are potentially valuable in biotechnology. Some uses of yeasts in the food, beverage and fermentation industries (Jacobson and Jolly 1989) are shown in Table 3. The present review focuses on yeast species with current or potential value in biotechnology.

The use of yeasts dates back to ancient days. Before 7000 BC, beer was produced in Sumeria. Wine was made in Assyria in 3500 BC and ancient Rome had over 250 bakeries which were making leavened bread by 100 BC. Milk has been made into Kefyr and Koumiss using *Kluyveromyces* species in Asia for many centuries.

Yeasts are producers of the four leading fermentation products in terms of tons/year worldwide. These are beer (60 million tons), wine (30 million tons), single cell protein and fodder (800 000 tons), baker's yeast (600 000 tons). A fifth product is citric acid (500 000 tons) which is made by yeasts and molds.

2. *Saccharomyces cerevisiae* and other yeasts for bioethanol production

This group is represented by numerous strains that were chosen and adapted for specific industrial fermentations. They include baker's yeast (different strains for compressed and active dry yeast), wine yeasts (including special flocculent strains for the production of champagne and film-forming strains for the production of flor sherry), sake yeast, top and bottom fermenting brewing strains (varying in the degree of flocculation occurring during fermentation), and distiller's strains used for alcohol production from cereal starch. Strain improvement by genetic manipulation and protoplast fusion has contributed superior strains for the above processes. About two million tons of yeast are produced for the distilling, brewing and baking industries each year. The production of beverage alcohol is restricted to the use of microorganisms (e.g., yeast) but that of industrial and fuel alcohol was usually carried out by chemical synthesis from petroleum. This has changed in favor of yeasts. For example, in 1977, yeast production of beverage, industrial and fuel alcohol was 20% less than by chemical synthesis. By 1984, yeasts provided 87% more ethanol than did chemical synthesis. The percentage of total alcohol made by yeasts from sugars and starch has continued to increase.

Although hydrolyzates of plant materials such as cellulose and hemicellulose contain sugars not utilizable by *S. cerevisiae*, other yeasts such as *Candida lusitanae* and *Pachysolen tannophilus* can convert cellobiose and xylose, respectively, to ethanol. Inulin from Jerusalem artichokes can be fermented to ethanol in concentrations of 5–7% v/v by *Kluyveromyces marxianus* (synonyms *K. fragilis*, *Candida kefyi*, *C. pseudotropicalis*, *C. macedoniensis*), *Torulaspora delbrueckii* (synonym *Saccharomyces fermentati*), *Debaryomyces occidentalis*

Table 3
Some present and potential uses of yeasts in the food, beverage and fermentation industries

Application	Yeast
Ale fermentation	<i>Saccharomyces cerevisiae</i>
Bread and dough leavening	<i>S. cerevisiae</i> , <i>Saccharomyces exiguus</i> , " <i>Saccharomyces rosei</i> "
D-Arabitol (sweetener)	<i>Candida diddensiae</i>
Emulsifier	<i>Candida lipolytica</i>
Ethanol fermentation	<i>S. cerevisiae</i>
Fish and poultry feeds (astaxanthin)	<i>Phaffia rhodozyma</i>
Fodder and single cell protein	<i>Candida utilis</i>
Lactose and milk fermentation	<i>Candida pseudotropicalis</i> , " <i>Kluyveromyces fragilis</i> ", <i>Kluyveromyces lactis</i>
Lager beer fermentation	" <i>Saccharomyces carlsbergensis</i> " (= <i>S. pastorianus</i>)
Mannitol (humectant)	" <i>Torulopsis mannitofaciens</i> "
Shoyu, Miso	<i>Zygosaccharomyces rouxii</i>
Wine fermentation	<i>S. cerevisiae</i>
Xylitol (sweetener)	" <i>Torulopsis candida</i> "
D-Xylose fermentation	<i>Candida shehatae</i> , <i>Pachysolen tannophilus</i> , <i>Pichia stipitis</i> , <i>Pichia segobiensis</i>

(*Schwanniomyces castellii*) and *Torulopsis colliculosa* (= *Torulaspora delbrueckii*) (Guiraud et al. 1982).

3. Enzymes

Certain yeast enzymes have been extremely useful in industry. These include invertase from *K. marxianus*, *Saccharomyces carlsbergensis* (= *S. pastorianus*) and *S. cerevisiae* for candy and jam manufacture, β -galactosidase (lactase) from *K. marxianus* or *K. lactis* for production of syrups from milk or whey, and α -galactosidase from *S. pastorianus* for crystallization of beet sugar. Inulinase from various yeasts has the capability to produce fructose in high concentration from inulin in Jerusalem artichokes and chicory.

4. *Kluyveromyces marxianus* and related species

Several species of the genus *Kluyveromyces* are good lactose fermenters and are therefore useful in alcohol production from milk whey, an abundant byproduct of the cheese industry (Moulin and Galzy 1981, O'Leary et al. 1977). DNA hybridization experiments (Fuson et al. 1987) among the species recognized by van der Walt (1970c) have shown that DNAs from the type strains of *K. fragilis*, *K. bulgaricus*, *K. cicerisporus*, and *K. wikenii* exhibit between 90–100% complementarity with *K. marxianus* DNA. All are therefore synonyms of *K. marxianus*, which has priority. However, the lactose-fermenting ability of the strains varies from absent to strong, with "*K. fragilis*" strains (or its anamorph *Candida pseudotropicalis*) giving the strongest fermentation and thus being the most useful in whey fermentations.

5. *Candida utilis* for animal feed (fodder)

C. utilis is the most widely used species for the production

of feed yeast in animal diets. Its ability to grow on cheap substrates, not suitable for most other yeasts, has made it the organism of choice for this purpose. *C. utilis* requires no added vitamins, can utilize ammonium or nitrate nitrogen, can utilize many carbon sources (including cellobiose and D-xylose), and grows at 37°C. Crude substrates, such as sulfite waste liquor (a byproduct of the paper industry) and wood hydrolyzate, are used for its propagation. *C. utilis* was formerly known as *Torulopsis utilis*, and the product is sometimes referred to as Torula yeast. The sexual state is known as *Pichia (Hansenula) jadinii* (Kurtzman et al. 1979, Manachini 1979).

6. Bioconversions

Yeasts can be used for a number of bioconversions (De Mot and Verachtert 1984). These include ketoreduction, oxidation of hydroxyl groups, ester hydrolysis and hydrogenation of double bonds in steroids; conversion of alkaloids and xenobiotics; L-lysine production from L-aminocapro lactam; L-phenylalanine from *trans*-cinnamic acid; conversions of *n*-tetradecene to 1-tetradecene, and phenol degradation.

7. Flavor compounds

A number of yeast products are useful in the flavor industry. Ethyl acetate and acetaldehyde are produced by *C. utilis*. Acetaldehyde is also formed by film yeast in the production of Spanish flor sherry (Phaff and Amerine 1979). Esters and other volatiles are made by *K. lactis* and monoterpene are formed by *Ambrosiozyma monospora*. Terpenes and lactones are produced by *K. lactis*, *Torulaspora delbrueckii* and *Sporobolomyces odoratus* (Drawert and Berger 1984). Citric acid, an acidulant which is also used by flavor companies, is made by various yeasts (see below) as well as the mold *Aspergillus niger*.

8. Yeasts capable of growing on hydrocarbons

A large number of yeast species are currently recognized for their ability to utilize hydrocarbons as sole sources of carbon and energy. Bos and de Bruyn (1973) listed 114 species and varieties of hydrocarbon-assimilating yeasts. Some of these have since been reduced to synonymy with other species. Species are found in the genera *Candida*, *Debaryomyces* (including *Schwanniomyces* and *Wingea*), *Lodderomyces*, *Clavispora*, *Metschnikowia*, *Pichia*, *Stephanoascus*, and *Yarrowia*; basidiomycetous species are in genera *Leucosporidium*, *Rhodospiridium*, *Sporidiobolus*, *Sporobolomyces*, *Rhodotorula*, and *Trichosporon*. All hydrocarbon-utilizing yeasts appear to have coenzyme Q-9 (Co Q-9) in the respiratory chain, but the reverse is not necessarily true, i.e., some yeasts with Co Q-9 do not assimilate hydrocarbons. No species of *Saccharomyces* and *Kluyveromyces*, all of which have Co Q-6, grow on hydrocarbons. Only straight-chain hydrocarbons (*n*-alkanes or *n*-alkenes) are utilized and those with 10–18 carbons are superior to those with shorter or longer chains. The rate of growth on hydrocarbons varies greatly. *Candida maltosa* (syn. *Candida cloacae*, *Candida subtropicalis*) (Meyer et al. 1975), *C. lipolytica* (sexual state = *Yarrowia lipolytica*), and *Candida tropicalis* (with many synonyms) (Barnett et al. 1990, Meyer et al. 1984, and the current volume) are among the best hydrocarbon utilizers. The metabolism of hydrocarbons by yeasts and the cell organelles involved has been reviewed briefly by Phaff (1985). The biotechnology industry has spent much money and effort in developing an economically feasible process for the production of single cell protein (SCP) from yeasts grown on *n*-alkanes (Tannenbaum and Wang 1975, Tuse 1984), but the industry experienced many disappointments. Thus SCP from hydrocarbons has virtually disappeared, partly due to economic factors, but mainly to failure to obtain approval for marketing the product from public health officials in some countries (Chen and Peppler 1978, Tuse 1984). Hydrocarbon-utilizing yeasts also play a significant role in the microbial oxidation of oil spills on land and in aquatic environments. Iizuka and coworkers (Iizuka and Goto 1965, Iizuka and Komagata 1965) described the microflora found in oil fields and oil brines in Japan, which included several hydrocarbonoclastic strains. Turner and Ahearn (1970) reported that hydrocarbon-utilizing yeasts increased more than 1000-fold after a spill of waste oils into a watershed pond. Bartha and Atlas (1977) reviewed in detail the role of microorganisms in stimulating biodegradation of aquatic oil spills, especially with help from dispersants to make the oil more accessible to microbial attack.

9. Methanol-utilizing yeasts

After the discovery in 1969 that some yeast species can grow on methanol (Ogata et al. 1969), interest in using methanol as a pure, water-miscible, and relatively

inexpensive substrate for the production of SCP (Cooney and Levine 1975, Tuse 1984) increased rapidly. The metabolism of methanol by yeasts is different from that in bacteria, and its pathway has been elucidated by Quayle and coworkers (see Phaff 1985). Sahn (1977) listed several processes for the production of certain amino acids, citric acid, α -ketoglutarate, and hypoxanthine by methylotrophic yeasts. He reported that approximately 26 yeast species are known for their ability to grow on methanol as the sole carbon source. Some of these have been reduced to synonymy with other species and some more recently discovered species have been added (Barnett et al. 1990, and the current volume).

10. *Phaffia rhodozyma*

This pigmented, fermentative species has potential in biotechnology because its carotenoids are mainly astaxanthin (Andrewes et al. 1976), a pigment that is also responsible for the orange to pink color of salmonid flesh and the reddish color of boiled crustacean shells. Feeding of pen-reared salmonids with a diet containing this yeast induces pigmentation of the white muscle (Johnson et al. 1977, 1980b). Fish absorb the pigment better from cells that are mechanically disrupted than from intact cells (Tangerås and Slinde 1994). Enzymatic digestion of the cell wall of *P. rhodozyma* with a commercial multi-component enzyme Novozym™234 from *Trichoderma harzianum* or with a β -glucanase complex from *Bacillus circulans* WL-12, greatly improves the extractibility and availability of the carotenoid in the diet of salmonids (Johnson et al. 1978, 1979, 1980b, Okagbue and Lewis 1983, Tangerås and Slinde 1994). Laying hens deposit astaxanthin in egg yolks when fed broken *P. rhodozyma* cells in their diet, but not with intact cells (Johnson et al. 1980a).

One problem with *P. rhodozyma* as a source of astaxanthin (as compared to synthetic astaxanthin) is its low pigment content in wild-type strains (~350 $\mu\text{g/g}$). Johnson and coworkers were able to raise the astaxanthin content of *P. rhodozyma* by a series of mutagenic treatments with antimycin A, resulting in yeast strains containing ~1500 μg of astaxanthin/g of yeast (An et al. 1989, 1991). Currently, at least two commercial companies have produced mutants of *P. rhodozyma* with astaxanthin contents of more than 3000 $\mu\text{g/g}$ (Sanderson and Jolly 1994, Anonymous 1994). At this level of pigment content, the yeast-derived astaxanthin appears to be economically competitive with the synthetic product, which became available in 1984. Cultural conditions for *P. rhodozyma* are also important for highest astaxanthin titers. A low substrate concentration (<1.5%) throughout the growth cycle using the fed-batch technique and highly aerobic conditions are essential. Temperature for growth must be maintained at ~22°C (maximum growth temperature = 25–26°C) at which the doubling time is 4–5 h (Tangerås and Slinde 1994). Molasses appears to be an excellent

substrate for growth. The use of cellobiose as a carbon source also gave high astaxanthin yields in a wild-type strain (Johnson and Lewis 1979), but is uneconomical compared to molasses.

11. Riboflavin-producing yeasts and yeastlike organisms

Riboflavin (vitamin B₂) is not required for the growth of any yeast. All yeasts appear to produce enough riboflavin to satisfy their growth requirements, but a few are natural overproducers of this vitamin. This tendency of uncontrolled synthesis of riboflavin was found primarily in two species: *Eremothecium (Ashbya) gossypii* and *Eremothecium ashbyi*. Overproduction in natural strains of *E. ashbyi* was discovered by Guilliermond (1936) and in *E. gossypii* by Wickerham et al. (1946a). During the stationary phase of growth, the vacuoles become yellowish but, in some vacuoles, rosettes of needle-shaped crystals of riboflavin are observed. This has led to its long-time use for the industrial production of riboflavin in animal feed formulae (Perlman 1979). Later, *E. ashbyi* was replaced in industry by the more stable *E. gossypii*. The effects of composition of growth media and strain modification by mutation on riboflavin synthesis have been reviewed in detail by Demain (1972). Recently, Kurtzman (1995) placed *A. gossypii* in the genus *Eremothecium* based on ribosomal DNA sequence comparisons. Strains of *Candida famata* have been obtained which produce 20 g/liter of riboflavin by protoplast fusion and by mutations to resistance to the following: 2-deoxyglucose, ultraviolet, iron, the purine analogs tubercidin and 4-aminopyrazolo(3,4d) pyrimidine, spent medium, and adenosine monophosphate (Foster et al. 1992, Heefner et al. 1992, 1993).

12. Citric acid-producing yeasts

The discovery in the late 1960s that very high yields of citric acid could be produced from *n*-alkanes by *Yarrowia lipolytica* caused this yeast to be competitive with *Aspergillus niger* (see Kapoor et al. 1982 for literature on this subject). Phaff (1985) reviewed the biochemistry and physiology of citric acid production by *Y. lipolytica*. Later studies have shown that citric acid can also be produced from vegetable oils or glucose under aerobic conditions by *Y. lipolytica*, *Candida zeylanoides*, and *C. citrica* (Kapoor et al. 1982, Phaff 1985).

13. Extracellular polysaccharide-producing yeasts

A large number of microbial species produce extracellular polysaccharides that can be recovered from growth media (Kang and Cottrell 1979, Slodki and Cadmus 1978). Most of the polysaccharides that have found industrial applications (e.g., xanthan gum) are produced by bacteria, but a few polymers from yeasts or yeastlike organisms have shown potential utility in foods or are used in industrial processes. The attractiveness of microbial polysaccharides

is due in part to their differential stability and physical behavior in solution.

Several species of the genus *Pichia (Hansenula)* produce copious quantities of extracellular phosphomannans (Slodki and Cadmus 1978) from glucose under aerobic conditions. A strain of *P. capsulata* is able to convert 40–55% of the substrate into phosphomannans (Slodki and Cadmus 1978). In spite of attractive viscosity and gel properties for possible use as food additives, application of these water-soluble gums has been hampered because of their sensitivity to salts, shear, and heat, as well as their instability at low pH (Kang and Cottrell 1979).

A second example is the production of the glucan pullulan by strains of the dimorphic yeastlike fungus *Aureobasidium pullulans* (syn. *Pullularia pullulans*) often referred to as “black yeasts”. Typical pullulans are linear polymers of predominantly repeating units of maltotriose connected by α -(1 → 6)-bonds, with molecular weights ranging from 1×10^4 to 4×10^5 (Kang and Cottrell 1979). The induced biosynthesis of pullulans has been reviewed by Slodki and Cadmus (1978). Fermentation yields of pullulan from starch hydrolyzates in 10% concentration are as high as 75%. Kang and Cottrell (1979) reviewed the proposed and patented applications of pullulans, which include use as a flocculator of clay slimes in hydrometallurgical processes, in coating and packing material for foodstuffs and pharmaceuticals, in adhesives, and in the manufacture of special fibers and fabrics.

14. Additional applications

A number of additional activities carried out by yeasts may have industrial or environmental significance. These include degradation of paraquat and diquat by *Lipomyces starkeyi*, depolymerization of tannin extracts by *Zygosaccharomyces (Saccharomyces) rouxii*, ascorbic acid production from galactose by *Candida norvegensis*, formation of α -carotene by *Rhodotorula glutinis* and L-phenylalanine production by *Rhodotorula rubra*.

15. Yeasts as hosts for expression of recombinant DNA

The introduction and expression of heterologous (foreign) genes in yeasts serves as an alternative to bacteria for the expression of foreign polypeptides. *S. cerevisiae* is not ordinarily pathogenic to humans (see chapter 2) and thus foreign proteins synthesized in this yeast may be more acceptable in pharmaceuticals and in food products for human consumption. Additional advantages that can be attributed to *S. cerevisiae* are: (i) the high stability of its cells; thus, there is little or no lysis under various adverse conditions of growth. (ii) Defined growth media used for yeasts contain few extracellular protein species under ordinary growth conditions and provide good conditions for secretion studies and recovery of gene products of recombinant DNA. (iii) Yeasts, in contrast to most bacteria, can glycosylate proteins. Glycosylation in

recombinant yeast of normally non-glycosylated bacterial proteins results in more stable proteins. (iv) *S. cerevisiae* has had a long history of use in industrial fermentations. (v) Yeasts are much more able than *Escherichia coli* to secrete heterologous proteins into the extracellular medium.

The procedure is to insert a heterologous gene in a plasmid capable of replication and selection in yeasts. Also needed is a 5'-flanking DNA promoter sequence to increase transcription. These have been derived by various investigators from the 5'-flanking sequences of genes such as yeast alcohol dehydrogenase 1, yeast glyceraldehyde-3P-dehydrogenase, 3-phosphoglycerate kinase, α -factor, or acid phosphatase. A transcription terminator must be present in the 3'-flanking fragment.

To obtain relatively pure gene products, it is desirable that they are secreted into the growth medium by the yeast. It has been found that translocation of secretory proteins (such as yeast invertase and acid phosphatase) across the endoplasmic reticulum involves the recognition and cleavage of a hydrophobic amino-terminal extension, the so-called signal sequence. Schekman and Novick (1982) showed that the secretion pathways in yeasts and mammalian exocrine cells are similar. After translation of the preprotein at the endoplasmic reticulum, the signal peptide is removed after passage through the membrane, and the processed protein is then transported to the Golgi apparatus where vesicles are formed which transport the protein to the cytoplasmic membrane of the bud. Fusion of the vesicles with the membrane releases protein from the cell, either in the periplasmic space of the cell envelope or into the medium. Because of the ubiquitous nature of the signal sequences in different eukaryotic secretory proteins, yeast enzymes involved in the processing and secretion have been found to work also with foreign gene products. A large number of heterologous proteins are secreted by yeasts using the yeast mating factor (MF α 1) signal sequence, i.e., the prepro- α -factor directed system.

The following are examples of some heterologous genes cloned in *S. cerevisiae* and secreted by the recombinant yeast: human interferons (Hitzeman et al. 1982, 1983), wheat α -amylase (Rothstein et al. 1984), human epidermal growth factor (Brake et al. 1984), human interleukin- α , calcitonin, human growth hormone-releasing factor, human serum albumin, human insulin-like growth factors, prochymosin, insulin and somatostatin (Brake et al. 1984). Human interferon- γ is produced at 5–10% of total cell protein (Egan and Bitter 1984) and human hemoglobin continuing endogenous heme at 2–3% of total protein (Wagenbach et al. 1991). Human superoxide dismutase is made in stationary phase cells at a remarkable level: 70% of total cell protein (Hallewell et al. 1987). The sweet-tasting plant protein thaumatin is synthesized in yeast with plasmids encoding preprothaumatin (Edens et al. 1984). Although the signal sequence was found to be indispensable for thaumatin synthesis in yeast, the protein (which is about 2000 times sweeter than sucrose on

a weight basis) was not secreted into the growth medium. Similarly chymosin, a proteinase found in the fourth stomach of unweaned calves and used commercially in the first stages of cheese making, is not secreted by *S. cerevisiae* carrying the cloned genes of the various forms of this protease (Mellor et al. 1983). The zymogen, prochymosin, is inactive but becomes activated by an autocatalytic process at low pH. Calf prochymosin was synthesized to over 5% of total yeast cell protein. Bacterial proteins have also been synthesized and processed in yeast as exemplified by β -lactamase (Breunig et al. 1982) and the *E. coli* outer membrane protein A (Janowicz et al. 1982). The most important commercial yeast recombinant process has been the incorporation of the genes encoding surface antigens of the hepatitis B virus resulting in the first safe hepatitis B vaccine (Wilson 1984).

The methylotrophic yeasts, *Pichia pastoris* and *Pichia angusta* (*Hansenula polymorpha*), have some advantages over *S. cerevisiae* as hosts for heterologous genes. (i) These yeasts can be grown at extremely high cell densities (100–130 g dry weight per liter) in protein-free media. (ii) They have a higher level of protein productivity. (iii) In contrast to hyperglycosylation by *S. cerevisiae*, the methanol-utilizing yeasts do not overglycosylate. (iv) Foreign genes are incorporated in multiple copies into the chromosomes of methylotrophic yeasts. (v) The levels of production by these yeasts are relatively high (Table 4). The *P. pastoris* system (Brierly et al. 1990) employs a methanol-regulated alcohol oxidase gene promoter which yields alcohol oxidase at 30% of soluble protein. The expression cassette is stably integrated into the host genome at specific locations. The organism is haploid and amenable to traditional mutagenesis.

Table 4
Recombinant proteins produced by methylotrophic yeasts

Protein	Level (g/l)
Bacterial streptokinase	0.3
Epidermal growth factor-like protein	0.5
Bovine lysozyme (secreted)	0.6
Hepatitis B surface antigen	1.0
Glucoamylase (secreted)	1.4
Hirudin (secreted)	1.5
<i>S. cerevisiae</i> invertase (secreted)	3.0
Tumor necrosis factor	10.0

16. Improvement of yeasts by mutation, protoplast fusion and recombinant DNA methodology

Because of the conservatism of the food industry, many improvements in yeasts via construction of new strains by recombinant DNA methods (see below) have not yet been commercialized. However, mutation and protoplast fusion methods have been used to transfer genetic characteristics because this methodology does not come under

the heading of recombinant DNA techniques. Mutation of *Saccharomyces diastaticus* (= amylolytic strains of *S. cerevisiae*) to 2-deoxyglucose resistance resulted in increased rates of wort fermentation and unchanged beer flavor (Stewart et al. 1985). Mutation of *Candida boidinii* to ethionine-resistance increased methionine content from 0.5–9 mg/g dry cells in the intracellular amino acid pool and from 6–16 mg/g in the cells themselves (Tani et al. 1988). Some of the genetic characters transferred from one yeast to another by protoplast fusion are (i) osmotolerance (from osmotolerant yeasts to the food yeasts *S. cerevisiae* and “*S. diastaticus*”, (ii) flocculation (Panchal et al. 1982), (iii) lactose utilization (Farahnak et al. 1986), (iv) the “killer” character (Bortol et al. 1986), (v) cellobiose utilization (Pina et al. 1986), and (vi) methionine overproduction (Brigidi et al. 1988).

With regard to recombinant DNA techniques, the endoglucanase gene has been transferred from the mold *Trichoderma reesei* into brewer's yeast for hydrolysis of barley β -glucans, thus decreasing haze in beer and improving filtrability (Penttilä et al. 1987). Brewer's yeast has also been the recipient of the amyloglucosidase gene from *Aspergillus niger* for hydrolysis of unfermentable dextrans in production of light beer (Hammond 1988). The same gene from *Aspergillus awamori* (Cole et al. 1988) and the mouse pancreatic α -amylase gene have been incorporated into distiller's yeast allowing ethanol production directly from starch. Brewer's yeast containing the α -acetolactate decarboxylase gene from *Enterobacter aerogenes* no longer makes diacetyl and produces beer with a markedly reduced maturation time (Sone et al. 1988). Lower acidity and enhanced flavor in wine has been achieved by transformation of wine yeast with the gene encoding the malolactic conversion enzyme from *Lactobacillus delbrueckii*. Plant α -galactosidase, introduced into *S. cerevisiae*, allows the yeast to modify guar gum to achieve the desirable properties of locust bean gum. In 1990, a recombinant baker's yeast containing heterologous genes encoding melibiase and maltose permease was approved in the U.K. for breadmaking but has not yet been used, presumably due to fear of consumer response.

17. Yeasts as plant pathogens

Yeasts are generally not known to be plant pathogens, but members of the genus *Eremothecium* (synonyms *Ashbya*, *Holleya*, *Nematospora*) are exceptions. As discussed earlier, two species of this genus, *E. ashbyi* and *E. gossypii*, are used for commercial production of the vitamin riboflavin.

Batra (1973) provided a thorough review of the host range for many of the Eremotheciaceae and it was noted that infections are usually insect-vectored. *Eremothecium cymbalariae*, *E. ashbyi* and *E. gossypii* commonly infect cotton (*Gossypium* spp.) as well as the fruits of *Citrus* spp. Infections often take the form

of surface lesions, especially on fruits, but the fibers from infected cotton bolls may show yellow discoloration as well. Other economically important plants that are infected by these three species include coffee (*Coffea* spp.) and *Hibiscus* spp. *Eremothecium coryli* has a wider host range than the preceding species and commonly infects cotton, tomato (*Lycopersicon esculentum* Mill), *Citrus* spp., soybean (*Glycine max* (L.) Merr.) and hazel nuts (*Corylus avellana* L.). In contrast, infections caused by *E. sinecaudii* are restricted to seeds of oriental mustard (*Brassica juncea* (L.) Coss.) and yellow mustard (*B. hirta* Moench) (Holley et al. 1984).

18. Biological control of post-harvest diseases of fruits and grains

Rotting of stored fruits, vegetables, and grains following harvest represents a significant loss to agriculture, but control of rotting through chemical treatment may introduce health and environmental risks. An alternate strategy to prevent fungal decay relies on surface treatment of stored crops with bacteria and yeasts antagonistic to fungi (Wilson and Wisniewski 1989). Yeasts are favored over bacteria because they do not produce antibiotics and they are perceived as less likely to cause human disease when consumed.

Droby et al. (1989) and Chalutz and Wilson (1990) reported that citrus fruits treated with a strain of *Debaryomyces hansenii*, which was reidentified as *Pichia guilliermondii* (McLaughlin et al. 1990), were protected from common mold-induced rots. Protection appeared to result from competition for nutrients because *P. guilliermondii* did not inhibit the molds (*Penicillium digitatum* (Pers. ex Fr.) Sacc. and *P. italicum* Wehmer) when it was cocultivated with them on laboratory media or when the molds were exposed to filter-sterilized media following growth of *P. guilliermondii*. Similar results were obtained by Roberts (1990), who reported control of gray mold (*Botrytis cinerea* Pers. ex Pers.) disease of apples following treatment with living cultures of *Cryptococcus laurentii*.

The use of yeasts to prevent molding of stored grains shows some promise. Paster et al. (1993) demonstrated that growth of *Aspergillus flavus* Link:Fr. on soybeans was significantly inhibited when the seeds were coinoculated with *Pichia guilliermondii*. Björnberg and Schnürer (1993) showed *Pichia anomala* to inhibit the grain storage molds *Penicillium roqueforti* Thom and *Aspergillus candidus* Link when grown together on laboratory media. Inhibition apparently did not result from competition for nutrients.

19. Food and beverage spoilage yeasts

Spoilage of foods and beverages from growth of contaminating yeasts results in major economic losses worldwide. The extensive literature on this subject precludes a thorough treatment in this book. Further information can

be found in Phaff et al. (1978a, pp. 224–237), Pitt and Hocking (1985), and Fleet (1990).

Briefly, undesirable changes caused by yeasts in fresh and processed foods, or during and after their fermentation, may consist of pellicles or turbidity in liquid products or as a slimy or powdery coating on solid products, causing the formation of off-odors and flavors. Species responsible for food spoilage are not known to cause food poisoning as is the case with certain bacteria.

Yeasts responsible for food spoilage are usually well-defined and even predictable species, which depend on the chemical composition of the product, its pH, temperature of storage and the presence or absence of oxygen. Improperly cleaned processing equipment is often the source of contamination. Yeasts occurring in products with a high sugar content (40–70% by weight) grow slowly, especially at the higher concentrations, and are usually represented by species of the genus *Zygosaccharomyces* or by *Torulaspota delbrueckii*, *Schizosaccharomyces octosporus*, *Pichia subpelliculosa* and a few other species. If a high osmotic pressure is created by the addition of NaCl as a preservative, different yeast species

develop, depending on the salt concentration. During the lactic acid fermentation of Spanish style olives, the salt concentration is ~6.5% and *Pichia membranifaciens* and other *Pichia* species predominate. During the fermentation of cucumbers (salt concentration 10–16%), *Candida etchellsii*, *C. versatilis* and some other species develop. The highest salt concentration (to nearly saturation) favors the development of species of the genus *Debaryomyces*, which are found in aged cheeses, dry salami and similar meat products. Spoilage of fresh fruits (e.g., grapes, pears, tomatoes) is commonly caused by *Candida stellata*, *Pichia kluyveri*, *P. fermentans*, *Metschnikowia pulcherrima* and species of *Hanseniaspora* and its anamorph *Kloeckera*. Species of *Brettanomyces* (sexual state *Dekkera*) may cause turbidity and off-flavors in wines, beer, and soft drinks. Yeasts associated with dairy products are usually endowed with lactase activity (*Kluyveromyces marxianus*, *K. lactis*, as well as some *Rhodotorula* species). Yeasts with lipolytic enzymes (*Yarrowia lipolytica*, *Candida oleophila*) are found in triglyceride emulsions (e.g., olive pulp), while those containing amylases (species of *Saccharomycopsis*) can cause spoilage of starchy foods.

1. Introduction

Louis Pasteur, Emil Christian Hansen and Martinus Beijerinck figure prominently among early students of yeast ecology. Although educated as a chemist, Pasteur was the first to put forward the notion that microorganisms are essential in the global turnover of living matter, and that yeasts are necessary components of the microbiota of fermenting wine or beer by effecting the conversion of sugar to ethanol. According to Dubos (1976), Pasteur's ecological thinking was a major determinant of the success of his endeavors. Hansen, recognized as the founder of yeast systematics, provided the first insights on the distribution of yeasts in their natural habitats (Phaff et al. 1978a). Beijerinck described his own work as "microbial ecology", years before the coming of age of that science (van Iterson et al. 1940). Better known for his creative uses of bacterial enrichment techniques and his studies of geochemical cycling, Beijerinck also made important contributions to yeast ecology, including studies on the resistance of yeast ascospores to physical stresses, and the application of this phenomenon to the isolation of yeasts from soil samples.

Because ecology is the study of any aspect of organisms in the context of their environment, all investigations of yeast morphology, physiology, or genetics, be they descriptive or predictive, may be spiced with an ecological flavor. Yeast ecology has, therefore, progressed largely in parallel with the development of studies of yeast taxonomy and physiology by workers who may not have viewed themselves as ecologists. Many aspects of these developments have been reviewed comprehensively by Phaff et al. (1978a) and by various contributors to volumes 1 and 2 of Rose and Harrison's (1987) treatise.

Ecology often addresses the study of life from many of the same perspectives as evolutionary biology, but on

a different time scale. Whereas evolutionary responses involve changes in gene frequencies over generations, ecological adaptation may occur repeatedly during the life of an organism and does not usually involve changes in the genotype of that organism. At the interface of these two sciences, evolutionary ecology examines the interaction between the genetic profile of organisms as members of communities interacting with their environment. This relatively new approach had its first major manifestation in yeast ecology when a multidisciplinary congregation of researchers combined efforts to examine the interdependence of cacti, yeasts, and drosophilids. The early results of this research were brought together in a monograph by Barker and Starmer (1982).

Because the impact of human activity on nature is overwhelming, yeast ecology can be of economic or political importance. Often overlooked in the past was the potential role of yeasts in environmental ecology, specifically as agents of pollution, bioremediation, or biological pest control. Of course, some yeasts are well known as the central components of some industrial processes, which may in fact constitute complex microbial ecosystems. The theoretical framework underlying the selection of industrial yeast strains from the standpoint of known or presumed selective forces acting upon yeasts in nature has been dealt with by Lachance (1990b).

This chapter, rather than paraphrasing the publications cited above, will focus on yeast ecology in general as an art and a science, on its possible future developments, and on some connected topics of current interest.

2. Taxonomic descriptions are the basis for yeast ecology

As Phaff et al. (1978a) stated in conclusion to a general discussion of yeast ecology, "we are convinced that imaginative research by yeast ecologists will lead to the discovery of many additional interesting associations and the isolation of novel yeast species." This prophetic view has been substantiated by the spectacular growth in the number of known yeast species from 341 in Lodder's 1970 edition of *The Yeasts, a Taxonomic Study* to 597 in the 1990 monograph of Barnett et al. (1990), in spite of the substantial number of synonymies elucidated by molecular taxonomists in the interval. Unfortunately too many times in the past, workers engaged in yeast isolation have not gone beyond the mere nomenclatural description of new

species, failing to typify also their community, habitat, and possible interactions. A significant number of species listed in taxonomic monographs are known only through a single strain whose origin is vaguely described.

In view of the rapid decline of many natural habitats due to urban and industrial development of the few remaining wilderness areas worldwide, the need to search for new yeasts is pressing. The urgency of the problem as it applies to all forms of life has been expressed by E.O. Wilson: "I think a world biological survey would do more for humanity during the next 20 years than the genome mapping project" (Horgan 1994). The increased awareness, among world leaders, of the importance of documenting biodiversity allows one to be filled with optimism about the future of taxonomic research. However, it is vital that new taxonomic surveys be couched in an ecological framework, and that isolation methods be devised to yield ecological insights. The alternative is a meaningless catalogue of names, devoid of any real biological relevance. A tangible risk exists that such an inventory could even be used as an excuse to justify further destruction of natural habitat.

3. Yeast community, niche, or habitat: some definitions

Yeasts do not occur randomly throughout the biosphere. They form communities of species. Each community may be defined by its habitat, which is the actual place where an assemblage of yeasts lives, and by the niches of its component species. The niche consists of the attributes that make a yeast capable of sharing a habitat with other members of the community. The niche is thus the sum of all physical, chemical, or biotic factors required for successful existence. The members of a community may have different niches that happen to overlap in a given habitat. It is important to distinguish, among species found in a habitat, those that are essential components of the community from those that are transient or present fortuitously. The former are termed autochthonous, and the latter allochthonous. In practical terms, when evidence exists that particular yeast species actually grow regularly in a substrate, the species may be considered autochthonous members of a community. If that substrate repeatedly yields the same small array of species, it is considered to be a highly specific habitat. Likewise, yeast species endowed with a broad niche and as a consequence occupy many habitats are regarded as generalists. Other yeasts only occur in very unique habitats, and thus are considered specialists. It goes without saying that the one time observation of a yeast species in a substrate does not allow one to draw any such conclusions.

3.1. The yeast niche

By their very nature, yeasts are generally limited in the range of habitats they can occupy. In addition to many mineral nutrients that serve as building blocks for most of

their cell constituents, yeasts require significant amounts of an organic source of carbon and energy of relatively small molecular weight. The high surface/volume ratio of yeasts favors rapid nutrient absorption. Their unicellular nature often makes them better suited for deep liquid substrates or moist and uneven surfaces, unlike molds, which form hyphae that can penetrate and liquefy semisolid substrates or spread over smooth, inert surfaces. The size and shape of yeast cells may be a major factor in the ease and selectivity with which they are vectored by certain insects, and the volatiles that they produce may serve as specific attractants.

Yeasts usually grow over a broad range of pH values, allowing them in particular to colonize materials that have already been the site of fermentative activities by bacteria. Conversely, yeasts are not truly thermophilic. A maximum growth temperature of 46–48°C is observed in the intestinal species *Arxiozyma* (*Saccharomyces*) *telluris* and related taxa (Watson 1987). Some yeasts (e.g., *Pichia* and *Debaryomyces* spp.) possess hydrophobic wall components that cause them to form a film at the surface of liquids, while others (e.g., *Saccharomyces* or *Hanseniaspora* spp.) may have the ability to form dense flocs. These features define the niche of yeasts, and in turn allow us to predict that yeast habitats will most often be rich in simple organic carbon, liquid or very high in moisture, acidic or occasionally alkaline, and nutritionally complex. Such conditions are met by plant tissue undergoing various forms of decay, as well as exudates of roots, leaves, or flowers. Some yeasts may be better adapted to conditions met in association with the body of certain animals, usually acting as intestinal commensals.

It is useful to distinguish between the intrinsic attributes that affect the potential distribution of yeasts from the sum of all factors that actually determine their effective distribution. The terms *fundamental* versus *realized* niche are used to specify those two aspects of the niche (McNaughton and Wolf 1979). Although one generally expects the two to go hand in hand, Starmer (1981a) deduced a negative correlation between the fundamental and realized niches of certain cactophilic yeasts, based on the observation that some nutritionally specialized species had a broader host range than some nutritional generalists. The latter may be an exception. Cosmopolitan yeast species such as members of the genera *Debaryomyces* and *Cryptococcus* are most heterogeneous in their nutritional abilities, whereas yeasts that have predictable, specialized habitats, for example species of *Saccharomyces*, *Pichia*, or *Hanseniaspora*, exhibit narrower nutritional potentials. At the extreme, the yeast *Cyniclomyces guttulatus* possesses probably the narrowest known fundamental niche, being defined by unusually stringent nutritional requirements and a limited range of growth temperatures and redox potentials. The realized niche of *C. guttulatus* is further restricted by the coprophagous behavior of its host, the rabbit.

3.2. The yeast habitat

Gams (1992) stated that saprophytic microfungi behave according to the principle that "everything is everywhere, the environment selects." He incidentally attributes the well-known phrase to Bass-Becking, and not to Beijerinck, as is thought by many (Atlas and Bartha 1993). Notwithstanding, a literal adhesion to this postulate could lead one to believe that with enough persistence, it might be possible to isolate any yeast almost anywhere. The opposite extreme would be to limit the search for yeasts entirely to known yeast habitats, with the consequence that many new species could be missed altogether. Between these two absurd positions, the middle ground is the conduct of taxonomic studies within an ecologically sensible framework. The discovery of new yeast habitats may be serendipitous in some cases and guided by previous knowledge in others. Regardless, once yeast populations have been located for study, an effort should be made to identify their actual habitat, which in turn will generate an appreciation for the actual community. For example, many yeasts found in the sea may not always be autochthonous components of a seawater community. A search for the primary habitat, although not easily accomplished, is desirable. Many new yeast species, some of which are represented by a single strain, have been recovered from soil after some kind of selective treatment to eliminate molds and bacteria. Since soil is the ultimate repository of all life forms, any effort aimed at testing whether soil isolates are in fact autochthonous to soil would be worthwhile.

3.2.1. Aquatic habitats: Fresh and estuarine waters are difficult to characterize as specific yeast habitats, given that their microbiology is highly affected by the surrounding terrestrial fauna and flora, soil run-off, or effluents of human sources. In their review of this topic, Hagler and Ahearn (1987) noted the predominance, in fresh water habitats, of yeasts normally considered ubiquitous or associated with pollution. Vincent (1988) noted that the basidiomycetous yeasts recovered in Antarctic lakes were clearly the result of wash-in from adjacent soils. Moreover, polar soil yeasts, which occur in significant numbers, were found mostly in soil samples that "also contained moss, lichen or microalgal material". The reported isolations would gain a more profound significance if the actual yeast habitats were identified at the source.

Sieburth (1979) observed that yeasts are the dominant fungi in the oceans, although they are outnumbered by bacteria. Whereas basidiomycetes appear ubiquitous, ascomycetous yeasts seem more responsive to the concentration of organic debris. Among ascomycetes, the generalistic *Debaryomyces* species abound, specially near shores. Also frequently isolated are *Metschnikowia* species known to be associated primarily with marine invertebrates such as calanoid copepods, with fish, or with algae (Fell 1976). Up until recently, *Kluyveromyces aestuarii* had been isolated exclusively, albeit sporadically,

from the sea. This was of interest, because (according to our laboratory records) that species is significantly more resistant to sodium chloride than other members of the genus. Recent work by Hagler's group (de Araujo et al. 1995) has demonstrated the abundance of *K. aestuarii* in crabs, which could account entirely for its scattered occurrence in the sea.

The mostly psychrophilic *Leucosporidium* spp., *Rhodospiridium* spp., *Candida austromarina*, *Candida natalensis*, and *Sympodiomyces parvus* are probably autochthonous marine species, since they are recovered at relatively high cell concentrations from open ocean samples in specific circumpolar locations (Fell 1976). These are not usually isolated elsewhere. According to Fell (1976), marine yeasts are best defined by their combined ability to survive for long periods in seawater and to utilize a broad array of carbon compounds. Differential responses to salt are not likely to be significant. Because this broad definition might also apply to many generalistic yeasts, it remains of interest to wonder if some yeasts are intrinsically marine by virtue of specific physiological characteristics, such as psychrophily. MacLeod (1965) defined marine bacteria as having a highly specific need for sodium cations, in some cases a requirement for halide ions, and a higher dependence on magnesium and calcium than terrestrial bacteria. He remarked that contrary to common belief, the halophily and psychrophily of many bacteria isolated in the sea were not genetically stable. The essential feature of marine bacteria is their ability not only to survive, but also to grow in the sea, which ostensibly involves complex physiological attributes. A large proportion of marine bacteria grow poorly if at all on laboratory media. Whether the same criteria can be extended to yeasts is questionable. Hagler and Ahearn (1987) remarked that dilute media such as water or soil extract agar are of no advantage in isolating yeasts of marine origin, unlike for many marine bacteria.

As is the case for freshwater yeasts, many yeasts found in the sea may be allochthonous. Many are species of *Rhodotorula* or *Sporobolomyces* or other phylloplane genera (Hagler and Ahearn 1987) and thus marine isolates of these yeasts may originate from plant foliage. The frequent isolation of *D. hansenii* in seawater is consistent with its general ubiquity. Yeasts found both in the sea and in fresh water are most certainly allochthonous. They include *Candida* species thought to originate from fecal contamination, and some *Cryptococcus* species also found in soils and on plant surfaces.

3.2.2. Terrestrial habitats: Terrestrial yeasts are most abundant in plants, animals, and soil. This is a very broad topic which was reviewed extensively by Phaff and Starmar (1987), and so only a few special issues will be raised here. As mentioned above, the recognition of soil as a yeast habitat is problematic. In terms of overall abundance, it would appear that filamentous fungi tend to outnumber yeasts in most soils (Gams 1992). Nonetheless,

as outlined by Phaff and Starmer (1987), the existence of yeasts that are isolated repeatedly and exclusively from the soil, such as *Lipomyces* species, *Debaryomyces (Schwanniomycetes) occidentalis*, *Schizoblastosporion* sp., and certain species of *Cryptococcus* suggests that some habitat specificity may be at play. Vishniac (1994) demonstrated that *Cryptococcus albidus*, a dominant soil organism, was capable of rapid growth when introduced into autoclaved soil, following which viability was retained for 2 months. She argued that the sterilization treatment altered the nutritional value of the soil in a manner similar to natural weathering factors. Consistent with this, the growth of indigenous soil yeasts would be a function of the frequency and intensity of disturbances in soil.

Terrestrial ecosystems in general are the most amenable to studies of yeasts which participate in complex relationships with other organisms. Atlas and Bartha (1993) compiled an extensive list of possible community interactions as follows. Microbe-microbe interactions include neutralism (sparse independent populations sharing the same habitat), commensalism (a population benefits from the activity of another), synergism (cooperative modification of resources leading to close spatial relationships), mutualism or symbiosis (very strong synergistic association), competition (utilization of limited common resources), amensalism (chemical interference), predation (ingestion), and parasitism (long term destructive contact). Plant-microbe interactions are defined by the terms rhizosphere and rhizoplane, mycorrhizae (mutualistic), phyllosphere and phylloplane, epiphytes, and pathogens. Animal-microbe interactions encompass grazing, food enrichment, and epizoic relationships. Several of these have been documented in yeasts (Phaff and Starmer 1987). Some examples will be given below.

Starmer et al. (1991) summarized the major factors that can shape complex yeast communities, using as an example the cactus-yeast-*Drosophila* system. The first factor, dispersal, can be highly specific as it may involve insects that feed only on certain cactus species. *Drosophilids* are grazers that inoculate specific yeasts into injured plants. The yeast community developing in the cactus phyllosphere may become fashioned by the action of toxic compounds present in the host tissue (plant-microbe amensalism). Specifically, cacti in the genus *Stenocereus* produce saponins, some of which are toxic for many yeasts. Moreover, yeasts (and bacteria) already present in the host tissue may interact with newly introduced species (microbe-microbe interactions). In some cases, the interaction is mutualistic, and in others, it may involve competition for nutrients (Starmer and Fogleman 1986). Amensalism is also suspected in cases where species exclusion may be correlated with their reciprocal responses to killer toxins (Starmer et al. 1987). Last, the yeasts present in the resulting assemblage must provide sufficient benefits (food enrichment, detoxification) to the

vector for the latter to carry on further dispersal of the community to a new host.

Evidence that killer toxins play an ecologically significant role as a form of amensalism involving different yeasts is still limited. Yeasts collected from decaying fruits are generally more likely to be killers than yeasts from other communities such as tree fluxes or cactus rots (Starmer et al. 1987). Cross-classification of yeasts from within and between communities demonstrated more killing activity between communities. This would suggest that yeasts within a community have adapted to their respective toxins, and that killer toxins may act to exclude yeasts from other communities. Moreover, Ganter and Starmer (1992) found that the killer activity of cactophilic yeasts was dependent on the geographic region, the host plant, and the habitat from which the yeasts were collected.

Many naturally selected wine yeasts are killers (Young 1987). This phenomenon is widespread, but evidence that killer toxins actually serve as an instrument of competition between yeast strains in wine is only starting to accumulate (Carrau et al. 1993). Brewery contaminants capable of taking over from cultured strains and of causing bad flavors are usually killers, whereas non-killing contaminants are of lesser consequence (Young 1987). Conversely, a recent study of a natural tequila fermentation suggests that killing is not a significant factor in the development of a stable yeast community in that case (Lachance 1994).

Ultimately, the composition of a yeast community depends on the niche compatibility of its member species. Autochthonous components may interact together in a synergistic manner or cohabit in a neutral relationship due to resource partitioning. Non-members may be excluded by various forms of competition, or simply remain present, but as allochthonous elements due to the unsuitable nature of their fundamental niche.

4. Yeasts in the food chain

The role of yeasts in geochemical cycling is probably negligible in comparison to that of bacteria. On the other hand, it is now quite clear that yeasts frequently fulfill an important role in the food chain. Insects not only feed on substrates known to serve as yeast habitats, but also exhibit several adaptations to yeast utilization as a feedstock. Since the beginning of the 20th century, yeasts have been recognized as important and essential components of drosophilid nutrition (Delcourt and Guyénot 1910, Baumberger 1919). In addition, the importance of yeasts may go well beyond mere nutrition. Recent research indicates that yeasts may affect drosophilids by (1) effecting the detoxification of chemicals that are harmful to larvae or adults (Starmer 1982b, Starmer et al. 1986), (2) producing cues used by larvae or adults to find food (Fogleman et al. 1981, 1982), (3) signalling the location of egg deposition sites (Vacek et al. 1985, Barker

et al. 1986), (4) altering pheromones released by adults to attract mates (R.J. Bartelt, personal communication), and (5) influencing the behavior of adults during courtship and mating (Cook and Cook 1975, McRobert 1986, Starmer et al. 1988b).

The principal function fulfilled by ascomycetous yeasts as insect food appears to be the conversion of mineral or other low complexity nitrogenous compounds to a rich mixture of proteins and other complex nutrients beneficial for the insects. It is less clear whether basidiomycetous yeasts occupy a similar position along the hierarchy of trophic levels. Clearly their utilization of phylloplane and cauloplane exudates could cause a nutritional enrichment of these habitats in favor of grazing invertebrates. In the sea, yeasts may serve as food for filter feeding animals. However, the amount of yeast biomass on plant surfaces or in the sea is presumably much lower than that found in the deeper layers of the phyllosphere.

5. Characterizing yeast communities

5.1. Yeast isolation

Because yeasts hardly ever occur naturally as pure cultures, a balance must be struck between the wish to identify all components regardless of abundance and the need to recognize which components are most significant. In this respect, direct streak plating of suitably diluted substrate (with a calibrated loop) offers the advantage that it preserves the abundance ratios of different yeast types. YM agar is preferable to simpler formulations such as malt extract, which is poor in certain nutrients. We favor acidification to pH 3.7 over the addition of antibiotics to inhibit bacterial growth completely. Some laboratories opt for the incorporation of chloramphenicol (50–100 mg l⁻¹). If interference occurs between fast and slow growing species on the same plate, selective agar media can be formulated, and the sample plated in replicate. Natural substrates that yield intractable mixtures of yeasts and molds that must be treated by selective filtration, with or without liquid enrichment, may not actually harbour a genuine community of autochthonous yeasts. In cases where they do, enrichment methods can and should be altered to yield a quantitative assessment of yeast occurrence (e.g., most probable number techniques). A search for the true habitat may be more productive, in the long run, than the devising of complex isolation procedures. The isolation of rare ascosporegenous yeasts in soil can be facilitated by the use of Beijerinck's enrichment (van Iterson et al. 1940), which consists of subjecting soil to gradual desiccation and heating, with periodic sampling and inoculation of the soil. It is not clear how the method could be modified to generate a sense of the community to which those yeasts belong.

5.2. Sample size

Once a habitat has been identified and suitable methods designed, a collection scheme should be formulated to

yield sufficient numbers of samples. Sampling strategies have been the object of numerous publications in general ecology, but not in yeast ecology. We (Lachance and Starmer 1986) have determined empirically that a minimum of 15 independent samples is required to obtain an accurate reflection of community composition for cactus necroses, insects, tree exudates, or flowers. The number varies according to the frequency of empty samples. If empty samples are present, the sampling size should be corrected to obtain a minimum of 8 non-empty samples.

Higher sampling intensities are sometimes useful if minor community components are sought. For example, the yeast *Sporopachydermia quercuum* occurs in low numbers (and presumably at low frequencies) in red oaks of the Great Lakes area. In an attempt to obtain a larger number of isolates to study variation (J.E. Kaden and M.A. Lachance, unpublished results), 50 trees were sampled and their exudates plated in duplicate on YM agar and Yeast Nitrogen Base agar with *myo*-inositol as sole carbon source, plus 10 mg l⁻¹ cycloheximide. Only five separate isolates were obtained. At another locality, 20 trees were sampled and only one isolate was recovered.

5.3. Purification

The art of picking colonies for further study is an important aspect of community description. The isolation plates should be examined daily until the colonies acquire a sufficient size to allow discriminating between the types. It is generally advantageous to use some kind of magnifying device. High power (4×) reading glasses are convenient and suitable. A representative of each colony type should be recovered, and the number of colonies of this type estimated. We have found little advantage to picking replicates of each colony type unless the mating type ratios of a haploid heterothallic species are being investigated. The possibility that a species is missed because its colonies are identical to others is compensated by processing an adequate number of samples. Ideally, each colony should be immediately suspended in water and streaked out for purification. When this is not possible, colonies may be transferred directly to small (1–3 ml) agar slants and purified later.

5.4. Identification

Yeast identification methods have been standardized to some degree since the keystone publication of Wickerham (1951). The details, however, vary from one laboratory to another. For ecological studies, we favor replica plating with a multipoint inoculator (see Lachance 1987, for a description) for several reasons. Many ecological insights emerge from examining numerous yeast strains for growth on the broadest possible variety of media, whether or not all media are required for species identification. The number of informative tests may approach 90, and a typical field study may yield over 300 isolates. Simple arithmetic will show how onerous is the task of conducting these tests in separate tubes. We inoculate 21 strains

per plate. The preparation of enough media for 8 series of 90 media takes less than two days. One series requires about 2 hours to inoculate and 1 hour to read. Importantly, colony characteristics may vary from one medium to another, which may in itself constitute valuable information. Contamination is more easily detected on agar media than in broth. Special shaking equipment is not required. Replica plating has also some drawbacks such as cross-reactivity. For example, the urease hydrolysis test cannot be performed on replica plates, and tests for the assimilation of certain sugars (i.e., sucrose, raffinose) are sometimes difficult to assess correctly. These weaknesses of replica plating are largely outweighed by the advantages.

Complete identification of every isolate is essential. The use of simplified characterization procedures may be permissible in studies of already well characterized communities (Davenport 1980a), but in exploratory studies, "an accurate picture of yeast habitats cannot be assembled if the yeast species cannot be correctly identified" (Phaff and Starmer 1980). As newer molecular identification methods develop, one can easily conceive of the possibility that a primary isolation plate, a microscope slide, or even a fixed section of a yeast habitat could be treated with a mixture of DNA probes, each tagged with a different chromophore, in such a way that direct identification of individual colonies or even single cells *in situ* would be achievable. Nonetheless, the determination of a yeast's physiological abilities will never cease to be of importance in understanding its ecological niche.

Exhaustive physiological characterization is useful in identifying intraspecific variation. The taxonomist's search for stable characters is foiled by the fact that phenotypic variation is an intrinsic feature of evolving species. Strain variation, which may represent an annoyance in practical taxonomy, is an important element in the recognition that yeast populations in certain communities may constitute distinct biotypes subject to unusual forms of selection. The regularly advanced proposals to disregard completely various characters because they vary within a species should be resisted if taxonomy is to retain an ecological significance. In fact, if taxonomy is to preserve any biological relevance at all, taxonomists should not lose sight of the fact that in variation lies the very essence of biology.

5.5. Community definition

The description of a yeast community can range from a simple list of the species and their frequencies to a complex series of ecological parameters. Various measures of diversity based on the species names and frequencies are available (Atlas and Bartha 1993). We have found a quantity termed the effective number of species (Starmer 1982a) usually adequate and conceptually simpler than most entropy based expressions. Other workers (P. Morais, personal communication) have preferred the use of a related quantity termed the "odds" measure of diversity

(Kvalseth 1991). Both measures are based on the probability of re-isolation of a species.

It may also be interesting to describe communities as the sum total of the phenotypic properties of their components. Again various statistics are available in the general ecological literature. We have used vectors of the mean results of identification tests to define yeast communities associated with different plant families (Lachance and Starmer 1982) and formulated a number of descriptors based on these vectors adjusted in reference to expected identification results (Lachance and Starmer 1986). This allows one to define a community on the basis of a higher or lower than expected performance on each test. For example, cactophilic yeasts constitute a highly specific community characterized by their significantly less than expected growth on most tested carbon sources, and more than expected growth at 37°C, whereas yeasts isolated from exudates of trees in the birch family, while less specific, exhibit a broader than expected carbon compound utilization and no significant departure from expectation vis-à-vis 37°C growth.

5.6. Analysis

Collections of yeast species and their frequencies, as well as their responses to identification tests, can be analyzed in the form of structured tables, in which similar communities and similarly distributed species are juxtaposed. Species frequencies are also eminently suitable for visualization by means of multivariate methods. A basic understanding of the assumptions and properties of relevant methods should be secured by prospective users, but the procedures, although complex, are easily executed using algorithms available commercially, through internet, or on most institutional computers. A comprehensive discussion of multivariate methods can be found in Legendre and Legendre (1983). The following discussion will be limited to some basic hierarchic clustering and ordination methods.

Clustering is most often performed with the UPGMA algorithm, which results in the erection of a dendrogram depicting the various degrees of similarity between communities. Users should be keenly aware that every clustering method imposes distortions, sometimes severe, upon the real structure of the data being analyzed. UPGMA engenders less distortion than many other clustering algorithms, but it will produce a hierarchic dendrogram no matter whether a hierarchic structure exists in the data or not. Clustering should therefore be used with a very critical eye and in conjunction with other methods.

Ordination allows complex data to be reduced to a small number of variables (usually 2) whose coordinates are plotted on a graph. Because multivariate data are multidimensional, reduction to two sets of coordinates will inevitably result in some misrepresentation of reality. A most useful ordination method in species-based community ecology is correspondence analysis (CA), because it is designed for the analysis of frequency tables.

Habitats and the species they contain can be plotted on the same graph on the basis of coordinates that represent the most significant departures from expectation. Species that cluster strongly with a particular habitat may represent a distinct community. Another ordination method, non-metric multidimensional scaling (MDS), creates a plot intended to represent the distance matrix describing communities according to species composition or any other descriptors. Although MDS does not allow the superimposition of species and communities on the same graph, it is applicable to any kind of data and achieves the same purpose as cluster analysis, but without creating a hierarchy that may not exist. A more widely known ordination method, principal components analysis, extracts from the data information elements that exhibit the highest amount of internal correlation. Each resulting component contains information that is uncorrelated with the information in the next. PCA should be restricted to normally distributed data, which are less frequently available in yeast ecology. However, in many cases, this analytical method may help generate insight from large sets of data even if many of its mathematical constraints are not followed to the letter.

6. Molecular ecology

6.1. Molecular identification of biotypes

Characterization of DNA sequences that are strain-specific allows the study of biotype distributions in yeast communities. This approach has been used to study natural yeast populations, but has received most attention in the control of implantation and contamination of commercial yeast strains in industrial fermentations. The simplest strategy is the production of strain-specific electrophoregrams by restriction endonuclease digestion of whole genome DNA. This has been used by Lachance (1990a) to study the global dispersal of a cactophilic yeast, *Clavispora opuntiae*. In that and many other species, tandemly repeated ribosomal DNA is present in such excess that simple agarose electrophoresis of restriction digests produces a clear rDNA banding pattern against a background of other sequences. The pattern can be used as a fingerprint or transformed into a map of the gene cluster. Most of the variation is due to spacer polymorphisms.

Electrokaryotyping can also yield unique patterns capable of differentiating strain genotypes. This has been applied successfully to yeasts of oenological (Vézinhel et al. 1990) and clinical (Iwaguchi et al. 1990) interest.

A further refinement to molecular identification is the use of labelled DNA probes applied to DNA transferred from a gel to a membrane. Probes are selected from highly variable regions of the genome (Degré et al. 1989) or designed arbitrarily (Walmsley et al. 1989).

A variation on the same theme is the use of arbitrarily designed probes to amplify polymorphic DNA fragments randomly by PCR (RAPD, Hadrys et al. 1992). The fragments are separated by electrophoresis. Because of

its "black box" nature, RAPD is mostly useful at the preliminary levels of an ecological study, and should give way to other, less ambiguous methods when the community being studied becomes better understood.

As DNA sequencing technology progresses, it is quite clear that the complete sequence of suitably chosen DNA markers will constitute the most valuable sort of fingerprinting data. This requires the identification of hypervariable sequences of manageable size, flanked by more highly conserved regions that serve to design primers for amplification. Numerous methods presently exist to perform PCR amplification directly on a few yeast cells. In some laboratories, sequencing reactions are performed directly on amplification products in a few minutes. As rapid, non-isotopic methods for visualizing sequencing gels develop further, it should become possible to obtain a short (e.g., up to 300 bp) sequence from a few yeast cells in less than a day.

6.2. Molecular species tracking

Future developments in yeast ecology will no doubt include the application of molecular methods to the tracking of yeast species or individual lineages in their natural habitat. One such approach is the use of reporter genes to study the fate of introduced yeast clones into a habitat, or the movement of genes within natural yeast populations. One of the most promising is the bioluminescence (*lux*) gene cluster (Kado 1992).

Species-specific DNA probes also have much potential in this area. Whereas the technology that would allow exact *in situ* localization of individual yeast cells or colonies is still under development, the detection of designated species in small samples is now reality. Fell (1993) used a 3-primer system whereby DNA extracted directly from a dilute cell population is subjected to PCR. Each reaction contains two universal primers designed to generate a moderately sized rDNA fragment in any yeast. A third primer, specific to a chosen species, causes instead the appearance of a fragment that is approximately half as large if that species is present. With the rapidly progressing PCR technology, it is conceivable that the presence or absence of a dozen designated species can be assessed within one or two hours from the time the sample is recovered.

7. Ecological aspects of yeast sexuality

Theoreticians dealing mostly with organisms for whom reproduction is either exclusively or predominantly sexual have formulated numerous hypotheses regarding the evolutionary significance of sexuality (Michod and Levin 1988), some of which have become part of the biological canon, but none of which is entirely satisfactory. Andrews (1993) examined sexuality as a source of ecologically significant variation, contrasting microorganisms with complex eukaryotes. In differentiated multicellular organisms, the profound specialization opposing germinal

and somatic tissues has the important result that the environment only indirectly affects gene transmission, by influencing the reproductive output of each individual. In organisms capable of clonal reproduction, different ramets (clones) of the same genet (genetic individual) may transmit genetic variation acquired by mutation or other means to the next generation. Microorganisms are similar to clonal organisms, and thus their evolution is presumed to be less affected by sexuality in the strict sense and more by other factors. In the specific case of the yeasts, Andrews (1993) proposed that the Ty and mating type elements of *Saccharomyces* could represent potentially important sources of genetic variation.

Clonal reproduction notwithstanding, the frequent occurrence of heterothallic sexuality in haploid yeasts suggests that the sexual mating process is adaptive for those yeasts. However, the considerable success afforded to yeasts by their non-sexual reproduction makes it difficult to assess the effect of sexuality upon their fitness through ecological time. This is further complicated by the frequent occurrence of homothallism. We still do not know how extensive sexual reproduction is in natural yeast populations. A general tendency exists for heterothallic haploid yeasts to exhibit local imbalances in their mating-type ratios, which suggests that sexual mating is in fact rare, at least in ecological time. Lachance et al. (1994) examined this question from various angles in *Clavispora opuntiae* and observed that mating-type imbalances may be self-amplifying because the mating process itself is hindered by imbalances at the population level. Put differently, mating is maximum in an equal mixture of cells of the two mating types, and in turn, frequent mating would be an important factor in maintaining an even ratio of mating types. In that and several other yeasts, G₁ arrest is prerequisite to mating, and the arrest is often triggered by nitrogen starvation. It would then appear that ecological pressures favor the elimination of sexual reproduction in haploid yeasts, but that significant evolutionary forces are at work to maintain the process. Future research on the determinants of senescence in eukaryotic microorganisms (Andrews 1993) may provide elements towards understanding the nature of the selective forces involved in the maintenance of sexuality in yeasts.

More easily explained in ecological terms is the occurrence of haploid homothallic yeasts, specially those which form fewer than four ascospores, e.g., certain species of *Nadsonia*, *Debaryomyces*, *Citeromyces*, *Torulasporea*, *Hanseniaspora*, and others. Homothallism does not preclude cross-fertilization and consequently may well be responding to the same evolutionary pressures as other forms of sexuality. At the ecological level, however, the use of the sexual process to form one or two dormant spores which may exhibit accrued resistance to environmental stress is not only advantageous, but also economical, since it makes use of mechanisms that are already in place in the cell for its sexual functions. The

fact that genetic recombination is not necessarily achieved in this case becomes unimportant.

If sexuality occurs freely enough in yeast populations, the various alleles in that population should be distributed randomly with respect to one another except in cases of genetic or selective linkage. Strong allele associations (linkage disequilibria) involving genes that are not linked physically can also be an indication of quasi-exclusively asexual reproduction in populations subject to significant fluctuations in size. Little work has been done in that area.

Cactophilic yeasts exhibit a wide diversity of sexual life histories. At one extreme, the common cactus yeast *Candida sonorensis* is always asexual wherever it has been collected throughout the world (i.e., four different continents). Yeasts classified as *Sporopachydermia cereana* are in fact a mixture of cryptic species, some of which are self-fertile, some asexual, and some which exhibit what appears to be a pheromone-mediated interaction that could be interpreted as vestigial sexuality. *Pichia cactophila*, another very common cactus yeast, occurs in nature in the homothallic and diploid state. *Pichia heedii* is heterothallic, but occurs mostly in the diploid state because its asci are persistent, which causes the fusion of sister spores of opposite mating types. The heterothallic *Pichia amethionina* and its close relative *Pichia caribaea* occur in nature in both the haploid and diploid states, and the spores are released early from the asci. *Pichia opuntiae* and the related saguaro-specific *Pichia thermotolerans* occur as haploids in their habitats. As mentioned earlier, *Clavispora opuntiae* exhibits clear-cut heterothallism and is predominantly haploid. The reasons for the differences in modes of sexual reproduction in these yeasts are not entirely clear, especially because some of them occur side by side in the same habitat (e.g., *P. heedii* and *P. thermotolerans*) and are subject to the same selective pressures.

8. Clinical ecology and the yeast connection

A relatively new ecological interest in yeasts stems from the proposal by Truss (1978) that *Candida albicans* may be responsible for numerous persistent ailments, ranging from chronic fatigue to depression. Termed "The Yeast Syndrome" (Trowbridge and Walker 1986), the condition allegedly results from three major activities of intestinal populations of *C. albicans*. One is the conversion of sugars to acetaldehyde; another is a disruption of the integrity of the intestinal lining, allowing large immunogenic molecules to enter the bloodstream; last, the problem is thought to be exacerbated by the release of a large number of antigenic and toxic substances by the yeast.

The belief that systemic candidiasis is a major factor associated in some way with a wide number of debilitating conditions, including schizophrenia, memory loss, sexual impotence, multiple sclerosis, rheumatoid arthritis, or chronic fatigue is attributed to Crook (1986), a proponent

of so-called clinical ecology, which is also known by some as "orthomolecular medicine". *Candida albicans* is even claimed to produce, in some cases, enough alcohol to result in chronic drunkenness, although at least one attempt to use this as a defense by a person charged with impaired driving has not borne fruit. The issue is complicated by the fact that diagnosis of systemic candidiasis typically does not require evidence that yeast is present in any significant amounts in the host, but is based on indirect evidence, including some rather obscure blood tests.

An integrated treatment is proposed, entailing oral intake of ketoconazole, caprylic acid, numerous "natural" preparations including lactic acid bacteria and garlic, vitamins including vitamin C, minerals, essential fatty acids, or massive doses of nystatin. Vaccination and other less obvious forms of immune desensitisation may also be advocated, as well as intravaginal applications of yogurt, or enemas with coffee or other preparations (Trowbridge and Walker 1986). The use of antibacterial antibiotics and steroid medication is discouraged. An unusual diet which eliminates anything thought to be connected with fungi is also advocated. The prohibited foods include sugars, breads, cheeses, alcohol, vinegar, malt and other grains, processed meats, mushrooms, and many nuts and fruits. Eggs, most vegetables, and most lean meats are allowed. Treatment must often be prolonged over several months or even years. The more drastic remedies can apparently trigger a major response of discomfort, nausea, or fatigue in patients. Termed "yeast die-off" or "Herxheimer reaction", the condition is attributed not to the possible side effects of antifungals, but instead to the toxicity of substances released by the killed yeast.

Given the extensive popularity and the anecdotal nature of alternative medicine, it is difficult to evaluate the well-foundedness of this new aspect of yeast ecology. It would be presumptuous and unfair to reject broadly all claims that many idiopathic conditions may be aggravated or even stimulated by *Candida albicans*, and most insensitive to dismiss the suffering of many as inconsequential. Conventional medicine remains sceptical (Bennett 1990), because of the refusal of clinical ecologists to approach their treatment scientifically, and the negative evidence obtained in controlled clinical trials. It is clear that systemic infections by *Candida albicans* are widespread and very serious (Edwards 1991) as a complication in patients whose health is critically compromised. It is less clear whether chronic candidiasis is one of the most prevalent and debilitating conditions afflicting modern humanity.

9. Yeasts as probiotics

In sharp contrast to the claim that ingestion of non-pathogenic yeasts, their byproducts, or those of other microorganisms might act as predisposing factors in systemic candidiasis, a growing body of evidence suggests

that some yeasts may have significant beneficial effects. Indeed, the administration of baker's or brewer's yeast to patients suffering from diarrhea caused by *Clostridium difficile* has been shown, in clinical tests, to improve recovery (Schellenberg et al. 1994, Chia et al. 1995).

A commercial preparation made up of viable cells of "*Saccharomyces boulardii*" (possibly a biotype of *S. cerevisiae*) is effective in the treatment of various intestinal disorders, including chronic diarrhea in humans receiving antibiotics or nasogastric alimentation and in AIDS patients (McFarland and Bernasconi 1993). The treatment requires the presence of a sustained population of this yeast in the intestine, and has no significant effect on the normal intestinal microbiota. Upon cessation of the treatment, the yeast is eliminated in 2 or 3 days. Pathogens successfully antagonized by *S. boulardii* in gnotobiotic animals include, in addition to *Clostridium difficile*, *Candida albicans*, *Vibrio cholerae* and *Entamoeba histolytica*. The activity on *C. albicans* includes a decrease in the abundance of pathogenic yeast translocated to the lymph nodes. Although the mechanisms by which yeasts inhibit microbial pathogenic action are not completely understood, it appears that the cell wall glucans play a role in the detoxification and reduction of antigenicity of bacterial effectors.

10. Yeasts and microbial ecology

When asked why he had not pursued a lifetime research career in the study of yeasts, a prominent contemporary bacterial ecologist replied that "yeasts do not have an ecology". An extensive treatise entitled "Microbial ecology, principles, methods, and applications" (Levin et al. 1992) was published recently in response to the growing importance of the environmental role of microorganisms, in particular those used for biotechnological purposes. Although the yeast genera *Saccharomyces*, *Candida*, and *Kluyveromyces* are listed in the first chapter as having a potentially significant impact on human activity, no further mention of these or any other yeasts is made throughout the book. References to yeasts are also conspicuously rare in other major microbial ecology treatises (Andrews 1993, Atlas and Bartha 1993, Stolp 1988). Such a "poor cousin" figure is neither unexpected nor alarming, if it is realized that to a large degree yeasts play a rather minor role, in the biosphere, compared with other microorganisms that may act as primary producers, predators, pathogens, or important agents of nutrient cycling.

The role of yeasts in geochemical cycling takes second place to that of bacteria. As carbon cyclers, yeasts respire and often perform a fermentative glycolysis, but are rather restricted in the nature of the carbon sources they may assimilate. Few if any yeasts excrete cellulases or chitinases, thus restricting their contribution to decay. Extracellular amylases, lactases, maltases, proteinases, ureases, lipases, or other enzymes produced by yeasts are usually dwarfed by more powerful counterparts in

the bacteria or the filamentous fungi. The contribution of yeasts to nitrogen cycling sometimes involves nitrate reduction or ammonification of nitrite, but is usually restricted to the assimilation of ammonia or amino acids into organic nitrogen. Most yeasts act as sulfate reducers, and some are sulfur auxotrophs. Although many yeasts can grow at pH values as low as 2.5, none can challenge *Thiobacillus*, which is capable of growth at pH values near 0. The growth of *Debaryomyces hansenii* in 3.0 M sodium chloride is no rival to that of halophilic bacteria in saturated (5.2 M) salt, and no yeast could conceivably survive alongside thermophilic bacteria able to grow at 100°C. The list of examples of how meagre is the potential of yeasts to colonize extreme environments could go on for pages, but the point has undeniably been made that our preoccupation with yeast ecology cannot be enkindled by the same incitements as the bacteriologist's quest for more and more unusual habitats and for examples of organisms responsible for geologically significant phenomena. Instead, the study of yeasts in an ecological context has to address phenomena in which yeasts do participate.

In spite of the profound difference between yeasts and bacteria, yeasts lend themselves to most of the methodologies so useful in the study of bacteria. As a result, microbial ecologists with a bacteriological leaning may try to identify in yeasts patterns that may not apply to yeasts. At the same time, plant and animal

ecologists, accustomed to observations based on more immediate identifications of their target organisms, often do not integrate microbial components in their otherwise powerful models. Andrews (1993) addressed this matter by drawing an extensive comparison of the ecologies of large and small organisms. Among the main fundamental differences he identified between these two kinds of organisms, the capacity of most microorganisms for extensive dormancy, high growth rates, narrow permissible growth conditions, a high degree of metabolic adaptability, the direct exposure of unicellular forms to selection, large numbers, a predominantly haploid condition, and a diminished role for sexuality. Not unexpectedly, most of the comparisons drawn by Andrews were directed at microorganisms other than yeasts.

We are convinced that yeasts can and should be studied extensively in an ecological and evolutionary perspective, and that such studies will yield bounteous rewards. Yeasts were a major focus of microbial ecology at very early stages, and could represent the organisms of choice to tackle the new challenges facing evolutionary ecology today. Moreover, future progress in yeast taxonomy should benefit greatly from accentuating its ecological flavor. But the nearly obligate association between yeasts and other living organisms will make it advantageous to use a multidisciplinary approach, and consequently yeast ecologists will gain by joining forces with specialists of other biological disciplines to pursue common endeavors.

4. Sexual cycles	41

1. Introduction

Classification of fungi is based extensively on morphology, mostly as determined by light optics. During the past 30 years, however, electron microscopy has provided critical new observations that have enlarged this foundation to include micromorphology (see Hohl 1987, Moore 1989a, 1994, 1996a). This new information, and that provided by molecular biology (Bruns et al. 1992), has sharpened and clarified the delimitations of a number of taxa, including the distinction between ascomycetes and basidiomycetes. One consequence of this expanded knowledge has been the general recognition of the Fungi as a kingdom on a par with those of plants and animals (Moore 1996c); another aspect has been the challenge of adapting the nomenclatural framework to reflect the additional taxonomic information (Moore 1974, 1994).

The kingdom Fungi is eukaryotic and characterized by cell walls that have a major chitin component (Bartnicki-Garcia and Lippman 1989), hyphae that extend apically (Wessels 1986, Bartnicki-Garcia et al. 1989, Howard 1981, Kotov and Reshetnikov 1990) and divide by centripetal invagination of the plasma membrane (see Moore 1985 and below). In general, fungal nuclei are haploid, small (~1 μm in diameter), have envelope pore complexes similar to those of other eukaryotes (Allen and Douglas 1990, Carter 1978, Nehrbass et al. 1990), and amounts of chromosomal DNA intermediate between that of bacteria and plants and animals (Sparrow et al. 1972, Durán and Gray 1989). Microtubular organizing centers (MTOCs) called spindle pole bodies (SPBs), chromosomes, and modes of nuclear division are unique. There is a single SPB (Fig. 1) intimately associated with the nuclear envelope (Heath 1981, O'Donnell and McLaughlin 1984a, Rout and Kilmartin 1990, O'Donnell 1992) that divides during nuclear division. Mitotic chromosomes are difficult to discern by light microscopy and they rarely become organized into a metaphase plate (see King and Hyams 1982, Burns 1988). In most species, the nuclear envelope persists during both

Fig. 1. Spindle pole body (SPB). SPB localizations and spindle components (from Rout and Kilmartin 1990).

mitosis (Boekhout and Linnemans 1982, King and Hyams 1982, Heath et al. 1982, Bourett and McLaughlin 1986, Tanaka and Kanbe 1986) and meiosis (Howard and Moore 1970, O'Donnell and McLaughlin 1984a). During nuclear division, the SPB divides and each SPB generates spindle and astral microtubules (mt's) as they migrate around the nuclear envelope to opposing polar positions (Heath 1981, O'Donnell 1992).

2. Cellular growth

2.1. Introduction

Yeasts, for the most part, are single-celled, typically uninucleate fungi that reproduce by forming new cells serially. The nature of the cell wall provides the initial dichotomy in classification. The difference in wall structure between ascomycetous and basidiomycetous forms is indicated by the electron microscopic image of the budding site. Ascomycetes (Fig. 2) have two closely appressed wall layers (that of the emerging bud and that of the parent cell) whereas for Basidiomycetes (Fig. 3), the parent cell wall is multi-layered and ruptured, appearing as a collar consisting of a series of splayed wall layers (Kreger-van Rij and Veenhuis 1971a, Miller et al. 1976b, Simmons and Ahearn 1987). Biochemical traits parallel this dichotomy: (1) ascomycetes give no visible response to diazonium blue B (DBB) while those of basidiomycetes give a reddish to purple color (van der Walt and Hopsu-Havu 1976, Hagler and Ahearn 1981, Simmons and Ahearn 1987); (2) only ascomycetous species give a positive response to certain protoplast releasing enzymes (Bastide et al. 1979, 1986); and (3) pyrophosphatidic acid

(pyro-PA) is found exclusively in basidiomycetous species (Goto et al. 1988).

Studies that examine changes during specific times in the cell cycle of yeasts and other fungi (Herskowitz 1988, Nasmyth 1996) frequently use cell division cycle (*cdc*)

Fig. 2. Ascomycete-type budding (*Saccharomyces cerevisiae*). Grazing section of an early bud showing a number of rings in the neck region (from Byers and Goetsch 1976). Bar=250 nm.

Fig. 3. Basidiomycete-type budding: (A) initial bud cell of *Filobasidiella (Cryptococcus) neoformans* (courtesy of R. Calderone, from Pelczar and Chan 1981). The dark:light:dark wall layers of the parent cell are prominent and are discontinuous at the budding site. The wall layers of the emergent bud are discrete from those of the parent cell and consist mostly of a shell of light material bounded on either side by just discernible layers of dark material. Bar=1.5 μ m. (B) Budding cell of *Filobasidium floriforme* (from Moore and Kreger-van Rij 1972). Several generations of budding have produced a ruff around the budding site. Four collars of dark material are evident (arrows) and are considerably thicker than the intervening light layers. Bar=250 nm.

mutants. Four phases are commonly recognized in the *cdc*: G_1 – gap 1, an interval before DNA synthesis; S – an interval of DNA synthesis; G_2 – gap 2, an interval between the end of DNA synthesis and the initiation of mitosis; and M – mitosis.

2.2. Blastic cell division

2.2.1. Bud formation in ascomycetous yeasts: At the start of bud formation in ascomycetous yeasts (see Moore 1987b) vesicles aggregate at the bud site (Moor 1967a, Byers and Goetsch 1975, 1976, Crandall et al. 1977; see Fig. 4: c,l). Some of these vesicles probably contain enzymes (Moor 1967a) that cause plasticizing of the glucans and mannans that, in turn, allow the chitinless cell wall to stretch as the bud balloons out and generate wall layers confluent with those of the parent cell (Fig. 2) (Djaczenko and Cassone 1971). Cytokinesis

Fig. 4. Cell and nuclear division and conjugation in *Saccharomyces cerevisiae* (redrawn from Byers and Goetsch 1975). (a–f): (a) cell that has reached the critical size necessary for division; (b) division of the spindle pole body (SPB); (c) daughter SPBs start to separate and generate spindle microtubules (note persistence of astral microtubules), the bud initial contains a number of vesicles formed from the endoplasmic reticulum; (d) daughter SPBs migrate to opposite sides of the nucleus, cytokinesis starts; (e) beginning of nuclear division and start of daughter nucleus moving into bud cell; (f) just before cell separation the nucleus becomes dumbbell-shaped, septum formation starts. Conjugation (b, g–l): (b \rightarrow g) after haploid cells, facilitated by mating substances, become synchronized and gametic, maximum cell-to-cell contact is achieved; (g) lytic vesicles partially dissolve the fusion wall effecting plasmogamy; the SPBs retain their opposing orientation; (h) the SPBs have lead the nuclei to the narrow intercellular opening which will restrict nuclear passage to the extended, SPB-bearing region; (i–k) interpolated perspective views of karyogamy (note the regular size and spacing of nuclear pores). (i) Aster-to-aster fusion and initial contact of the nuclear envelopes; (j) fusion of the two SPBs resulting in the fusion of the contiguous nuclear envelopes; (k) fusion SPB with aster; (l) the first bud of the zygote usually emerges from the fusion site. (l \rightarrow c) SPB duplication as in a typical cell division.

occurs in the neck of the bud (Fig. 4: f) and involves the formation of a highly ordered ring of 10 nm filaments lying on the interior surface of the plasma membrane and, in glancing electron micrographs of the bud/parent cell isthmus, appear as stria parallel to the long axis (Byers and Goetsch 1976, Byers 1981, Heath et al. 1982, Takeo et al. 1987) (Fig. 2). The initial circumferential space formed by the invaginating plasma membrane is subsequently filled by an electron translucent "constricting ring" of chitin (Cabib and Farkaš 1981). As invagination proceeds, chitin extends across the cell (Bowers et al. 1974) and at completion has a central punctum (Cabib and Bowers 1971). Later, secondary wall layers like those of the homogeneous main cell wall (Cabib 1975) and of similar electron dense appearance are laid down on both sides of the primary septum. Bud separation leaves a flanged discus of chitin on the parent cell as the principal component of the bud scar. In *Candida albicans*, bud scars lack anionic sites (Horisberger and Clerc 1988). The one bud per locus mode of budding limits the number of buds that a parent cell can produce (Mortimer and Johnson 1959, Freifelder 1960, Gyllenberg 1986).

Budding by members of the genera *Hanseniaspora*, *Nadsonia*, *Saccharomyces*, *Wickerhamia* and their anamorphs is bipolar, i.e., budding occurs just at the poles of the ovoid parent cell. Polar budding can occur repeatedly through the previous bud scar on a broad base, and leaves a succession of appressed, annellidic rings corresponding to the formation of each new bud.

At the time of bud initiation in *Saccharomyces cerevisiae*, the duplicated SPB divides (King and Hyams 1982, Rout and Kilmartin 1990) and the separated SPBs migrate to opposite poles of the nucleus (Fig. 4: a-f). In the course of this movement around the nuclear envelope, the SPBs generate extranuclear mt's (i.e., cytoplasmic or astral) and an intranuclear spindle composed of pole-to-pole and chromosomal mt's. In *Saccharomyces cerevisiae* (Byers and Goetsch 1974, 1975) the SPB acquires a satellite during the latter part of the cdc G₁ phase (prior to bud initiation, see below); early in budding, near the start of the cdc S phase, a pair of SPBs become evident that, by the end of this phase, have formed a complete spindle. Spindles in *Saccharomyces cerevisiae* (Moor 1967b, King and Hyams 1982), *Schizosaccharomyces pombe* (Ding et al. 1993), *Rhodospiridium* (Boekhout and Linnemans 1982), *Taphrina* (Heath et al. 1982), and other yeasts have been shown to be composed of two types of mt's, each composed of 13 proto-filaments (Kilmartin 1981): (1) those mt's of equal length that constitute a prominent central fascicle formed as they pass in opposite directions through the nucleoplasm to become attached, respectively, to the opposite SPB and (2) those mt's of varying lengths that attach to the chromosomes and form opposing May-pole-like splays around the central bundle. In most plant and animal cells the mt attachment site is marked by a primary chromosome constriction, the centromere/kinetochore complex (see Fitzgerald-Hayes

1987); this configuration is absent in *Saccharomyces cerevisiae* (Peterson and Ris 1976). Peterson and Ris (1976) have also shown that the number of SPB-to-chromosome mt's in *Saccharomyces cerevisiae* closely approximates the known number of linkage groups ($n=17$) in haploid and diploid cells. In *Saccharomyces cerevisiae* there are two possible growth ontogenies (Gimeno and Fink 1992): haploid cells express an axial budding pattern in which new buds emerge at the parent/bud cell junction; diploid cells, which are more prevalent in nature, express a polar budding pattern in which new buds emerge from the previous bud cell on the side opposite the junction of that cell with its progenitor, forming a pseudohypha. Towards the end of division, the nucleus becomes dumbbell-shaped with an attenuated membrane isthmus between the incipient sibling nuclei. Telophase spindle elongation takes place across the bud/parent cell isthmus.

2.2.2. Bud formation in basidiomycetous yeasts:

Budding in basidiomycetous yeasts occurs repeatedly from a single locus (Fig. 3B). After several generations, this produces a ruff around the budding site composed of accumulated ruptured wall layers (e.g., Baharaeen and Vishniac 1982, Vishniac and Baharaeen 1982, Pore and Sorenson 1990). While the chitin composition of ascomycetous yeasts localized in the bud scar is only 1–2% (Simmons 1989), in *Cryptococcus* spp. it is 5–8% (see Fleet 1985), and in a strain of *Rhodotorula glutinis* it is also relatively high (Berthe et al. 1981). Distribution of chitin (Simmons 1989) can occur evenly throughout the wall (*Cryptococcus neoformans*) or be localized in the collarette (*Malassezia* spp.). In electron micrographs the cell wall appears to have the characteristic basidiomycete profile composed of alternating electron transparent and electron dense layers (Fig. 3B); the dense layers are relatively thick and easy to see, the intervening transparent layers are thin and hard to discern in most micrographs, causing them to appear as transparent space.

The electron transparent layer in Fig. 3A, however, is prominent. In this figure of *Cryptococcus neoformans*, the bud is probably the initial bud cell because the dark material around the exit site is homogeneous. The sandwiched transparent layer, which is about the same thickness as the bounding electron dense layers, is probably chitinous. The transparent layer is the principle component in the bud; further, the wall layers of the bud originate in the parent cell cytoplasm and are not an integral extension of the parent cell wall. Separation probably conveys most of the bud scar to the bud, i.e., the central chitinous transparent layer and the subtending, outer, amorphous electron dense layer (Moore 1989b).

There are several notable differences between nuclear division in ascomycete and basidiomycete yeasts. In ascomycete yeasts (Figs. 1, 4), spindle formation takes place in the parent cell and the nucleus enters the bud directly as it is being formed (Soll et al. 1978). In basidiomycete yeasts (Fig. 5), the initial event of spindle

Fig. 5. Nuclear division in *Leucosporidium scottii* (from McCully and Robinow 1972a). (A) Initial bud formation (note the break in the parent cell wall and the orientation of the nucleus and SPB); (B) the nucleus has become pear-shaped with the pointed portion extending towards the bud; (C) nucleus enters the bud led by the asters and SPB; (D) division of SPB, start of daughter SPBs migration; (E) the initial event of elongation takes most of the nucleus into the bud, the small piece left behind containing the nucleolus is absorbed, the nuclear envelope partially dissociates; (F) continued spindle elongation separates the chromosomes; (G) further spindle elongation injects a nascent daughter nucleus into the parent cell; (H) daughter nuclei occupy each end of the budded cell, cytokinesis will occur in the constriction.

elongation takes most of the nucleus into the bud, leaving behind a small piece containing the nucleolus, which typically disappears. Division and spindle formation occur within the bud. A second phase of elongation of the intranuclear spindle carries a developing bud nucleus back into the parent cell; during this phase there is also a partial breakdown of the nuclear envelope. This mode of nuclear division has been reported for *Bullera* (Taylor and Wells 1979), *Leucosporidium* (McCully and Robinow 1972a, Boekhout and Linnemans 1982), *Rhodospiridium* (McCully and Robinow 1972b, Abe et al. 1984), and *Ustilago* (Poon and Day 1976a,b).

2.2.3. Conidiogenesis vs. budding: Von Arx (1979b) considered yeast buds as blastoconidia or arthroconidia. There are, however, several fundamental differences

Fig. 6. *Geotrichum candidum*. Scanning electron micrograph showing arthric cell division (from Cole 1975). Length of a single cell is about 13.5 μm .

between an aerial, hypha-produced conidium (Smith and Anderson 1973) and a single self-replicating yeast cell (Davies 1987): (1) conidiogenous cells draw on, package, and disperse resources of a growing, translocating mycelium (Wessels 1986, McKerracher and Heath 1987, Moore 1987b); (2) hyphal walls and conidia have a sizeable chitin component (Farkaš 1990); ascomycete yeasts, however, lack chitin (see Horisberger and Clerc 1988, Simmons 1989) except for the bud scar, while basidiomycete yeasts have only a small, though perceptible, chitin fraction (Simmons 1989); (3) β -1,4-glucan is a component of conidial walls but not of corresponding hyphal walls (Benhamou et al. 1990); (4) filamentous fungi, unlike yeasts, give inconsistent DBB results (Summerbell 1985) unless treated with cold KOH (Hutchinson and Summerbell 1990).

Conidial differentiation (abstriction) generally requires complete septation (Minter 1984, Cole 1986) and may be arthric or blastic. Arthric abstriction involves progressive septation within a hypha (e.g., *Geotrichum*, Fig. 6) or an existing cell (e.g., *Schizosaccharomyces* and part-spore formation in the Clavicipitales). Blastic abstriction accompanies a brief period of rapid expansion and new wall formation after turgor pressure balloons-out a local softening of the parent cell wall (see Moore 1987b) and ends with septum formation at the base of the new cell. Spore separation (disarticulation) is effected by the breakage or lysis of the hyphal wall opposite the septum.

2.2.4. Pseudohyphae formation: Species of some yeasts have the capacity to form pseudohyphae, a series of coherent, sausage-like, "elongate blastospores" (Schervitz et al. 1978). Dimorphism in *Candida albicans* is pH regulated. Under conditions of high pH (Anderson and Soll 1986) a constricting filament ring, the anlage of the septum, is initiated a half-hour after the start of bud emergence (Soll 1986). In addition, actin remains clustered in the growing tip rather than becoming re-distributed as in normal budding (Adams and Pringle

Fig. 7. Model of the crosswall of *Candida albicans* (from Gooday and Gow 1983).

1984, Kilmartin and Adams 1984, Anderson and Soll 1986, Heath 1990). There is also evidence that nutrition can affect which morphology is expressed (Shepherd and Sullivan 1976). Elongate pseudohyphal cells are separated by constricted septa, each with a micropore (Gow et al. 1980) (Fig. 7). When these cells break apart each septum appears composed of two chitinous plates, one going to each cell. In *Saccharomyces cerevisiae* only the diplophase forms pseudohyphae (Gimeno and Fink 1992).

2.2.5. Dimorphism in filamentous species: Dimorphism, in which there is an environmentally controlled, reversible interconversion of yeast and true hyphae or pseudomycelium, $Y \leftrightarrow M$, occurs in a number of species (Romano 1966). The Y-phase, depending on the species, will exhibit characteristic budding of either ascomycetous or basidiomycetous yeasts, and the M-phase, in filamentous species, will be characterized by hyphae with representative ascomycete- or basidiomycete-type septa, and in many species there is a specialized hyphal tip region called a Spitzenkörper (Grove 1978, Howard 1981, Howard and Aist 1979, Hoch and Howard 1980).

For a dimorphic basidiomycete to complete its life cycle, it is necessary that Y-phase cells generate secondary mycelium comprised of hyphae that are either dikaryotic (Flegel 1981) or diploid (Abe and Sasakuma 1986). Hirata et al. (1980) observed that by placing *Tremella mesenterica* Y-phase cells in a hormone solution in which cells of the opposite mating type had been grown, they were able to induce mating-tube formation. The sites and manner of initiation and emergence of these germ tubes was similar to that of buds. As the tube emerged it assumed linear growth and the nucleus, preceded by mitochondria, moved into the tube with the SPB at the leading end of the nucleus.

In *Rhodosporidium toruloides*, mating-tube formation is also under hormonal control (Tsuchiya et al. 1978, Miyakawa et al. 1986). A complete repression of nuclear division occurs with the induction of mating-tube formation; as tube elongation proceeds the nucleus moves into the tube and migrates to the apex. Removal of the hormonal factor causes the resumption of growth by budding (Abe et al. 1977).

Conditions for the phase change are known for a few other species (e.g., Brunton and Gadd 1991, Gimeno and Fink 1992) and there is a growing body of information concerning the molecular biology of the shift between the two morphologies (Schultz et al. 1974, Moore 1987b, Kreisel and Schauer 1989, Maresca and Kobayashi 1989, Kotov and Reshetnikov 1990, Wessels 1990). The yeast/mycelium transition has also been studied electron microscopically (Hirata et al. 1980, Borgia et al. 1989) and computer simulated (Bartnicki-Garcia et al. 1989, Bartnicki-Garcia 1990). There are no substantiated examples of a yeast phase in the Homobasidiomycotina (Laaser et al. 1988, 1989); however, dimorphic life cycles are characteristic of many heterobasidiomycetes (Wells 1994).

2.3. Arthric cell division

2.3.1. *Geotrichum candidum*: In *Geotrichum candidum* (Fig. 6) and other species with similar holoarthric conidiogenesis (Cole and Samson 1979, pp. 108–116) growth is by hyphal tip extension with septation and disarticulation proceeding centripetally. The initial septum is electron transparent but the mature septum has electron dense layers on either side (Steele and Fraser 1973). The end walls of the mature arthrospores are composed only of the respective secondary septal layers and are generally characterized by plasmodesmata or micropores (Table 5).

Karyological differences exist between *Geotrichum candidum* and *Schizosaccharomyces pombe*. Nuclei of *Geotrichum* behave like those of hyphae, dividing and reforming before septogenesis (Cole and Samson 1979, Cole 1986) whereas the nuclei of *Schizosaccharomyces* are typical of yeasts and divide concomitantly with septogenesis (see Hayles and Nurse 1989).

2.3.2. *Schizosaccharomyces pombe*: Mitosis in *Schizosaccharomyces pombe* starts with SPB division and migration of the SPBs to opposite sides of the nucleus (Tanaka and Kanbe 1986). In the course of this movement around the nuclear envelope the SPBs generate extranuclear astral mt's and an intranuclear spindle. Early in division, the central fascicle of continuous SPB-to-SPB mt's assumes a sigmoidal shape. However, reconstructed spindles reveal that mitosis in *S. pombe* is like that of other eukaryotes (Ding et al. 1993). Cytokinesis is not initiated until the nucleus has become dumbbell-shaped. Centripetal invagination of the septum ultimately partitions the sibling nuclei in separate cells. The initial events of cytokinesis occur at the end of karyokinesis (Johnson et al. 1982, Tanaka and Kanbe 1986) before the isthmus connecting the separating sibling nuclei has parted. The electron transparent part of the completed septum fluoresces brightly when stained with Calcofluor or primulin (Streiblová 1981).

Chitin is absent in *S. pombe* (Horisberger and Rouvet-Vauthey 1985); β -glucan and α -galactomannan are interwoven in the cell wall; in the cell plate the former

Fig. 8. Perforate septa of various fungi (from Moore 1972). (A) Ascomycete type of an unidentified anamorph. Bar=250 nm. (B) Basidiomycete type (*Polyporus biennis*). Bar=250 nm. (C) Basidiomycete type (*Leucosporidium scottii*). Bar=250 nm.

is associated with the primary septum while the latter is associated with the secondary septum; on the cell surface, β -glucan, in exact opposition to α -galactomannan, is detected only on the wall layers generated by division but not on those growing by extension. As a consequence of the lysis of the primary septum, the new end wall of each cell is one of the secondary wall layers formed on either side of it. Each new end wall (see Miyata et al. 1990) is like the original wall layer of the parent cell but thinner; one sibling cell, however, retains a jacket of old wall material. As a result of this mode of cell division, the pattern of wall scars is different for each cell (Streiblová 1981). When growth resumes, it starts at the old ends (see Hagan and Hyams 1988, Mitchison 1990).

Ultrastructural observations of *S. pombe* are complemented by light microscopic and biochemical studies. According to Hagan and Hyams (1988): (1) cytoplasmic mt arrangement most closely resembles that of filamentous fungi (possibly a consequence of cylindrical cell shape); (2) interphase occupies ~75% of the cdc during which time cells more or less double in size (from 7 to 14 μ m); (3) certain cytoplasmic mt's, which longitudinally span the cell and disappear at the time of mitosis, may play a role in positioning the nucleus and in establishing the cell's polarity (this array is reestablished by a pair of MTOCs at the cell equator after the mt's of mitosis depolymerize); (4) disruption of mt function leads to a controlled loss of wall deposition, resulting in distended or branched cells (in *Saccharomyces cerevisiae*, however, enlargement continues normally in the absence of mt's even though nuclear positioning becomes random); (5) F-actin undergoes structural rearrangements during the cdc at three distinct points – (a) in G₂ phase, at the transition from monopolar to bipolar cell growth; (b) in M phase, at the initiation of septation; and (c) at the cell division/G₁ phase boundary at the reinitiation of monopolar growth. Cellular distribution of F-actin varies during the course of the cdc (Marks et al. 1986, Steer 1990): (1) during final cell elongation, prior to division, it is predominantly located at the growing ends of the cell; (2) in the course of division, the least amount is observed

during karyokinesis, while during cytokinesis it becomes concentrated equatorially; (3) as division proceeds to cell separation, it becomes concentrated at both the new (post-division) ends, as well as, again, at the original ends.

γ -Tubulin has been found to occur throughout the cell cycle and to be associated with mt development in the regions of the SPBs (Horio et al. 1991). It probably has a role in mt formation because mutants in which its function is disrupted display condensed, undivided chromosomes with aberrant spindle structures that result in cell death.

3. Hyphae

3.1. Septal ontogeny

Cell division in filamentous species is first discernible when a narrow annulus of the plasma membrane is formed (Girbardt 1979). Centripetal growth of this annulus partitions the cytoplasm with an infolded membrane. New wall material is deposited on the outer surface of the membrane: beneath the lateral wall layer and along the ingrowing annulus (Moore 1965). Septal ontogeny can have any of several different conclusions depending on the taxon or the particular cell type: (1) in most species of the Chytridiomycota and Zygomycota and in some yeasts, particularly the Schizosaccharomycetales (Eriksson et al. 1993, Kurtzman 1993a), constituting a small percentage of fungi, the final ingrowth of the annulus results in complete cytokinesis and the formation of an abscissional septum; (2) in a few species of yeastlike fungi the center of the mature septum is characterized by a punctum or minute micropore; (3) in the great majority of fungi – certain mucors and trichomycetes (see Moore 1987b, Saikawa 1989), ascomycetes, and basidiomycetes – the mature septum is perforate (Fig. 8) (Markham 1994). These studies have demonstrated that septal ultrastructure is a robust indicator of taxonomic relationships (Moore 1985, 1987b, 1988b, 1989a, 1994, 1996a).

3.2. Ascomycete-type

3.2.1. Perforate septa: In ascomycete hyphae, septa are, for the most part, homogeneous and electron transparent.

Pores (Fig. 8A) are large (of sufficient size for the passage of nuclei), have rounded rims, and frequently are accompanied on either side by Woronin bodies (Markham and Collinge 1987), which are membrane bound electron dense inclusions with paracrystalline material. Hyphae of *Ambrosiozyma* (synonym *Hormoascus*) have greatly centrally-thickened septa (van der Walt and von Arx 1985).

3.2.2. Micropores and plasmodesmata: In some yeasts and yeastlike fungi a minuscule membrane cylinder in the center of the final septum (Fig. 7) may appear as either a micropore (with a central channel) or a closure line (that looks like a punctum in surface view) (Table 5). Micropores are not the same as plasmodesmata. Distribution of plasmodesmata can be random or circular (Table 5). General reviews of plasmodesmata can be found in Marchant (1976) and Robards and Lucas (1990). Van der Walt et al. (1991) consider the plasmodesmatal canals in *Zygozoma* to be further evidence for the connection between the Lipomycetaceae and Dipodascaceae. Multiperforate septa in the basidiomycete *Kriegeria eriophori* (Platyglaoales) (Kao 1956, Doublés and McLaughlin 1991) may have an ontogeny similar to those in ascomycetes.

3.3. Basidiomycete-type

3.3.1. Introduction: Basidiomycete walls and septa, in toto, are tripartite (Figs. 3, 8B,C). They are composed of a central electron transparent layer, probably chitin or chitinous, bounded on either side by electron dense layers. The basidiomycetous yeast *Malassezia* is unusual in having corrugated inner walls (Simmons and Ahearn 1987). Septa, with rare exception, are perforate. Clamp connections are a common feature of dikaryotic hyphae (secondary and tertiary mycelium). Basidiocarps are composed of tertiary mycelium.

3.3.2. Septa: The basidiomycetes, from the evidence of morphology and molecular biology, are a natural group (Bruns et al. 1992, Suh and Sugiyama 1994, Swann and Taylor 1995b). Septa in several orders are characterized by the dolipore/parenthesome (d/p) complex (Moore 1985, 1996a). Hoch and Howard (1981) have shown that the toroidal swellings of the dolipore septum are an artifact of conventional chemical fixation. Such barrel-shaped swellings are absent in samples that have been quick-frozen and freeze substituted. Nevertheless, these fixation artifacts appear to be reproducible and therefore interpretable within a systematic context (Table 5). Dolipore septa possess three basic structures (Figs. 8B, 9): (1) a barrel-shaped dolipore, (2) occlusions within the pore channel, and (3) parenthesomes on either side that delimit the pore domain. The diameter of the pore channel is 89 to 266 nm (Patton and Marchant 1978) and is occupied by opposing cylindrical occlusions. In many taxa, the outer portion of the occlusion is homogeneous and electron dense (O_1 type: Figs. 8B, 9); in

Fig. 9. Summary diagram of the basic variations to be found in dolipore/parenthesome (d/p) septa of the phylum Basidiomycota (from Moore 1985). Particular taxa are generally associated with certain d/p combinations (Moore 1996a): O_1/P_1 septa occur only in the Hymenomycetes and Gasteromycetes; O_1/P_2 septa characterize the Clavariomycetes and the monomorphic jelly fungi (Auriculariales and Exidiales) (Wells 1994); $O_2/P_{3,4,6}$ septa occur only in the orders Tremellales and Filobasidiales (Table 5); O_2/P_5 septa are unique to *Wallemia sebi* (see Moore 1986).

the Tremellales s. str. and Filobasidiales (Moore 1996a) it appears as a striated band (O_2 type: Fig. 9). Moore (1985) postulated that the pore results from the final ingrowth of the annulus being physically blocked. The dolipore domain is delimited by parenthesomes (Fig. 9), double membrane septal caps with an intervening line that are differentiated from the endoplasmic reticulum. Depending on the taxonomic group, parenthesomes may be perforate (P_1 : Fig. 8B), imperforate (P_2), vesiculate (P_3 – P_5), or absent (P_6). The several morphologies of the d/p septal complex are diagnostic of specific major taxa (Table 5; Fig. 9).

4. Sexual cycles

4.1. Class Hemiascomycetes

4.1.1. Ascospore formation: Ascospore formation starts with meiosis which, like mitosis, is intranuclear (Moens and Rapport 1971, Peterson et al. 1972, Moens 1974). Ascospore development in the Euascomycetes (Marchant 1979, Mims et al. 1990, van Wyk and Wingfield 1991) and in *Schizosaccharomyces octosporus* (Czymmek and Hammill 1989) occurs by free cell formation. A similar ontogeny occurs in most budding yeasts, but with some significant differences. An ascus sac is not formed and after meiosis the sibling nuclei do not separate but persist as lobes attached to a central mass of nucleoplasm; each lobe has an SPB that forms internal spindle mt's (Fig. 10). Each SPB becomes associated with a forespore envelope (FSE), a double membrane cupule that comes to enclose its respective lobe. An FSE

Fig. 10. Summary diagram of ascospore formation in *Saccharomyces cerevisiae* (from Moens and Rapport 1971). At the start of sporulation (a, b) the SPB replicates and the daughter SPBs move apart (c, d) and generate the primary spindle; (e) the primary SPBs, in turn, replicate when the meiosis I spindle has achieved its maximum length; (f) the resulting pairs of secondary SPBs separate to form a pair of shorter meiosis II spindles. Between stages (f) and (g) two significant events occur: 1) the formation, outside each primary SPB plaque, of secondary SPB plaques along with vesicles that are the anlagen of the forespore envelopes (FSE); 2) the formation of a nuclear bulge forming adjacent to each SPB that enlarges while the central part of the nucleus shrinks. (g) Around each nuclear lobe an FSE forms and increases at the margins (h), following the contours of the nuclear lobes (Guth et al. 1972, Beckett et al. 1973, Moens 1974). (i) The pursing of the FSEs finally isolates the lobes, initiating the ascospores. The excluded central portion of nucleoplasm becomes part of the epiplasm. The primary ascospore wall is deposited in the FSE as the nuclear lobe is being severed and it may become quite thick while there is still a gap in the spore wall.

initially appears as a flattened vesicle just outside the SPB with a lumen of the same density as the rest of the cytoplasm; it soon becomes compressed and filled with a dense matrix (Moens 1971, 1974, Zickler and Olson 1975). The primary ascospore wall is deposited in the FSE as the nuclear lobe is being severed and it may become quite thick. A comparable ontogeny occurs in *Wickerhamia fluorescens* (Rooney and Moens 1973a,b) and *Eremothecium ashbyi* (Rosing 1987).

The primary ascospore wall layer is electron transparent, smooth, and generally is of uniform thickness. Secondary wall material is deposited on the outside of the primary wall under the outer membrane and is usually electron dense and distinctively patterned (Kurtzman et al. 1972, 1980b, Kreger-van Rij and Veenhuis 1975a, 1976a, Kreger-van Rij 1977a, 1979, Kurtzman and Kreger-van Rij 1976, Mikata and Banno 1987). Sometimes, however, the secondary wall material has

nearly the same density as the primary wall, e.g., *Ascoidea* (Ashton and Moens 1979), *Cephaloascus* (Ashton and Moens 1979), *Pichia* (Bandoni et al. 1967, Black and Gorman 1971), *Hanseniaspora* (Kreger-van Rij 1977b), and *Saccharomycodes* (Simmons and Ahearn 1985). In *Sporopachydermia* the secondary wall, uniquely, becomes very thick and irregular (Rodrigues de Miranda 1978, Kreger-van Rij 1978, Simmons and Ahearn 1987).

In *Debaryomyces hansenii* karyogamy generally occurs in the budding isthmus after which only one nuclear lobe, FSE, and subsequent ascospore is formed, while the rest of the nucleus disappears (Kreger-van Rij and Veenhuis 1975a). Nuclear separation prior to FSE formation and primary wall deposition occurs in *Ascoidea* (Ashton and Moens 1979), *Cephaloascus* (Ashton and Moens 1979), *Dipodascopsis* (Curry 1985), *Pichia* (Black and Gorman 1971), *Saccharomycopsis* (Kreger-van Rij and Veenhuis 1975b, Ashton and Moens 1979), *Schizosaccharomyces* (Yoo et al. 1973, 1990), and *Taphrina* (Syrop and Beckett 1972).

4.1.2. Conjugation: When suspensions of the mating types of *Pichia canadensis* (synonym *Hansenula wingei*) are mixed, up to 80% of the cells fuse in pairs (Conti and Brock 1965). The process of agglutination causes considerable wall deformation as maximum cell-to-cell contact is achieved. Subsequently, the cells elongate in the contact region, the walls fuse and then partially dissolve, and plasmogamy occurs. Nuclei move toward the isthmus and quickly fuse on contact. Following karyogamy a bud develops from the conjugation tube; its occupation by the zygote nucleus establishes the teleomorph phase (see Crandall et al. 1977).

A similar ontogeny occurs in *Saccharomyces cerevisiae* (Osumi et al. 1974, Byers and Goetsch 1975, Cross 1988) (Fig. 4: g-l). Conjugation, here and probably in other heterothallic species, requires synchronization of haploid cycles that are regulated by mating substances. SPBs of gametic cells have satellites and extranuclear mt's that, initially, are associated with the developing intercellular connection and, later, with the SPB of each nucleus as they migrate together. SPBs retain their opposing orientation as they lead the nuclei towards the intercellular gap where they meet and fuse. The narrow intercellular opening restricts nuclear passage to the extended, SPB-bearing region. Karyogamy proceeds by the fusion of the two SPBs and contiguous nuclear envelopes. Formation of the fusion SPB marks the end of the prolonged cdc G₁ arrest, coincident with conjugation, and is followed by SPB duplication as in a typical cell division. The first bud of the diplophase usually emerges from the fusion site. In *Saccharomycopsis* (*Guilliermondella*) *selenospora* (Kreger-van Rij and Veenhuis 1976a), conjugation tubes from different hyphae fuse at their tips and karyogamy occurs in the channel; subsequently a new wall is formed in the channel and the parent cells become asci.

4.2. Phylum Basidiomycota

Species that produce highly diverse basidiocarps are made up of tertiary mycelia, specialized hyphae that have the characteristic dolipore/parenthesome septal complex. Meiosis occurs in basidia that may, after division, remain entire (holobasidia) or become variously septate (phragmobasidia). Generally four ballistospore basidiospores are produced on basidia but in some taxa (i.e., Gasteromycetes, Filobasidiales) spores are passively released.

Members of the Uredinales are highly evolved plant parasites and have complex life cycles with as many as five spore stages. Teliospore germination produces a metabasidium which, after meiosis, becomes a four-celled phragmobasidium. Dikaryotic mycelium of the rusts lacks clamp connections, is generally intercellular, and is limited to parts of leaves and other aerial organs of the host; basidiocarps are not formed. Sorus and spore ontogeny are determinant and regular (Hiratsuka and Sato 1982).

Teliospores in several orders are formed from dikaryotic hyphae; initially binucleate, they become diploid by maturity. During germination the diploid nucleus may divide mitotically before it or a sibling nucleus moves into a metabasidium and undergoes meiosis. Ontogeny of thin-walled teliospores in *Rhodosporidium toruloides* (Johnson-Reid and Moore 1972, Abe et al. 1977) is interpreted as follows: clamp-like hookcells emerge near septa as outgrowths on a broad base and develop into crozier-like, double clamp configurations in which the penultimate cells, after further development, become

Fig. 11. Teliospore formation above a hookcell in *Rhodosporidium* (from Johnson-Reid and Moore 1972). The spore forms from a penultimate cell in a "crozier" over "clamp" system in which the hookcell ("clamp") is the antepenultimate cell that later fuses with the ultimate cell (see Fig. 12D/E). Bar = 2.5 μ m.

Fig. 12. Interpretation of teliospore formation in *Rhodosporidium*, original drawing based on Seyfert (1927) and Johnson-Reid and Moore (1972): (A-B) terminal hookcell type that mimics crozier formation (see Banno 1967); (C-E) lateral double-clamp or hookcell ("crozier")-on-clamp type.

teliospores (Fig. 11); teliospores may also be formed from apical crozier-like cells. A diagrammatic interpretation of teliospore development is given in Fig. 12. Similar teliospore ontogenies appear to be present in *Leucosporidium* (Moore 1972), *Rhodosporidium (Konodoa) malvinellum* (Fell 1970b, Yamada et al. 1989a), and *Sporidiobolus pararoseus* (de Hoog and Boekhout 1982).

Teliospore germination usually starts with a mitotic division in which one nucleus remains in the spore while the other enters the developing basidium (Zundel 1953); iterations of this ontogeny probably explains the formation of additional basidia (Fischer and Holton 1957, Christensen 1963, Durán and Safeeula 1968, Ingold 1983). Exceptions have been reported in *Tilletia*: Goates and Hoffman (1987) found that meiosis in several species occurred within the teliospores before the metabasidium emerged. Therrien et al. (1988) also found that teliospores of *Tilletia indica* were multinucleate at the time of germination. The order Ustilaginales (smuts) is characterized by metabasidia that become septate after meiosis. The basal cell of the phragmobasidium occupies the teliospore; the basidiospores (also called sporidia) generated from each cell usually arise near a septum. Meiosis in *Ustilago maydis* (O'Donnell and McLaughlin 1984a, O'Donnell 1992) is similar to that reported for other basidiomycetes (Uredinales excepted). In *Exobasidium* (Blanz 1978, Mims et al. 1987), basidial initials develop within the dikaryotic stroma and give rise to lateral, uninucleate holobasidia on the lower leaf surface. After meiosis four to seven sterigmata develop per basidium. The tip of each sterigma enlarges into a basidiospore which remains attached abaxially; a hilar appendix body and discharge droplet are not produced. Instead, basidiospores are passively released and grow in a yeastlike manner (Mims and Richardson 1987, Mims et al. 1987).

4.3. Phylum Ustomycota

Moore (1972, 1987b, 1988a, 1996a-d, 1997) proposed

that there are basic phylogenetic differences between the rusts and the smut fungi and assigned the latter group to the phylum Ustomycota. Although the phylum Ustomycota has not been adopted in this book, readers may become familiar with this alternative system of classification by consulting the foregoing references.

Chapter 6

Chemotaxonomy based on the polysaccharide composition of cell walls and capsules

H.J. Phaff

Contents

1. Introduction	45
2. Ascomycetous cell envelopes	45
3. Basidiomycetous cell envelopes	46
4. Capsular polysaccharides	47

1. Introduction

Comparison of the composition of polysaccharides that make up the cell wall and capsule of capsulated yeasts has had a significant impact on the systematics and phylogeny of yeasts. Such information has proven to be of value mainly at the generic and suprageneric level. Only a small number of species of yeasts has been investigated in depth with regard to the constituent monosaccharides and derivatives, and even fewer studies have focused on the structural details of their constituent polysaccharides. The cell wall composition of additional species is often inferred from information obtained with related species.

Historical reviews on the development of our knowledge of the yeast cell envelope have been published by Phaff (1971, 1977), Fleet and Phaff (1981), Fleet (1984, 1985, 1991), Golubev (1991a), Cabib (1981), and Cabib et al. (1984). An excellent review on the assembly of the various cell wall components of yeasts was recently published by Klis (1994). Most information based on chemical analyses has been derived from studies of cell walls from *Saccharomyces cerevisiae* and a few related ascomycetous species. It is often assumed that other multilaterally budding ascomycetous yeasts have a similar composition, although there is evidence from studies with cell wall lytic enzymes that there are quantitative as well as structural differences among the component polysaccharides of different species (Tanaka et al. 1966).

2. Ascomycetous cell envelopes

Ascomycetous budding yeasts contain an alkali-insoluble acid-insoluble β -(1 \rightarrow 3)-glucan as the major structural component. Associated with this polysaccharide is a low proportion of an alkali-insoluble acid-soluble highly branched β -(1 \rightarrow 6)-glucan and an alkali-soluble β -(1 \rightarrow 3)-glucan with a significant number of β -(1 \rightarrow 6)-bonds in its branched structure (see Fleet and Phaff 1981) for structural details). There is a very low chitin content in ascomycetous, multilaterally budding yeasts, which is

mainly confined to the bud scar areas of the wall and thus the proportion of chitin varies with the number of daughter cells that have been produced (Cabib 1981).

The remaining major component of the cell wall of these yeasts is a glucomannan-protein complex (Ballou 1976). More recently, Van Rinsum et al. (1991) and Montijn et al. (1994) have explored the attachment of the glucomannoproteins to the other polysaccharides of the cell wall. Their findings show that the glucomannoproteins contain β -(1 \rightarrow 6)-linked glucose-containing side chains (in addition to the already known N- and O-linked chains) to the protein moiety of the mannoprotein. Evidence presented suggests that the glucose-containing side chains might be extended with β -(1 \rightarrow 3)-linked glucose chains that could interweave with the β -(1 \rightarrow 3)-glucan fibrils in the wall and thus anchor the glucomannoproteins. Presumably this linkage is eliminated during the extraction procedures of the glucomannoprotein.

Significant differences in the carbohydrate moiety have been demonstrated, particularly in the mannan side chains of the branched molecule (Ballou 1976, 1982). Selective acetolysis has played a major role in the elucidation of yeast mannan structure (Kocourek and Ballou 1969, Ballou 1976). With controlled acetolysis, the α -(1 \rightarrow 6) linkages of the mannan backbone are selectively cleaved, and the oligosaccharides thus formed (representing the mannose side chains including one mannose residue originally part of the backbone) can be separated according to size by gel filtration. The elution pattern appears to be reproducibly characteristic of a particular yeast species, thus providing a "fingerprint" of this mannan.

The molar ratios of the various oligosaccharides can be determined from the areas under the elution peaks. A comparison of elution patterns (fingerprints) of a significant number of species has shown that this approach can constitute a useful parameter in yeast taxonomy. Although this method provides information on the proportion and size of the oligosaccharide side chains in various mannans, it does not reveal without further analysis the types and distribution of the linkages between the mannose units in the side chains.

Another approach to the fingerprinting of mannans was developed by Gorin and Spencer (for a comprehensive review see Gorin and Spencer 1970). They determined and compared proton magnetic resonance spectra of

isolated mannans from a large number of yeast species. These spectra provided sensitive criteria for distinguishing mannans of different species or for showing their similarity. At 70°C the H-1 and DOH signals give complex patterns in the τ 4.0–5.0 region. The chemical shifts of the H-1 proton signals depend on the structure of the parent anhydrohexose unit, the position(s) substituted in the unit, the structure of the substituent unit, the structure of the aglycone unit if one is present, and the position(s) substituted in such an aglycone unit. With this technique, a large number of water-soluble mannose-containing polysaccharides could be distinguished. Gorin et al. (1969b) concluded that polysaccharides with similar proton magnetic resonance spectra have related chemical structures, and thus mannans from different yeast species that produce similar or identical spectra indicate that these species are closely related.

This technique has been helpful in confirming or rejecting postulated anamorphs and teleomorphs of the same species (Manachini 1979), and in establishing tentative groups of seemingly related species in heterogeneous asexual genera such as *Candida* (Spencer and Gorin 1969a). Proton magnetic resonance spectra have also been used (a) to evaluate various types of evidence for proposed phylogenetic lines in *Pichia* (synonym *Hansenula*) species (Spencer and Gorin 1969b), (b) to obtain presumptive evidence for the occurrence of β linkages in the side chains of mannans, resulting in distinctive H-1 signals at a higher field than τ 4.55 (Gorin et al. 1969a), and (c) to detect sugars other than mannose in the mannans (Gorin and Spencer 1968).

As mentioned briefly above, multilaterally budding ascomycetous yeasts contain about 1–2% chitin that is confined almost entirely to the bud scar areas. However, a small percentage (around 0.1%) is located throughout the lateral walls (Molano et al. 1980, Roncero et al. 1988a,b). Most of the evidence is based on studies with *S. cerevisiae* and it is assumed that other budding ascomycetous yeast species have a similar chitin distribution. In contrast, budding yeasts of basidiomycetous affinity, for example in species of the basidiomycetous anamorphs *Cryptococcus*, *Rhodotorula*, and *Sporobolomyces* (Bartnicki-Garcia 1968), have a much higher chitin content (up to approximately 10%) and this form of chitin is present as microfibrils and not concentrated as granular chitin in bud scar zones. The chitin content of walls of filamentous ascomycetes is significantly higher than in *S. cerevisiae*, e.g., in species of *Saccharomycopsis* and the euascomycete *Eremascus*. The chitin content of hyphal forms of *Candida albicans* has been found much higher than that in the budding form of that species. The chitin content of species of the bipolarly budding genus *Nadsonia* is much higher than that of species of the genera *Hanseniaspora* and *Saccharomycodes*, suggesting that *Nadsonia* is not closely related to the last two genera (reviewed by Phaff 1971, Fleet 1991). Ribosomal RNA comparisons also suggest *Nadsonia* to be only distantly related to the other two

genera (Kurtzman and Robnett 1994a). It should be added that detailed knowledge about the chitin content of species of most yeast genera is still lacking or incomplete, making its significance to yeast systematics uncertain.

The cell wall composition of the fission yeast *Schizosaccharomyces* differs in several major respects from that of the budding ascomycetous yeasts. Earlier conclusions that species of this genus do not contain chitin have proven to be incorrect. Sietsma and Wessels (1990) reported a small proportion (0.5% of the dry weight of the wall) of a partially acetylated glucosaminoglycan, that is covalently linked to β -(1→3)-glucan of the wall. Treatment of the walls with chitinase greatly decreased the content of alkali-insoluble β -(1→3)-glucan and increased the fraction of alkali-soluble β -(1→3)-glucan, suggesting that the chitinous fraction of this yeast is bound to the alkali-insoluble β -(1→3)-glucan component. These authors also demonstrated the presence of a chitin synthase in a membrane fraction of *S. pombe*. Further characterization of the chitin synthase gene of *S. pombe* has been reported by Bowen et al. (1992).

Species of *Schizosaccharomyces* contain in addition to the β -glucans of the budding yeasts another major structural polysaccharide, i.e., α -(1→3)-glucan, which is soluble in alkali (Bacon et al. 1968, Meyer and Phaff 1980). The mannan component of *Schizosaccharomyces* is also different from that of the budding yeasts in that it has single galactose units attached to the backbone rather than oligomannose chains (Ballou 1976). The fission yeasts thus have a unique cell wall composition and do not appear closely related to any other group of ascomycetous yeasts, an observation consistent with comparisons of rRNA (Kurtzman and Robnett 1994a). It should be pointed out that the occurrence of α -(1→3)-glucan in *Schizosaccharomyces* is not unique, because it is also found as a major cell wall component in *Cryptococcus* and *Phaffia* (Bacon et al. 1968, Meyer and Phaff 1977) and in numerous species of filamentous fungi (Fleet and Phaff 1981), but this polysaccharide appears lacking in *Rhodotorula* species (Meyer and Phaff 1977).

The presence of unusual sugars or sugar derivatives in the cell wall has had a large impact on the systematics of yeasts at the generic or suprageneric level. As mentioned above, the genus *Schizosaccharomyces* is characterized by the occurrence of *galactomannan* in the wall. Weijman (1977) compared the cell wall composition of *Dipodascus* and *Dipodascopsis* and found that the monotypic genus *Dipodascopsis* contains glucuronic acid in the cell wall but this uronic acid is absent in *Dipodascus* spp. This finding supports the separation of *Dipodascopsis* from *Dipodascus*.

3. Basidiomycetous cell envelopes

The presence or absence of D-xylose in the cell envelope or whole cell extracts also has had an important bearing on yeast systematics at the generic level. Von Arx and Weijman (1979) placed yeast species of heterobasidiomycetous

affinity (based on mode of bud formation) in two families depending on the presence or absence of D-xylose. The Sporobolomycetaceae (lacking xylose and frequently containing fucose) included species of *Rhodotorula*, *Rhodospiridium*, *Sporobolomyces*, and some species of *Candida*. The Filobasidiaceae (containing xylose and usually glucuronic acid) included species of *Bullera*, *Cryptococcus*, *Filobasidium*, *Phaffia* and some species of *Candida* and *Trichosporon*. Later, Weijman and Rodrigues de Miranda (1983) reported xylose in the majority of *Bullera* species, but a few *Sporobolomyces* species also contained xylose. No definitive steps for reclassification of the nonconforming species were taken by these authors. Subsequently, Suzuki and Nakase (1988a) established by a more sensitive analytical technique that xylose was lacking in *Bullera salicina* and *Bullera tsugae*, and Nakase and Itoh (1988) transferred these two species to the genus *Sporobolomyces*. Nakase and Suzuki (1986c) confirmed the finding by Weijman and Rodrigues de Miranda that *Sporobolomyces puniceus* contains xylose in the cells and they transferred this species to the genus *Bullera* as *B. punicea* comb. nov. These new combinations emphasize the lesser importance of ballistospore morphology and other minor morphological details in the systematics of these genera as compared to chemotaxonomic and other molecular criteria such as Co-Q (Nakase et al. 1991a). Studies on the presence of unusual sugars and sugar derivatives in cell walls have also given support for the separation of species in the genera *Candida* and *Trichosporon* with ascomycetous and basidiomycetous affinity (von Arx and Weijman 1979, Weijman and Rodrigues de Miranda 1988). Sugiyama et al. (1985), in their study of the genera *Rhodospiridium*, *Leucosporidium*, *Cystofilobasidium*, *Filobasidium*, and *Filobasidiella*, emphasized the importance of the presence of xylose in dividing the species into two major groups.

An important criterion of relating the carotenoid-containing new genus *Saitoella* to the ascomycetes, was the absence of xylose in the cells (Goto et al. 1987a). In spite of the many useful results referred to above, it should be emphasized that the carbohydrate composition of the yeast cell envelope is not a decisive criterion by itself in yeast systematics, but is valuable only in

combination with other chemotaxonomic and molecular approaches, including ribosomal DNA sequence analysis. Such a polyphasic approach has been advocated by a number of authors for a reliable taxonomic system.

4. Capsular polysaccharides

The composition of capsular polysaccharides (Golubev 1991a) has also been found useful as an aid in yeast systematics. Early studies on the slimy phosphomannans found in certain species of *Pichia* (*Hansenula* spp.) pointed to their common ancestry (Wickerham and Burton 1962). The presence of a linear mannan with alternating β -(1 \rightarrow 3)- and β -(1 \rightarrow 4)-bonds in some *Rhodotorula* species and an acidic heteropolysaccharide containing xylose, mannose and glucuronic acid in *Cryptococcus*, has supported the transfer of several species of *Rhodotorula* to *Cryptococcus* (Phaff and Spencer 1969) and has established a relationship between *Cryptococcus* and the heterobasidiomycetous genus *Tremella* (Slodki et al. 1966). It has been suggested by Slodki and Wickerham (1966) that the lack of D-galactose in the capsule of *Lipomyces lipofer* would be a useful criterion to separate this species from *L. starkeyi*, because these species are difficult to separate on the basis of the usual assimilatory reactions. However, as pointed out by Phaff and Kurtzman (1984), mutations have been reported where a capsulated strain of *L. lipofer* changed into a microcapsulated variant with a much higher galactose content (Gorin et al. 1978). The same authors also found that an occasional strain of *L. tetrasporus* contained an unusually low level of galactose in its capsule, making the differentiation between *L. tetrasporus* and *L. lipofer* difficult on this basis. Another complication in the use of chemical composition of capsular material in yeast systematics is the problem of purity of the preparation to be analyzed (Golubev 1991a). Because of the difficulty of separating capsular polysaccharides from exocellular, excreted polysaccharides and fragments of cell walls, there appears to be doubt that at least some of the literature reports were based on sufficiently purified capsular preparations.

1. Introduction

The differences in amino acid sequences found among enzymes of different organisms is a reflection of organismal genetic divergence. Amino acid substitutions can often be detected from the extent of migration shown by enzymes on electrophoretic gels and the visualized patterns are termed zymograms. Electrophoretic comparisons of enzymes have been used to study taxonomic relationships among molds and mushrooms (Blaich and Esser 1975, Jones and Noble 1982, Micales et al. 1986, Nasuno 1971, Nealson and Garber 1967, Okunishi et al. 1979, Royse and May 1982, Schmidt et al. 1977, Stout and Shaw 1973, 1974, Sugiyama and Yamatoya 1990, Toyomasu and Zennyozzi 1981, Yamatoya et al. 1990, Zambino and Harrington 1992, Zamir and Chet 1985) as well as among yeasts and yeastlike fungi (Baptist and Kurtzman 1976, Sidenberg and Lachance 1983, 1986, Smith et al. 1990b, Yamazaki and Goto 1985, Yamazaki and Komagata 1981, 1982a,b). The focus of our review is to examine the extent of genetic resolution provided by electrophoretic comparisons of enzymes and the use of this technique for solution of taxonomic problems among yeasts.

2. Commonly used methods

Different electrophoretic techniques, including starch gel electrophoresis, polyacrylamide gel electrophoresis (PAGE), and isoelectric focusing, can be used. Although gel support media differ, PAGE generally gives good separation and repeatability for yeasts. Advantages of the different methods of electrophoresis have been discussed by Murphy et al. (1990). The method used will often be determined by availability of equipment and expertise.

3. Preparation of cell-free extracts for electrophoresis

Cells can be disrupted with a mechanical cell homogenizer

(e.g., B. Braun, Melsungen, Germany) using a coolant such as liquid CO₂. After treatment, insoluble debris and unbroken cells are removed by centrifugation, and the liquid supernatant is used directly for electrophoretic analyses of enzymes (Sidenberg and Lachance 1983, 1986, Smith et al. 1990b, Yamazaki and Komagata 1981). The electrophoretic apparatus often used is for vertical slab gels. Polyacrylamide gels have been used by Davis (1964), Sidenberg and Lachance (1983, 1986) and Yamazaki and Komagata (1981), but starch gels also give good results (Baptist and Kurtzman 1976, Nealson and Garber 1967, Royse and May 1982, Singh and Kunkee 1977, Zamir and Chet 1985). Further details may be found in the work of Bonde et al. (1993) and Micales et al. (1986).

4. Enzymes commonly compared

The staining procedures for detection of enzymes in electrophoretic gels have been described by Siciliano and Shaw (1976). Yamazaki and Goto (1985), Yamazaki and Komagata (1981, 1982a,b, 1983a,b), and Yamazaki et al. (1982, 1983, 1985) compared the following enzymes: fructose-1,6-bisphosphate aldolase (EC 4.1.2.13), hexokinase (EC 2.7.1.1), phosphoglucosmutase (EC 2.7.5.1), alcohol dehydrogenase (EC 1.1.1.1), lactate dehydrogenase (EC 1.1.1.27), malate dehydrogenase (EC 1.1.1.37), 6-phosphogluconate dehydrogenase (EC 1.1.1.41), glucose-6-phosphate dehydrogenase (EC 1.1.1.49), glutamate dehydrogenase (EC 1.4.1.4), fumarase (EC 4.2.1.2), esterase (EC 3.1.1.1), catalase (EC 1.11.1.6) and tetrazolium oxidase. These enzymes were chosen because they play important roles in the metabolism of yeasts. The enzymes superoxide dismutase (EC 1.15.1.1), alkaline phosphatase (EC 3.1.3.1), α -glucosidase (EC 3.2.1.20), β -glucosidase (EC 3.2.1.21), and exo- β -glucanase (EC 3.2.1.58) were examined by Sidenberg and Lachance (1983, 1986).

5. Data analysis

The application of electrophoretic data in systematic studies has been discussed in detail by Buth (1984) and Murphy et al. (1990). After staining, gels are dried under a vacuum with warming, and the relative mobilities of the enzyme bands are calculated as the ratio of the distance that the enzymes move from the origin to the distance that the tracking dye moves (Yamazaki and Komagata 1981).

Similarity values for the electrophoretic patterns of the enzymes are calculated by the formula

$$\%S = NS/(NS + ND) \times 100,$$

with S = similarity value; NS = number of enzymes showing identical mobilities; ND = number of enzymes showing different mobilities.

Similarity for each enzyme is calculated by the following formula:

$$\%S = 2NAB/(NA + NB) \times 100,$$

with S = similarity value; NAB = the number of enzyme bands with identical relative mobilities; NA = the number of enzyme bands of strain A; NB = the number of enzyme bands of strain B (e.g., Hamamoto et al. 1986a). Clustering is achieved by means of the unweighted-average linkage technique by the method of Sneath and Sokal (1973).

Sidenberg and Lachance (1983, 1986) used reciprocal averaging to ordinate the strains as a function of correlated electromorphs. The amount of information provided by each enzyme is evaluated by the following measure of entropy (I_j):

$$I_j = (n \times t_j \times \ln t_j) - \sum_{i=1}^n [(a_{ij} \times \ln a_{ij}) + (t_j - a_{ij}) \times \ln(t_j - a_{ij})],$$

where n is the number of strains, t_j is the total number of different electromorphs for the j th enzyme, and a_{ij} is the number of electromorphs of that enzyme present in the i th strain. The results are expressed in a matrix having the dimensions $n \times p$, where n strains are described by the presence (scored as 1) or absence (scored as 0) of each of p electromorphs. Reciprocal averaging is used to ordinate rows and columns of a frequency matrix and simultaneously reveals correspondences between two kinds of information (i.e., strains and electromorphs).

6. Resolution of taxa

In this review, selected groups of taxa are compared with respect to their isozyme profiles and their extent of nucleic acid divergence. By this approach, perspective is added to the resolution offered from use of the different techniques.

6.1. Ascomycetous yeasts

6.1.1. *Debaryomyces*: Yamazaki and Komagata (1982a) examined the electrophoretic patterns of 10 enzymes of *Torulopsis candida* (= *Candida famata*), a species then regarded as the anamorph of both *Debaryomyces hansenii* and *D. marama*, and found that strains of *T. candida* fell into three groups. Nakase and Suzuki (1985a,b) compared phenotypically similar strains of *D. hansenii* and related yeast taxa with respect to DNA base composition, nuclear DNA (nDNA) reassociation,

ubiquinone structure, PMR spectra of mannans, and serological reactions. The 50 strains of *D. hansenii* examined were classified into three groups (I, II, III) based on nDNA reassociation (Price et al. 1978). Group I consisted of two subgroups, Ia and Ib, which are considered to represent two distinct varieties. The first and second groups of Yamazaki and Komagata (1982a) corresponded to subgroup Ia and group III, respectively. These groups and subgroups could be discriminated from one another by maximum growth temperature, assimilation of propylene glycol, and electrophoretic patterns of glucose-6-phosphate dehydrogenase and malate dehydrogenase. *Debaryomyces coudertii* and *D. marama*, which resemble *D. hansenii*, were distinguished from each other and from strains of groups I, II and III by electrophoretic patterns of the preceding two enzymes. On the basis of this information, groups I, II and III, and subgroups Ia and Ib were taxonomically described by Nakase and Suzuki (1985b).

Kurtzman and Robnett (1991) and Yamada et al. (1991a) estimated evolutionary affinities among species of *Debaryomyces* from partial rRNA (18S and 26S) gene sequences. Their phylogenetic studies showed that *D. hansenii*, *D. coudertii*, *D. marama*, and *D. nepalensis* are closely related. These results are congruent with data from other chemotaxonomic comparisons, including zymograms and nDNA relatedness, which suggest the four taxa to be biologically separate members of a closely related species complex.

6.1.2. *Kluyveromyces*: Species of the genus *Kluyveromyces* have been compared with respect to enzyme patterns and nuclear DNA relatedness. The type strains of 20 phenotypically defined species of *Kluyveromyces* were examined by gel electrophoresis of 11 isofunctional enzymes (Sidenberg and Lachance 1983). Polymorphisms were evident in most of the enzymes studied. Each type strain had a unique pattern when all enzymes were considered. The results of a multivariate analysis of the electrophoretic patterns supported the division of the genus into 13 species. Enzyme electrophoresis provided evidence that widespread gene flow does not occur between yeasts which are able to hybridize in the laboratory. Additionally, Sidenberg and Lachance (1986) described the results of an electrophoretic characterization of seven enzymes to assess the degree of variability within the *Kluyveromyces marxianus* complex and to determine the taxonomic relationships of these populations based on reproductive isolation as it appears to have occurred in nature. Some strains of *Candida* considered to be anamorphs of *Kluyveromyces* as well as one strain each of *C. sake*, *Saccharomyces cerevisiae* and *Pichia fluxuum*, were also examined. The enzyme patterns readily substantiated the relationships between putative anamorphs and teleomorphs and the nonmember status of strains not belonging to the genus. A multivariate analysis of the enzyme patterns indicated that isolates belonging to

Fig. 13. Similarity of strains of *Brettanomyces*, *Dekkera* and *Eeniella* based on relative electrophoretic mobilities of five cellular enzymes (Smith et al. 1990b).

K. lactis and *K. marxianus* DNA reassociation groups are not phenotypically continuous with one another. Results from studies of nuclear DNA reassociation demonstrated the same species groups within *Kluyveromyces* as defined from the preceding electrophoretic comparisons (Fuson et al. 1987, Vaughan-Martini and Martini 1987b).

6.1.3. *Brettanomyces/Dekkera/Eeniella*: Smith et al. (1990b) examined the taxonomic status of various species of the teleomorphic genus *Dekkera* and the anamorphic genera *Brettanomyces* and *Eeniella* by electrophoretic comparison of five enzymes (Fig. 13), with respect to nDNA relatedness (Table 6), and with respect to physiological reactions. Enzyme patterns demonstrated the presence of two *Dekkera* species [*D. anomala* with anamorph *B. anomalus* (= *B. clausenii*), *D. bruxellensis* (= *D. intermedia*) with anamorph *B. bruxellensis*] and three *Brettanomyces* species [*B. bruxellensis* (= *B. abstinens*, *B. custersii*, *B. intermedius*, *B. lambicus*), *B. custersianus* and *B. naardenensis*] that were recognized from low (0–29%) similarity values. Strains of each species (except *D. bruxellensis*) showed similarity values of 80–100%. *D. bruxellensis* strains were divided into two clusters: one cluster has a high similarity value (85–100%) while strains of the second cluster showed a

similarity value of 38–70%. Using the guideline that strains with a similarity level of 40% and greater belong to the same species (Hamamoto et al. 1986a), the two clusters were considered conspecific. *Eeniella nana* showed a unique enzymic pattern that differed from other *Brettanomyces* and *Dekkera* species (0–5% similarity). Results from nDNA reassociation supported the conclusions drawn from electrophoresis of enzymes because strains within each taxon showed 70% or greater complementarity.

More recently, Boekhout et al. (1994) determined partial nucleotide sequences (ca. 600 nucleotides) of a divergent domain near the 5' end of the 26S rDNA gene for species of *Dekkera* (anamorph *Brettanomyces*), *Hanseniaspora* (anamorph *Kloeckera*) and *Eeniella* to reconstruct the phylogenetic relationships of these taxa. As shown in Fig. 14, monophyly of the *Dekkera/Brettanomyces/Eeniella* clade is strongly supported by a high bootstrap value (100%), as is the branch supporting *D. anomala* and *D. bruxellensis*. However, the branching order for *B. naardenensis*, *E. nana* and *B. custersianus* is only weakly resolved (51%). Taxonomic conclusions based on comparisons of enzyme patterns (Fig. 13), nDNA relatedness (Smith et al. 1990b, Table 6) and partial 26S rDNA sequence divergence (Fig. 14) are generally complementary.

Table 6
Extent of nDNA reassociation among strains of *Brettanomyces* and *Dekkera*

6.2. Basidiomycetous yeasts

6.2.1. *Rhodosporeidum/Rhodotorula/Erythrobasidium/Cystofilobasidium*: Yamazaki and Komagata (1981) used slab gel electrophoresis with specific staining for seven enzymes to compare 108 strains belonging to the genera *Rhodotorula* and *Rhodosporeidum*. Subsequently, their data were analyzed numerically (Hamamoto et al. 1986a). Strains with coenzyme Q-10 were divided into six clusters, strains with coenzyme Q-9 separated into two clusters, and strains with coenzyme Q-8 were assigned to two clusters. At ca. 60% or greater similarity, strains of the teleomorphic species *Rhodosporeidum diobovatum*, *R. sphaerocarpum*, *R. dacryoidum*, *R. malvinellum*, and *R. infirmominiatum* segregated into species-level clusters. Among these species, the extent of intraspecific

nDNA relatedness (*R. malvinellum* was not compared) was high (64–99%). Consequently, nDNA complementarity, type of ubiquinones, and similarity of enzyme patterns (see Hamamoto et al. 1987) argue that the preceding taxa represent well-defined species.

Divergent enzyme patterns have served to signal phylogenetic diversity among other red yeasts. For example, three strains of *R. lactosa* divided into two groups based on their ubiquinone systems (Yamada and Kondo 1973), enzyme patterns (Yamazaki and Komagata 1981) and DNA base composition (Hamamoto et al. 1986b). The new species *Rhodotorula hasegawae* was proposed by Yamada and Komagata (1983) for one strain of *R. lactosa* having coenzyme Q-10(H2). Subsequently, Hamamoto et al. (1988a) found that the species produced a holobasidium from a single cell without prior mating, and described it in the new teleomorphic genus *Erythrobasidium* which was tentatively placed in the Filobasidiaceae. Recently, Sugiyama and Suh (1993), Suh and Sugiyama (1994) and Suh et al. (1993a) have suggested that *E. hasegawianum* occupies an unusual position within the basidiomycete lineage having simple septa as defined by Swann and Taylor (1995b). In another example, the anamorphic species *Rhodotorula sinensis* showed ca. 60% similarity to *Rhodosporeidum infirmominiatum*. Extent of relatedness between this taxon and species of *Cystofilobasidium*, as determined from similarity of isozymes, is shown in Fig. 15 (Hamamoto et al. 1986a,b, 1988b). The relationships depicted are strongly supported by partial rRNA sequence comparisons (Yamada and Kawasaki 1989a, Fell et al. 1992).

Fig. 14. Phylogenetic tree showing relationships among species of *Brettanomyces*, *Dekkera* and *Eeniella*. The tree was calculated using the branch-and-bound option of the program PAUP 3.1.1 and based on ca. 600 nucleotides from the 5' end of 26S rDNA (recalculated from the data of Boekhout et al. 1994). Numbers indicate bootstrap values.

Fig. 15. Dendrogram calculated from similarity values of the electrophoretic mobilities of enzymes from species in the genera *Rhodosporidium*, *Cystofilobasidium* and *Rhodotorula* having coenzyme Q-8 (Hamamoto et al. 1986a).

6.2.2. The *Sterigmatomyces* complex: Yamada and Banno (1984a) and Yamada et al. (1988a,b) reassigned species classified in *Sterigmatomyces* to four anamorphic genera having the following characteristics:

- *Sterigmatomyces*: separation of buds at mid-sterigma, coenzyme Q-9, cellular xylose absent.
- *Tsuchiyaea*: separation of buds at mid-sterigma, coenzyme Q-9, cellular xylose present.
- *Kurtzmanomyces*: distal separation of buds from the sterigma, coenzyme Q-10, cellular xylose absent.
- *Fellomyces*: distal separation of buds from the sterigma, coenzyme Q-10, cellular xylose present.

It is unclear from phenotypic data whether species assigned to the preceding genera and the teleomorphic genus *Sterigmatosporidium* are biologically distinct. Yamada et al. (1986a,b) examined genealogical relationships among these genera using numerical analysis based on the similarities of electrophoretic patterns of seven enzymes. All strains of *Sterigmatomyces elviae*, *S. halophilus*, and *Sterigmatosporidium polymorphum* compared gave a uniform enzyme pattern within their respective species. Strains of *S. halophilus* showed 43% similarity with strains of *S. indicus*. The similarity between *S. elviae* and *S. halophilus* was only 14%. Kurtzman (1990a) addressed the question of species separation among this group of taxa from the perspective of nDNA relatedness. Consistent with the preceding electrophoretic comparison of *Sterigmatomyces*, only *S. halophilus* and *S. indicus* showed more than low levels of nDNA relatedness. *S. halophilus* and *S. indicus* had nearly 100% nDNA relatedness and are considered to be conspecific although their similarity based on enzyme patterns is comparatively low (43%).

The three species of *Fellomyces* (*F. fuzhouensis*, *F. penicillatus*, *F. polyborus*), and *Kurtzmanomyces nectairei*, formerly classified in *Fellomyces*, had quite different enzyme patterns (0% similarity). Furthermore, the similarity between *K. nectairei* and *Sterigmatosporidium polymorphum* was only 14%. The extent of nDNA relatedness among *Fellomyces* species ranged from 0–8%, indicating that all of these taxa are genetically separate species. Similar low levels of nDNA relatedness were detected between *Fellomyces* species, *K. nectairei*, and *S. polymorphum*, a species whose anamorph is typical of the genus *Fellomyces*. Comparisons of enzyme patterns and nDNA relatedness showed that *Sterigmatomyces fuzhouensis* and *S. tursiopsis* are conspecific.

Guého et al. (1990) examined relationships among species in the preceding genera with respect to sequence comparisons of selected regions of small (18S) and large (26S) subunit rRNAs. Their sequence data support the concept of Yamada and Banno (1984a) and Yamada et al. (1988a,b) that *Sterigmatomyces*, *Fellomyces*, *Tsuchiyaea* and *Kurtzmanomyces* represent separate genera. The molecular data also indicate that the genus *Fellomyces* is closely related to the teleomorphic genus *Sterigmatosporidium*. The only point of doubt concerns *Tsuchiyaea wingfieldii* which invariably clusters closely with *Filobasidiella neoformans* in rRNA analyses.

In conclusion, the extent of genetic resolution derived from electrophoretic comparisons of selected enzymes generally parallels results from nDNA reassociation. Both methods resolve to the sibling species level, whereas rRNA sequence comparisons detect relationships at greater genetic distances.

Chapter 8

Mycocins (Killer Toxins)

W.I. Golubev

Contents

1. Introduction	55
2. Characteristics of mycocins	55
3. Taxonomic implications of sensitivity to mycocins	58
4. Taxonomic implications among the ascomycetous yeasts	58
5. Taxonomic implications among the basidiomycetous yeasts	59

1. Introduction

Almost 30 years ago strains of *Saccharomyces cerevisiae* were found to secrete a protein (killer toxin) lethal to other strains (sensitive) of the same species (Makower and Bevan 1963). These strains (killers) were immune to their own toxins. Some strains (neutral) neither secreted the toxin nor were they sensitive to it. Subsequent studies revealed that in most killer strains of *S. cerevisiae*, the toxin is produced by a linear dsRNA. Another dsRNA encodes a protein that encapsulates the dsRNAs into a virus-like particle (VLP). The VLPs are noninfectious and are transmitted by vegetative cell division or through sexual fusion (Tipper and Bostian 1984, Schmitt and Tipper 1990).

The killer phenomenon provides an excellent model system to study host-virus interactions in eukaryotic cells (Wickner 1989), and to investigate the mechanisms of protein processing and secretion (Douglas et al. 1988). Possible uses for killer phenomena, which have aroused great interest, include the protection of industrial fermentations against contaminating yeasts (Rosini 1989) and the differentiation of pathogenic (Morace et al. 1983/84) and patented strains (Vaughan-Martini et al. 1988). In addition, killer dsRNA was shown to have interferon-inducing activity (Nosik et al. 1984) and the killer toxin has a therapeutic effect (Polonelli et al. 1986).

For a proper understanding of the killer phenomenon, it is necessary to emphasize that it is not unique for yeasts. Production of proteins having toxicity specific for related organisms, which is associated with specific immunity, is known for smut fungi (Koltin 1988), paramecia (Quackenbush 1988), slime molds (Mizutani et al. 1990) and bacteria (Konisky 1982). The bacterial protein antibiotics are termed bacteriocins and, to accent the general nature of such antagonistic interactions, it is preferable to call yeast killer toxins mycocins and killer strains mycocinogenic strains.

In the yeasts studied, mycocin determinants are cytoplasmically inherited. Killer systems similar to that of

Saccharomyces cerevisiae dsRNA exist in *Hanseniaspora uvarum* (Zorg et al. 1988), *Sporidiobolus johnsonii* (*S. salmonicolor*) (Kitaite and Čitavičius 1988), and *Cystofilobasidium bisporidii* (Karamysheva et al. 1991). Mycocin production in *Kluyveromyces lactis* (Stark et al. 1990), *Pichia acaciae* (Worsham and Bolen 1990) and *P. inositolovora* (Ligon et al. 1989) is associated with linear dsDNA plasmids. The killer phenotypes in *Candida glabrata* (Sriprakash and Batum 1984) and some strains of *S. cerevisiae* (Goto et al. 1990) are encoded by chromosomal genes. In many cases the genetic basis for killer activity has not been characterized but is presumed to be of chromosomal origin.

2. Characteristics of mycocins

All yeast mycocins studied are proteinaceous. They are either proteins or glycoproteins that consist of two or three subunits. In most yeasts, the molecular weights of secreted toxins are around 10 000–20 000 D (Bussey and Skipper 1975, Middelbeek et al. 1979, Pfeiffer and Radler 1982, 1984, Ashida et al. 1983, Ohta et al. 1984, Yamamoto et al. 1986, Yokomori et al. 1988, Suzuki and Nikkuni 1989) although the molecular weights of glycoprotein mycocins produced by *Kluyveromyces lactis* and *Pichia anomala* are much higher (100 000 D and greater) (Sugisaki et al. 1983, Stark and Boyd 1986, Kagiya et al. 1988, Sawant et al. 1989). The secreted K1 mycocin (20 658 D) of *Saccharomyces cerevisiae* consists of α and β disulfide-linked polypeptides with a high content of hydrophobic and charged amino acids (Palfree and Bussey 1979, Zhu et al. 1987). The K1 precursor, which has been synthesized in cells, has a large single-strand polypeptide in which the α and β subunits are separated by an interstitial glycosylated γ -region (Bostian et al. 1984, Lolle and Bussey 1986).

After exposure to most mycocins, growing sensitive cells exhibit a reduction in intracellular pH and leakage of potassium ions, ATP and other cellular intermediates. Amino-acid transport and proton pumping to the culture medium are also inhibited (Skipper and Bussey 1977, Middelbeek et al. 1980b–d, Ashida et al. 1983). All of these effects are indicative of an increase in proton permeability in mycocin sensitive cells (de la Pena et al. 1981). Apparently, a mycocin becomes incorporated into the cytoplasmic membrane and creates ion permeable channels (Kagan 1983, Martinac et al. 1990). The overall

effect of pore formation disrupts the cell electrochemical potential across the membrane and eventually results in cell death. Many, but not all yeast mycocins are pore-forming glycoproteins. The *Khuyveromyces lactis* mycocin, for example, does not elicit leakage of potassium ions and ATP but causes an arrest in the G1 phase of the cell cycle (White et al. 1989, Butler et al. 1991). The mycocin from *Williopsis saturnus* var. *mrakii* inhibits β -1,3-glucan synthesis (Yamamoto et al. 1986) and the KT28 toxin of *Saccharomyces cerevisiae* inhibits DNA synthesis (Schmitt et al. 1989).

Regardless of the mode of action of mycocins, the first step of cell interaction is binding to the cell wall surface. In contrast to the time-lag process of membrane damage, binding of K1 mycocin to yeast cells is rapid and energy-independent (Al-Aidroos and Bussey 1978, Bussey et al. 1979). Binding is pH-dependent and may be responsible for the pH range of mycocin activity on yeast cells. Binding sites may be particular cell wall receptors, which have other functions, for instance, the uptake of nutrients. These receptors play a role not only in binding but, apparently, in translocation of mycocins through the wall inside the cell where they reach their targets and exert killing action.

Comparison of mycocin killing spectra on whole cells and on spheroplasts showed that the cell wall determines the specificity of mycocin action. *Saccharomyces cerevisiae* toxin K1 can kill cells of the same species and those of *Candida glabrata* (Bussey and Skipper 1976, Young and Yagiu 1978), but it has a wide spheroplast-killing action and can kill the spheroplasts from *Candida albicans*, *C. utilis*, *Khuyveromyces lactis* and *Debaryomyces (Schwanniomycetes) occidentalis* although the whole cells of these species are insensitive to the toxin (Zhu and Bussey 1989). It has been shown that β -1,6-glucan is a component of cell-wall receptors for the *S. cerevisiae* mycocin (Hutchins and Bussey 1983) and also for *Hanseniaspora uvarum* mycocin (Radler et al. 1990). Probably, the β -subunit of the K1 mycocin is a lectin-like domain that is essential for recognition and binding (Sturley et al. 1986, Douglas et al. 1988). The mannoprotein of the cell wall binds another mycocin, KT 28, of *S. cerevisiae* (Schmitt and Radler 1987, 1988). Mutations that change the molecular structure of cell wall glucans and mannans alter their capacity to act as receptors, prevent binding of the mycocins and induce resistance to them (Schmitt and Radler 1988, Nakajima et al. 1989). Yeast and hyphal forms of the same organism are different in their sensitivity to mycocins (Golubev and Boekhout 1992) as there are differences in the composition of their walls (Cole and Nozawa 1981).

The early studies of the killer phenomenon were limited to *Saccharomyces cerevisiae* and were devoted to genetic, biochemical and molecular biological aspects, although in the 1970s, mycocinogenic strains were reported in other yeast genera (Philliskirk and Young 1975, Stumm et al. 1977, Kandel and Stern 1979). Until recently there

has been little rational basis for selecting the sensitive strains employed and most surveys of the incidence of killer yeasts in culture collections or natural substrates used one or two strains of *S. cerevisiae* and *Candida glabrata*. The frequency of mycocinogenic strains proved low (Middelbeek et al. 1980a, Rosini 1983, Starmer et al. 1987). However, their frequency was higher when screening for killer activity was conducted between strains of the same species, for instance, *S. cerevisiae* (Naumov et al. 1986, Thornton 1986, Heard and Fleet 1987). Similarly, by cross-testing within a species and by using taxonomically related organisms as target cultures, it was found that 98% of 63 strains of *Rhodotorula mucilaginosa* (Golubev and Churkina 1990) and 35% of 62 strains of *Pichia membranifaciens* (Golubev and Blagodatskaya 1993) were mycocinogenic. These data demonstrated the principal trait of mycocins – their specific toxicity. They are active against organisms related to killers, and the choice of sensitive strains for detecting mycocinogenic strains has become a taxonomic problem.

At present, killer activity has been found in about 80 species representing almost 20 genera among both ascomycetous and basidiomycetous yeasts (Wickner 1985, Bruenn 1986, Young 1987) (Table 7). If one takes into account that several types of killers were identified in some species, then to date the number of killer types in yeasts is over 100.

One of the most important conditions for detecting killer activity is the pH of the test medium. Killer activity is expressed under acidic conditions, usually at a pH within the range of 3–6. As a rule, yeast mycocins are most active at pH 4–5 (Woods and Bevan 1968, Young and Yagiu 1978, Middelbeek et al. 1979, Tolstorukov et al. 1989). With some exceptions (Ohta et al. 1984, Vustin et al. 1989), mycocins are rapidly inactivated at increased temperatures, and 15–20°C is the preferred temperature range for incubation during the assay for killer activity. Addition of glycerol (10–15%) to the medium led to broader inhibition zones surrounding *Khuyveromyces* and *Pichia* killers and significantly increased the sensitivity of the bioassay (Lehmann et al. 1987b). Expression of killer activity by halotolerant yeasts is prompted and often enhanced in the presence of increasing (4–12%) NaCl concentrations (Kagiyama et al. 1988, Suzuki et al. 1989). Yeast mycocins are more stable in agar medium than in liquid, and agitation causes their inactivation (Woods and Bevan 1968, Wilson and Whittaker 1989). The concentration of sensitive cells influences the sensitivity of the bioassay; in the case of an abundant lawn of the sensitive strain and a small inoculum of the killer, the inhibition zone can be narrow and rapidly overgrown or not developed at all. In addition, the composition of the medium and buffer solution may contribute to the sensitivity of the assay (Panchal et al. 1985). As a rule, nutritionally rich organic media are more suitable than synthetic media. In most cases, glucose–yeast extract–peptone agar or malt agar with sodium citrate–phosphate

buffer are used. It is apparent that both the level and expression of mycocinogenic activity depends on a number of variables. In particular, the assay conditions can be crucial for detecting killers with low activity or those organisms that are weakly sensitive.

Yeast mycocins possess only antifungal activity and do not act against bacteria or protozoa. Further, no

pharmacological activity was detected in tests with animal organs (Ohta et al. 1984, Pfeiffer et al. 1988). A few reports of the antibiotic action of yeast killers against a wide variety of prokaryotic and eukaryotic organisms resulted from an unwarranted extension of the killer phenomenon to any observed growth inhibition (Polonelli and Morace 1986, Nagornaya et al. 1989). There were

no attempts to characterize the toxic substances cited in these reports and the growth inhibition observed was due to metabolic products other than mycocins. In many cases, the antibacterial activity of yeasts is caused by pH changes in the medium as a result of organic acid production or the selective uptake and exchange of ions. In respect to antifungal activity, it is necessary to distinguish the killer phenomenon from other inhibition effects, for example, arresting of growth from mating pheromones. The broad anti-yeast activity of fresh *Metschnikowia pulcherrima* isolates (Vustin et al. 1990) is probably associated with excretion of the iron-binding agent pulcherriminic acid.

3. Taxonomic implications of sensitivity to mycocins

It is well known that fungal cell walls are diverse in architecture and chemical composition, and some of these differences are of taxonomic importance (Bartnicki-Garcia 1968, Kreger-van Rij and Veenhuis 1971a, Fleet 1985, Weijman and Golubev 1987). Taking into account the proteinaceous nature of mycocins and the involvement of different cell wall components in their binding, it is reasonable to deduce that mycocin activity against whole cells may be restricted to taxonomically related organisms and that killer-sensitive interactions reflect taxonomic affiliation. Present evidence supports such a view although much experimental data need to be thoroughly examined as most workers engaged in research on the killer phenomenon do not consider taxonomic problems.

The main obstacle that delayed recognition of taxonomic specificity of mycocin action is the varying differences in host ranges. Although all mycocins are active against organisms taxonomically related to killers, the degree of relatedness may vary from strains of the same species to species of closely related genera or even higher taxa. Apparently, the diversity of cell-wall receptors involved in binding of mycocins can be both unique and common for some taxa and may be the basis of differences in mycocin action ranges. Until now, the primary functions of these receptors was not established in yeasts.

4. Taxonomic implications among the ascomycetous yeasts

Presently available information on killing patterns of mycocins produced by ascomycetous yeasts is extremely fragmentary and none of the screenings are wholly comprehensive. The sets of organisms used as target cultures are usually very limited and were not selected with a taxonomic perspective. As mentioned above, the K1 mycocin of *Saccharomyces cerevisiae* can kill the cells of the same species and *Candida glabrata*. Tolstorukov et al. (1989) reported that K1 mycocin is active against *Candida fluvialtilis*, *C. freyschussii* and *C. rugosa*, and the K2 mycocin of *S. cerevisiae* has a broad killing spectrum which additionally includes *Kluyveromyces marxianus*, *Pichia canadensis*, *Candida maltosa* and *C. tropicalis*.

The mycocins produced by *Kluyveromyces* spp. are active not only against species of this genus and their anamorphs (*Candida kefyri*, *C. pseudotropicalis*, *C. sphaerica*), but also inhibit the growth of a rather diverse group of yeasts (*Pichia anomala*, *S. cerevisiae*, *Zygosaccharomyces rouxii*, *Candida albicans*, *C. glabrata*, *C. intermedia*, *C. utilis* and *Kloeckera apiculata*) (Panchal et al. 1985, Lehmann et al. 1987a, Rosini and Cantini 1987). Vaughan-Martini and Rosini (1989) studied intrageneric killer-sensitive interactions in *Kluyveromyces*, and concluded that sensitivity is not a species-specific property, but is strain-related. However, such an interpretation did not consider a serious limitation of mycocin-sensitivity testing by simple plate assay, namely, it does not allow one to distinguish between immunity and resistance to mycocins. These two types of insensitivity differ fundamentally, both in their mechanisms and taxonomic significance. In *S. cerevisiae* the mycocins, or their precursors, contain a component which gives immunity (specific for only one mycocin type) to killer strains. Killers, when cured of the extrachromosomal genome which produces the mycocin, became sensitive to its action. Immunity appears to be conferred at the cytoplasmic membrane level and this component may act as a competitive inhibitor of mycocin by saturating membrane receptors (Boone et al. 1986, Hanes et al. 1986, Douglas et al. 1988). The so-called neutral strains contain the genetic determinants for mycocin synthesis, either the mycocin is produced in an inactive form or it is not secreted. Consequently, such strains retain immunity (Bussey et al. 1982, Wingfield et al. 1990). Thus, the insensitivity caused by immunity is a clone-related property, which, when coupled with possible cross-immunity between the killers and neutral strains-producing immunologically similar mycocins, may interfere with resistance shown at the cell-wall level and conferred by the nuclear genotype. All these reasons taken together can give a complicated picture of killer-sensitive relationships. For example, the study of the genus *Kluyveromyces* demonstrated that more than half of the strains examined were of killer and neutral phenotypes (Vaughan-Martini and Rosini 1989). The preceding observations are the major reasons why many authors consider the sensitivity patterns to be a strain-specific property and propose to use them as a fingerprinting tool to biotype strains of a species. In respect to closely related organisms, the responses to mycocins that are free from the effects of immunity are of taxonomic interest. In such instances, it was found that all *Kluyveromyces yarrowii* strains (which are a sensitive phenotype) have identical responses to *Kluyveromyces* mycocins. Interestingly, the strains of *K. marxianus* (*K. fragilis*) and *Candida pseudotropicalis* have the same sensitivity patterns but differ from *C. kefyri*, a synonym. These data are consistent with electrophoretic karyotypes, antigenic reactions, and long-chain fatty acid profiles (Caretta et al. 1980, Viljoen and Kock 1989a).

Many species in the genera *Pichia* and *Williopsis* produce mycocins (Table 7). No representatives of

these genera, except for *W. (Zygowillipsis) californica* (Nomoto et al. 1984), could be cured of their killer activity and none of the species had detectable dsRNA or DNA plasmids. The observations suggest that mycocin production in these species is determined by nuclear genes. Most mycocins produced by *Pichia* and *Williopsis* are heat stable but are protease-sensitive and function over a wide pH range (Ashida et al. 1983, Ohta et al. 1984, Vustin et al. 1989). They have broad activity and kill species in the ascosporegenous genera *Saccharomycopsis (Arthroascus)*, *Debaryomyces (Schwanniomycetes)*, *Kluyveromyces*, *Saccharomyces*, *Zygosaccharomyces*, *Pichia*, *Williopsis (Zygowillipsis)* and *Saccharomycodes*. By contrast, members of the genera *Clavispora*, *Hanseniopsis*, *Metschnikowia*, *Torulasporea*, *Williopsis* and *Schizosaccharomyces* were resistant to these mycocins (Kagiyama et al. 1988, Sawant et al. 1988, Vustin et al. 1988a, Suzuki et al. 1989). It should be noted that representatives of the genus *Candida* are heterogeneous with respect to their sensitivity patterns (Yamamoto et al. 1988, Vustin et al. 1988b, Tolstorukov et al. 1989) and species of basidiomycetous affinity are insensitive to the mycocins produced by ascomycetous yeasts. *Williopsis pratensis* is an exception. Its mycocin is active not only against *Debaryomyces hansenii*, *D. (Schwanniomycetes) occidentalis*, *W. (Zygowillipsis) californica* but also against some basidiomycetous yeasts, namely, sporidiobolaceous species (Vustin et al. 1991). In the genus *Pichia*, *P. acaciae* and *P. inositovora* differ

both in genetic determination of killer phenotype (see above) and apparently in the limited ranges of organisms susceptible to their mycocins (Worsham and Bolen 1990, Hayman and Bolen 1990).

5. Taxonomic implications among the basidiomycetous yeasts

With the exception of *Cryptococcus humicola* (Golubev and Shabalin 1994), none of the mycocins produced by basidiomycetous yeasts are active against ascosporegenous yeasts. Moreover, the host ranges of *Rhodotorula* and *Sporidiobolus* mycocins include only organisms classified in the family Sporidiobolaceae (Table 8) whereas mycocins of *Cryptococcus*, *Cystofilobasidium* and *Filobasidium* kill members of the order Tremellales including the Filobasidiaceae (Table 9). As a rule, sporidiobolaceous yeasts are insensitive to mycocins produced by tremellaceous species as well as the reverse. Recently, it was found that although *Rhodotorula fujisanensis* mycocin mainly acts against sporidiobolaceous yeasts, it also shows a weak activity against some strains of tremellaceous yeasts (Golubev 1992a). These differences between sporidiobolaceous and tremellaceous yeasts in sensitivity and killing patterns of their mycocins correlates with the whole range of important taxonomic and phylogenetic markers, for example septal pore ultrastructure (Moore 1987b), monosaccharide composition of capsular polysaccharides (Weijman and Golubev 1987), and sequence similarity of small (Gottschalk and Blanz 1985) and large subunit

rRNAs (Fig. 16). Similar to the activity found for ascomycetous mycocins, basidiomycetous mycocins generally have no fixed taxonomic level for their action. In practice, this feature dictates that the use of each mycocin as a taxonomic tool must be preceded by a careful study of the killing pattern. Owing to different host ranges, mycocins may serve to resolve different levels of taxonomic

organization. Broad-spectrum mycocins are apparently of more interest for overall phylogenetic evaluations, whereas narrow-spectrum mycocins may be used for clarification of the taxonomy of some closely related organisms.

The mycocin produced by *Rhodotorula pallida* has the narrowest known range of action; only strains of this species and *R. minuta* are affected by its action (Golubev

Fig. 16. Similarity of basidiomycetous taxa from partial 18S and 26S rRNA sequences (phylogenetic tree with bootstrap values recalculated by C.P. Kurtzman from the data of Guého et al. 1989), and the sensitivity (+) or insensitivity (-) of the species to mycocins produced by *Sporidiobolus johnsonii* (Golubev and Tsiomenko 1985), *S. pararoseus* (Golubev et al. 1988), *Rhodotorula glutinis* (Golubev 1989a), *Filobasidium capsuligenum* (Golubev and Kuznetsova 1989), and *Cystofilobasidium bisporidii* (Golubev 1990b).

1992b). Sensitive cultures show decreased budding, but cell viability is not affected. The mycocins secreted by *Sporidiobolus johnsonii* (*Sporobolomyces salmonicolor*) act mainly against species of *Sporidiobolus* and its anamorphs (Golubev and Tsiomenko 1985). The killing patterns from *Sporidiobolus pararoseus* (Golubev et al. 1988) and *Rhodotorula glutinis* are wider (Table 8). Yeast phases of smut fungi of the genera *Microbotryum*, *Sphacelotheca* and *Ustilago* are sensitive to *R. glutinis* mycocin (Golubev 1989a). The mycocin produced by the type strain of *Cryptococcus laurentii* has an inhibitory effect on yeast phases of the genera *Atractogloea*, *Itersonilia*, *Microstroma* and *Trimorphomyces* (Golubev and Kuznetsova 1989). Except for *Trimorphomyces syzygius*, these taxa are sensitive to *Cystofilobasidium bisporidii* mycocin. In addition, the latter acts against species in *Calocera*, *Guepiniopsis* and rust fungi of the genera *Puccinia* and *Gymnosporangium* (Golubev 1990b). According to our data, these rust fungi assimilate D-glucuronate, produce xylose-containing exopolysaccharides, have ubiquinones Q-8, 9, 10 (Sugiyama et al. 1988) and show high sequence homology in their 5S rRNA when compared with tremelloid yeasts (Gottschalk and Blanz 1985). Although this evidence supports the proposal that the Uredinales are the ancestral group which gave rise to the auricularioid and tremelloid fungi (Linder 1940), it is now believed that the yeast stages of the rust fungi that

were studied represent contaminating tremelloid yeasts (P.A. Blanz, unpublished data, chapter 10).

In many cases, all strains of the same species and closely related species of the same genus have identical responses to specific mycocins. However, some taxa are heterogeneous not only within a genus but also within a species. Several reasons for such heterogeneity were mentioned above (immunity of killer and neutral strains, mutants with modified cell-wall components), but there is one more important reason – the taxonomic heterogeneity of many yeast taxa. As a rule, the teleomorphic taxa (taking into account immunity) are homogeneous in this respect in contrast to the anamorphic species in which the heterogeneity in sensitivity patterns occurs much more frequently. For example, almost all strains of *Sporidiobolus* spp. are sensitive to *Rhodotorula glutinis* mycocin while the ballistosporogenous genera *Sporobolomyces* and *Bensingtonia* include both sensitive (Table 8) and resistant species (*S. gracilis*, *S. lactophilus*, *S. oryzicola*, *S. sasicola*, *S. subbrunneus*, *B. naganoensis* and *B. subrosea*). The reassignment of basidiomycetous *Candida* spp. to *Cryptococcus* and *Rhodotorula* (Weijman et al. 1988) resulted in higher heterogeneity of these anamorphic genera. The sensitivity to *Rhodotorula glutinis* and/or *R. mucilaginosa* mycocins supports the transfer of the species *Candida fragariorum*, *C. graminis*, *C. hylophila*, *C. ingeniosa*, *C. javanica*, *C. lignophila*, *C. muscorum*, *C. sonckii* and *Cryptococcus*

phylloplanus to the genus *Rhodotorula*. However, the species *Candida acuta*, *C. auricularia*, *C. bogoriensis*, *C. buffonii*, *C. diffluens*, *C. foliorum*, *C. philyla* and *C. pustula* are insensitive to the *Rhodotorula* mycocins. Among recently proposed combinations, *Cryptococcus amylolentus*, *C. hungaricus*, *C. marinus* and *C. podzolicus* are sensitive to *Filobasidium capsuligenum* and/or *C. podzolicus* mycocins (Table 9) but *Candida aquatica*, *C. curiosa*, *C. huempii*, *C. tsukubaensis* and *Cryptococcus yarrowii* are not. In contrast to typical cryptococci, the latter, besides containing xylose, also have fucose and rhamnose in their exocellular polysaccharides (Golubev and Blagodatskaya 1978, Roelijmans et al.

1989). Unlike *Sterigmatomyces* and *Kurtzmanomyces*, species of *Fellomyces* and *Sterigmatosporidium* are sensitive to mycocins produced by tremellaceous yeasts and this observation is in keeping with relationships determined from rRNA sequence comparisons (Guého et al. 1990).

Much of the preceding data suggest that killer-sensitive relationships reflect phylogenetic relatedness between yeasts. The presence of immunity to killer toxins and possible occurrence of resistant mutants limits the value of mycocin sensitivity for identification. However, the killer phenomenon may be an additional taxonomic tool with which to examine yeast classification.

1. Introduction

The definition of a species, whether of higher plants, animals, or microorganisms, has as its basis the principle of genetic isolation. Simply put, members of a species are considered interfertile, whereas genetically separate species are not (Dobzhansky 1976). However, until the late 1960s, the primary means for defining species of yeasts lay with the subjective appraisal and weighting of phenotypic properties such as cellular morphology and growth responses on various sugars and other compounds. Although it was known that the assimilation and fermentation of many compounds were controlled by one or only a few genes (Lindegren and Lindegren 1949, Winge and Roberts 1949) and that using growth reactions could result in an erroneous definition of species, practical genetic means for defining species often did not exist. With the development of methods for measuring DNA duplex formation came the opportunity to define species on the basis of overall genetic similarity. When measurements of DNA reassociation are used to define species, the extent of DNA relatedness expected between members of a biological species must first be determined. In the discussion that follows, various aspects of this issue will be examined.

DNA relatedness studies have had a major impact on yeast systematics, but in this era of increasingly sophisticated molecular techniques that often involve gene sequencing, it is sometimes forgotten that DNA hybridization has provided the framework upon which many other types of molecular genetic comparisons have evolved. For this reason, results from DNA reassociation are considered the "gold standard" by many because they provide the first approximation of whether or not strains are members of the same biological species.

2. Cellular DNAs

Several classes of DNA occur in eukaryotes, and their

presence affects estimates of relatedness between taxa since it is the intent of most studies to measure genomic similarity from complementarity of single-copy nuclear DNA (nDNA) sequences. Christiansen et al. (1971) reported up to 15% rapidly renaturing sequences in the nDNA of yeasts, which may be interpreted as analogous to the repeated sequences found in higher eukaryotes (Britten and Kohne 1968). However, the presence of rapidly renaturing, plasmid-like 2 μ m circular DNA in *Saccharomyces cerevisiae* (Bak et al. 1972) with a buoyant density similar to nDNA suggests the proportion of repeated sequences in nDNA to be smaller than first thought. Similar circular DNA species have been reported from *Pichia canadensis* (*Hansenula wingei*) and *Candida glabrata* (O'Connor et al. 1975, 1976). Linear DNA plasmids have been discovered in *Kluyveromyces lactis* and many other species (Gunge et al. 1981, Fukuhara 1995). These plasmids, which are lighter than the densities of both nuclear and mitochondrial DNA, appear to be associated with killer characters of yeasts. The work of Timberlake (1978) indicates the genome of the fungus *Aspergillus nidulans* to consist of approximately 97–98% unique sequences and 2–3% repeated sequences. The repeated sequences appear to code for ribosomal RNA.

Nuclear DNA represents the preponderance of cellular DNA in yeasts, and it has a kinetic complexity of 6.5–14 $\times 10^9$ daltons or about two to five times that found in *Escherichia coli* (Christiansen et al. 1971, Petes et al. 1973). Between 5 and 20% of the total DNA in *S. cerevisiae* is mitochondrial in origin. It is present in a variable number of copies and is arranged in closed circles with a G+C content noticeably lower than the nDNA (Hartwell 1974). Sedimentation studies (Blamire et al. 1972) and measurements of contour length (Hollenberg et al. 1970, Petes et al. 1973) suggest a molecular mass of 46 $\times 10^6$ daltons. The mitochondrial DNA (mtDNA) contour length for several other yeasts has been reported to be 25–50% of that of *S. cerevisiae* (O'Connor et al. 1975, 1976, McArthur and Clark-Walker 1983).

3. DNA isolation and purification

Methods for isolation and purification of yeast DNA were previously described in detail and the following account will serve only as a brief review to direct attention to pertinent references. Most methods for DNA reassociation

require substantial amounts of DNA, and it is not uncommon to process 5–50 g (wet weight) of cells.

For most yeast strains, DNA isolation is relatively straightforward. Cell wall breakage may be effected by mechanical or lytic means. Mechanical methods have the advantage of being relatively rapid but, unless cell breakage is carefully monitored, considerable shearing of the DNA may result. The Braun cell homogenizer is one of the more frequently used mechanical devices, and causes breakage by shaking of buffered cell suspensions in the presence of 0.45 mm glass beads (Bak and Stenderup 1969, Price et al. 1978, Kurtzman et al. 1980a). An inexpensive variation of this technique involves placing the buffered cell and bead mixture into a test tube and “vortexing” the mixture (Lipinski et al. 1976, Van Etten and Freer 1978). Less frequently reported methods include grinding acetone-dried cells in a ball mill (Martini and Phaff 1973) and grinding cells in liquid nitrogen with a mortar and pestle (Storck and Alexopoulos 1970, Mendonça-Hagler et al. 1974). Sonication is seldom used for cell breakage because it is inefficient for yeasts and it causes extreme and uncontrolled DNA shearing.

Lytic methods offer the possibility of isolating DNA with a higher molecular weight than might be obtained by mechanical cell disruption. Meyer and Phaff (1969) and Bicknell and Douglas (1970) used a modification of the Smith and Halvorson (1967) technique in which cells undergo autolysis in the presence of saline containing EDTA (ethylenediamine tetraacetate), 2-mercaptoethanol and sodium dodecylsulfate. The commercial enzyme preparations Glusulase and Zymolyase 100T may be used to prepare osmotically fragile sphaeroplasts by cell wall digestion. Following this step, high molecular-weight DNA is isolated from the lysed sphaeroplasts. Cryer et al. (1975) have given details of these procedures. Zymolyase 100T generally promotes more rapid cell-wall dissolution than Glusulase, but neither enzyme preparation is particularly effective with basidiomycetes. Rhodes and Kwon-Chung (1982), however, reported dissolution of *Cryptococcus neoformans* cell walls with the multienzyme preparation Mutanase.

Following rupture or lysis of the cells, DNA isolation and purification may be carried out by the methods of Marmur (1961) and Bernardi et al. (1970) as detailed by Price et al. (1978). Basically, this consists of making the buffered cell suspension 1 M in sodium perchlorate and 1% in sarcosate and emulsifying with an equal volume of chloroform/iso-amyl alcohol (3-methylbutan-1-ol) (24:1, v/v). After incubation and phase separation by centrifugation, DNA is precipitated from the aqueous phase with cold ethanol. The DNA is treated with a combination of α -amylase and pancreatic ribonuclease (RNase), and finally with Pronase. Following enzyme removal, the DNA is again precipitated with ethanol, spooled, redissolved and further treated with α -amylase, pancreatic RNase and T₁ RNase. Additional purification can include

hydroxyapatite fractionation and/or banding in a cesium chloride gradient.

Some yeasts have active deoxyribonucleases (DNases) that escape denaturation during the usual extraction procedures and cause sufficient degradation of the DNA to prevent spooling. Several methods have produced various degrees of success for deactivating nucleases and merit testing if problems are encountered. Diethyl pyrocarbonate, used at 0.5–1.0% at the time of cell breakage, gave encouraging results in studies of *Lipomyces* spp. (D.L. Holzschu and H.J. Phaff, personal communication) and *Sporidiobolus* spp. (Holzschu et al. 1981). Ehrenberg et al. (1976) discussed the interaction of diethyl pyrocarbonate with nucleic acids and nucleases and emphasized some of the precautions to be taken. Allergy to the compound may be a problem for some individuals. Kurtzman et al. (1986) found that the spermine/spermidine/sucrose buffer of Morris, as cited by Timberlake (1978), was much more effective at inactivating nucleases in *Aspergillus* spp. and *Neurospora* spp. than the sucrose buffer frequently used in yeast studies (Price et al. 1978). This was confirmed by Guého et al. (1984, 1985) for species of *Geotrichum*, *Dipodascus* and *Trichosporon*. Methods for assessing DNA purity include chemical analyses as well as spectrophotometric measurements and have been summarized by Price et al. (1978) and Johnson (1981).

4. DNA base composition

4.1. Methodology

Base composition of nuclear and mitochondrial DNA, expressed as molar percentages of guanine-plus-cytosine (G+C), can be determined from thermal denaturation profiles (melts), buoyant density in cesium salt gradients generated by ultracentrifugation, chemical analysis, absorbance ratios, or high-performance liquid chromatography (HPLC) of nucleotides or free bases (Johnson 1981, Hamamoto et al. 1986b). Many investigators use thermal denaturation (Marmur and Doty 1962), but Bak (1973) showed that results obtained by this method can be greatly affected by sample impurities and/or minor DNA species and must therefore be interpreted with caution. Cesium chloride buoyant density determinations (Schildkraut et al. 1962) generally show the greatest accuracy since they are unbiased by the presence of contaminating RNA, mtDNA and other impurities such as carbohydrates and proteins.

4.2. Taxonomic uses of guanine-plus-cytosine (G+C) values

The taxonomic uses of G+C values are mainly exclusionary, because the 800 or so yeast species range in nuclear G+C contents from approximately 27–70 mol%, and overlap between unrelated species is inevitable. For example, *Zygosaccharomyces mrakii* and *Z. florentinus* have nuclear G+C contents of 42.2 and 42.4%, respectively, yet they show only 6.0% base sequence complementarity (Price et al. 1978). Since similar G+C contents do not

necessarily mean similar base sequences in the DNA, it must be determined how dissimilar G+C values need to be to state that two strains represent different species. This depends to some extent upon the method used for determination of base composition. When buoyant density is used, the span of G+C values among strains of a species is usually less than 1% (Price et al. 1978, Kurtzman et al. 1980a,b, Phaff et al. 1985), which is approximately coincident with the accuracy of the method, i.e., a standard deviation of 0.00–0.50 mol%. Thermal denaturation shows greater variation, and strains of a species may exhibit a G+C range of as much as 2% (Meyer et al. 1978). Thus, strains showing a difference in G+C contents in excess of 1.0–1.5% by buoyant density or 2.0–2.5% by thermal denaturation may be expected to represent different species.

The nuclear G+C content of ascomycetous yeasts is about 27–50%, whereas that of basidiomycetous yeasts is approximately 50–70%. Except for the narrow range of 48–52%, where some overlap occurs, the taxonomic affinity of anamorphs can be reliably determined from their base composition. For species in the doubtful range, placement can be made by examining cell wall structure under the transmission electron microscope (Kreger-van Rij and Veenhuis 1971a) or through use of the diazonium blue B test (van der Walt and Hopsu-Havu 1976, Hagler and Ahearn 1981). The range of G+C contents among species within a genus is quite often 10% or less as found in *Debaryomyces*, *Hanseniaspora*, *Issatchenkia*, *Kluyveromyces*, *Metschnikowia* and several other genera. Genera showing a range among species of greater than 10% may be polyphyletic, but a narrower range does not ensure monophyly.

5. DNA relatedness

5.1. Methodology

The methods for assessing DNA relatedness vary, but short of sequencing, they rely on measuring the extent and stability of renatured DNA strands from test pairs, i.e., the fidelity of complementary base pairing. The theoretical and operational aspects of DNA hybridization were elegantly presented by Britten and Kohne (1968), and their paper has served as a primer for those now using DNA reassociation techniques. Depending upon the method, the DNA may or may not need to be labelled with radioisotopes. An interesting variation of the DNA–DNA hybridization technique was employed by Bak and Stenderup (1969). Radioactive complementary RNA was synthesized *in vitro* with each test DNA serving as a template, and the relatedness between taxa was then assessed from hybridization of single-stranded DNA with the synthesized RNA.

In vivo labeling of DNA is frequently done using ^{14}C , ^3H or ^{32}P . Each isotope has its particular advantages and disadvantages. The DNA may also be labelled *in vitro* with ^{125}I (Commerford 1971, Mendonça-Hagler and Phaff

1975, Holzschu et al. 1979) or by nick translation (Kelly et al. 1970, Maniatis et al. 1975). DNA labelled with ^{125}I *in vitro* must be highly purified to completely remove RNAs, proteins and carbohydrates. Banding the DNA in cesium chloride in a preparative ultracentrifuge is usually adequate. Following labeling, DNA reassociation reactions may be carried out using the membrane method which involves immobilizing single strands of one of the DNA species onto nitrocellulose filters and allowing sheared single strands of the second DNA to react with the immobilized DNA (Denhardt 1966). Alternatively, both DNA species may be allowed to react in free-solution, and the extent of reassociation assessed by the extent of binding of the resulting duplexes to hydroxyapatite (Brenner 1973) or from their resistance to hydrolysis by S_1 nuclease (Crosa et al. 1973). Price et al. (1978), Johnson (1981), Jahnke (1987) and Kurtzman (1993b) provided references and detailed procedures for these methods.

Besides following DNA reassociation with radioactive preparations, the reactions may also be monitored spectrophotometrically by measuring the kinetics of duplex formation. This technique has been refined to the point where results are comparable to data obtained using isotopes (Subirana and Doty 1966, De Ley et al. 1970, Seidler and Mandel 1971, Kurtzman et al. 1980a).

Another non-isotopic method that shows promise is based on chemiluminescence (Adnan et al. 1993). Single-stranded target DNA is covalently linked in the wells of special microtitre plates and hybridized with photobiotin-labelled probe DNA. Following incubation, extent of reassociation is determined with a chemiluminescent reagent. Sugita et al. (1994) reported good correlation with the spectrophotometric method. Because spectrophotometers with programmable thermal control are not presently being manufactured, chemiluminescence may be a reliable non-isotopic alternative.

A number of factors affect DNA renaturation reactions and so may have a marked effect on the results obtained. Highly purified DNA preparations are essential. Contaminating protein or RNA can result in falsely high or low relatedness values depending on whether the contaminants act as single-stranded or double-stranded DNA in the assay system (Brenner 1973).

If comparisons of taxa are to be made from single-copy nDNA, it is necessary to remove mtDNA, plasmid-like circular DNA and repeat sequence nDNA. Circular plasmid-like DNA as well as circular mtDNA may be relatively easily separated from nDNA by centrifugation in cesium chloride in the presence of ethidium bromide. Williamson and Fennell (1975) emphasized that resolution is poor should mtDNA break into linear fragments during isolation, a not uncommon event. However, they point out that linear mtDNA may be effectively resolved in cesium chloride gradients when treated with 4',6-diamidino-2-phenylindole (DAPI), a fluorescent dye that preferentially binds with AT-rich DNA. Repeated sequences may be

removed from nDNA by partial reassociation of sheared DNA fragments to a C_0t value of 0.1–0.2 (C_0t is the initial nucleotide concentration in moles per liter multiplied by the time in seconds; Britten and Kohne 1968) followed by fractionation with hydroxyapatite (Price et al. 1978). Because the rate of reassociation is affected by concentration, multiple copies duplex most rapidly and can be removed because of their ability to bind to hydroxyapatite (Britten and Kohne 1968). Price et al. (1978) and Fuson et al. (1979) used this method to remove repeated sequences from yeast DNA for taxonomic studies. The fractionation undoubtedly also removes mtDNA and plasmid-like DNA because both occur as multiple copies and their small molecular weight would allow rapid reassociation when in significant concentration. The same effect may be obtained in spectrophotometric determinations of relatedness if the time between melting and cooling to the reassociation temperature ($T_m - 25$) is not too rapid. Under the conditions used by Kurtzman et al. (1980a), a cooling period of 12 min allowed duplexing of most repetitive nDNA sequences as well as those of mtDNA. Relatedness values of strains common to the work of Price et al. (1978) and of Kurtzman et al. (1980a) were essentially identical, showing that similar results can be obtained with rather different methodologies.

For most studies, DNA fragment size and the ionic strength of the incubation medium may be maintained at any constant value within a fairly wide range without significantly affecting the results (Brenner 1973). However, increasing ionic strength increases the reaction rate. Seidler et al. (1975) and Kurtzman et al. (1980a) used relatively high concentrations of standard saline citrate (SSC, 150 mM sodium chloride/15 mM sodium citrate, pH 7.0) when assessing DNA relatedness spectrophotometrically in order to complete the determination within a few hours. Thus, when C_0t values are used as a measure of the extent of reassociation, the ionic strength of the reaction mixture must be known if values obtained in different studies are to be compared. For example, the incubation mixture used by Kurtzman et al. (1980a) allowed DNA reassociation to proceed nearly five times faster than that which occurred in the buffer system employed by Price et al. (1978). As noted in the definition of C_0t values, initial nucleotide concentration also affects the reaction rate; consequently, a solution containing 100 μg of DNA per ml reassociates twice as fast as one containing 50 μg .

Optimal DNA reassociation occurs at 25° to 30°C below the midpoint of the melting curve (T_m), and this is dependent on base composition since GC base pairs with their triple hydrogen bonds have greater thermal stability than do AT pairs with their double hydrogen bonds (Marmur and Doty 1962, Marmur et al. 1963). Assuming that two yeast DNAs have melting temperatures of 85°C and thus the optimum reassociation temperature ($T_m - 25$) is 60°C, pairs that are highly related at 60°C also show high relatedness at more stringent temperatures such as 65°C or at 75°C. Pairs showing only moderate

relatedness at 60°C show much less binding at higher temperatures than closely related pairs, reflecting the greater mismatch of base pairs present. These studies point out the need for proper reannealing temperatures, and also show that higher incubation temperatures allow an estimate of stability that indicates the extent of base pair mismatch. Temperatures below $T_m - 25$ would show even greater reassociation for sparingly related pairs. Relatedness may also be estimated from the thermal stability of the renatured heterologous DNA as compared with renatured homologous DNA. This may be done spectrophotometrically by monitoring thermal melts or with labelled DNA by thermal elution from hydroxyapatite columns (Ullman and McCarthy 1973, Lachance 1980), or by the batch method of Brenner et al. (1969) as modified by Price et al. (1978). Brenner et al. (1972) equated one degree of difference in thermal stability with 1% mismatch in base pairs. Lower thermal stability (ΔT_m) usually correlates well with lower DNA complementarity.

6. Interpretation of DNA relatedness

6.1. Quantitation of relatedness

Measurements of DNA complementarity are commonly expressed as percent relatedness. This usage can be misleading because DNA strands must show at least 75–80% base sequence similarity before duplexing can occur and a reading is registered on the scale of percent relatedness (Bonner et al. 1973, Britten et al. 1974). As seen from the preceding discussion, experimental conditions greatly influence extent of duplex formation. Although replicate determinations often vary by 5%, different methods of measuring DNA relatedness do give essentially the same result. Consequently, when measured under optimum conditions, percent DNA relatedness provides an approximation of overall genome similarity between two organisms. However, the technique does not detect single gene differences or exact multiples of ploidy, but aneuploidy can often be detected (Vaughan-Martini and Kurtzman 1985).

6.2. Correlation with biological relatedness

On the basis of extensive comparisons between species of enteric bacteria, Brenner (1973) proposed that strains showing 70% or greater DNA relatedness should be considered members of the same species. Johnson (1973) compared numerous anaerobic bacteria, and arrived at essentially the same guidelines. Price et al. (1978) examined yeast species in four genera and proposed that strains having 80% or greater DNA relatedness were conspecific, an opinion expressed earlier by Martini and Phaff (1973) from their studies of *Kluyveromyces* spp. From studies of divergence among biotypes of the *Cryptococcus vishniacii* complex, Baharaeen et al. (1982) suggested that strains showing 60% or greater DNA relatedness were conspecific. The preceding guidelines concerning relatedness were based on the observation that strains of

Table 10

<i>Issatchenkia orientalis</i> × <i>Issatchenkia occidentalis</i>	Infrequent conjugation, ascospores not produced	3–8	Kurtzman et al. (1980b)

^a The names used are those appearing in the original publications.

species characterized by traditional means usually show 60–100% DNA complementarity.

Species boundaries can be prescribed on the basis of a number of criteria, but for sexually reproducing species, ability to hybridize and produce fertile successive generations would seem to be of cardinal importance. Dobzhansky (1976) noted that, among sexually reproducing and outbreeding organisms, species can be defined as Mendelian populations or arrays of populations that are reproductively isolated from other population arrays. He cited a number of examples of higher eukaryotes where interspecific hybridizations have been documented (*Drosophila* spp., mammals, frogs, fishes and plants). Fertility varies among hybrids, being rather rare among animal species but much more common among plants. Since conjugation in bacteria is infrequent and may not involve the entire genome, genetic studies could not form the basis for interpretation of DNA complementarity studies among these prokaryotes. Many yeasts, on the other hand, have known sexual states and with such species hybridization offers a means for correlating results from DNA studies with actual biological phenomena.

Comparisons of extent of nDNA complementarity with measurements of fertility among pairs of heterothallic yeasts have shown that increasing DNA relatedness parallels increased fertility, and that strains showing DNA relatedness at 70% or greater are usually conspecific (Table 10). This same trend was noted for homothallic yeasts (Kurtzman 1987b, 1991a). This is not surprising because homothallics often show some outbreeding through conjugation between independent cells. From these comparisons, the following predictions can be made concerning DNA complementarity and biological relatedness among strains: (1) conspecific strains generally exhibit in excess of 70% DNA relatedness; (2) varietal designations can be accorded to those strains showing 40–70% DNA relatedness unless genetic crosses demonstrate

the absence of interfertility. *Issatchenkia scutulata* and its variety *exigua* show some intervarietal fertility and at 25% DNA relatedness appear to be an exception. Conversely, *S. cerevisiae* and *S. pastorianus* show 58% relatedness, but appear to be independent species (Vaughan-Martini and Kurtzman 1985); (3) strains showing less than 40% DNA relatedness are nearly always genetically isolated and represent independent species.

Application of the preceding predictions of relatedness to anamorphic species may not be appropriate and can be criticized on the basis that species not undergoing sexual reproduction may evolve at different rates than teleomorphic taxa. A counter argument is that since sexual states are being continually discovered for anamorphic species, perhaps few yeasts are actually devoid of a meiotic cycle. Furthermore, the frequency of sexual reproduction for teleomorphic species in their natural habitats is unknown and many may be functional anamorphs. Perhaps the most definitive observation at present is that there appears to be neither a greater nor lesser range of DNA relatedness among strains of anamorphic species than found among teleomorphic species. As a consequence, application of the preceding predictions for recognition of anamorphic species from comparisons of DNA relatedness does not appear unreasonable.

7. Impact of DNA reassociation studies on yeast systematics

The information provided by DNA reassociation studies has had a profound impact on yeast systematics. Most notably, it has shown that many morphological and physiological characters used for definition of species and genera are taxon-specific and without phylogenetic significance. These characters include fermentation of glucose, nitrate assimilation, and presence or absence of pseudo- and true hyphae (Table 11). DNA reassociation

has also demonstrated the synonymy of quite a large number of species. This is illustrated by Table 12 where it is shown that 15 *Saccharomyces* "species" are conspecific with *S. cerevisiae*. Numerous other equally important examples of the impact of DNA reassociation are found in the *Comments* sections of species and genus descriptions later in this book.

Chapter 10

Ribosomal RNA/DNA sequence comparisons for assessing phylogenetic relationships

C.P. Kurtzman and P.A. Blanz

Contents

1. Introduction	69
2. Methods for isolation and characterization of rRNAs and rDNAs	69
3. Estimates of relatedness from rRNA/rDNA comparisons	69
4. Reliability of rRNA gene trees to infer phylogeny	72
5. Rapid molecular methods for yeast identification	74

1. Introduction

Comparisons of ribosomal RNA (rRNA) and its template ribosomal DNA (rDNA) have been used extensively in recent years to assess both close and distant relationships among many kinds of organisms. The interest in rRNA/rDNA comes from two important properties: (1) ribosomes are present in all cellular organisms and appear to share a common evolutionary origin, thus providing a molecular history shared by all organisms, (2) some rRNA/rDNA sequences are sufficiently conserved that they are homologous for all organisms and serve as reference points that enable alignment of the less conserved areas used to measure evolutionary relationships.

In this review, we will describe the impact that rRNA/rDNA comparisons are beginning to have on our understanding of evolutionary relationships among the yeasts and how this knowledge will influence development of a system of classification based on phylogeny. Additionally, we will discuss application of this new information to the practical goal of rapid yeast identification.

2. Methods for isolation and characterization of rRNAs and rDNAs

rRNAs occur in several size classes in eukaryotes; the genes coding for large (25S to 28S), small (18S) and 5.8S rRNAs occur as tandem repeats with as many as 100 to 200 copies. The separately transcribed 5S rRNA gene may also be included in the repeat (Garber et al. 1988). Each of the rRNA size classes has been examined for the extent of phylogenetic information present.

The large quantities of rRNAs expressed by cells make isolation and purification of these molecules relatively easy despite the nearly ubiquitous occurrence of quite stable RNases. Numerous methods for isolation and purification have been described. The procedures of Chirgwin et al. (1979) and their modification by Kurtzman

and Liu (1990) are generally satisfactory. Techniques for the isolation and characterization of rDNA have been described by White et al. (1990) and Vilgalys and Hester (1990).

Methods for sequencing nucleic acids are now commonplace. Techniques for 5S rRNA sequencing have been summarized and discussed by Walker (1984, 1985a). The procedures used for sequencing large and small subunit RNAs and DNAs are based on the dideoxy method of Sanger et al. (1977). Lane et al. (1985) have described the application of this method to rRNA sequencing through use of oligonucleotide primers and reverse transcriptase. Most initial comparisons of yeasts and other microorganisms were based on reverse transcriptase mediated sequencing of rRNAs because of the relative simplicity of this method over earlier rDNA sequencing techniques. Complete sequences often were not determined because McCarroll et al. (1983) and Lane et al. (1985) demonstrated that partial sequences of small subunit rRNAs provided essentially the same phylogenies as complete sequences.

White et al. (1990) and Kaltenboeck et al. (1992) provided protocols for sequencing rDNA using specific oligonucleotide primers and the polymerase chain reaction (PCR). rDNA sequencing results in fewer artifacts than rRNA sequencing, and the method offers the opportunity to sequence both strands of the rDNA genes, thus further reducing errors. Recently, methodologies again evolved with the introduction of automated sequencers.

3. Estimates of relatedness from rRNA/rDNA comparisons

3.1. rRNA/rDNA reassociation

The first extensive use of rRNA comparisons for yeast systematics was described by Bicknell and Douglas (1970), who measured species divergence from extent of reassociation between tritium-labeled 25S rRNA and complementary sites on filter-bound nuclear DNA. This and similar methods have been used by other workers, but because all species pairs must be tested, the comparison of large numbers of taxa is quite laborious. Another aspect of this procedure is that as evolutionary distances increase, a point is reached at which there is insufficient base sequence similarity to allow duplexing of paired molecules. It has been suggested that sequences must

exhibit 75–80% or greater similarity before reassociation can occur (Bonner et al. 1973, Britten et al. 1974).

3.2. Restriction fragment length polymorphisms of rDNA

Because rDNAs occur in multiple copies, they lend themselves to analysis based on restriction fragment length polymorphisms (RFLPs). Magee et al. (1987) treated rDNAs from several medically important *Candida* species with a variety of restriction endonucleases and concluded that *C. guilliermondii*, *C. tropicalis* and *C. albicans* produced sufficiently different digestion patterns to allow recognition of each species. Similar results were obtained by Vilgalys and Hester (1990) for several species of the genus *Cryptococcus*. Lachance (1990a) used RFLP patterns to map the genetic profiles of 125 isolates of the cactus yeast *Clavispora opuntiae* that had been collected worldwide. Nearly all restriction sites that allowed discrimination of individual strains were located in the hypervariable intergenic spacer region.

Data from the preceding studies show that RFLP patterns allow recognition of individual species as well as individual strains of a species. Consequently, the method has considerable diagnostic value. Estimates of evolutionary relationships from RFLP patterns have been reported for species assigned to *Candida* (Magee et al. 1987) and to *Cryptococcus* (Vilgalys and Hester 1990). Such estimates would be expected to be less accurate than estimates derived from sequence comparisons because as evolutionary distances increase, the extent of pattern similarities becomes less certain.

3.3. 5S rRNA

Because of the conserved nature and small size (ca. 120 nucleotides) of 5S rRNAs, their sequences are easily determined and have been widely used for estimating broad phylogenetic relationships (Hori and Osawa 1979). Walker and Doolittle (1982) compared 5S rRNAs from eight basidiomycetes, including four yeasts, and concluded that sequence similarity correlated with the structure of hyphal septa (i.e., simple pores versus dolipores). The report of Gottschalk and Blanz (1984) that rust fungi, which have simple septal pores, cluster with the group defined by Walker and Doolittle as having dolipore septa proved incorrect because contaminating yeasts had been sequenced instead of the yeast stages of the rusts (P.A. Blanz, unpublished data).

Based on 5S rRNA data, organisms of unknown systematic position can be grouped with known taxa. 5S rRNA nucleotide sequences allowed placement of *Microstroma juglandis* among the basidiomycetes (Gottschalk and Blanz 1984) whereas *Kabatiella microstricta* was shown to be ascomycetous (Gottschalk and Blanz 1985). *Agaricostilbum pulcherrimum* was the most divergent of all basidiomycetes examined (Blanz and Unsel 1987), while *Septobasidium carestanum* is related to *Phleogenia faginea* (Blanz and Gottschalk 1986) and the rusts (Müller

1989). On the basis of 5S rRNA sequences, the smut fungi were found to form two distinct groups. One parasitizes dicotyledonous host plants while the other parasitizes grasses (Blanz and Gottschalk 1984). The profound genetic divergence between these two groups of smuts is consistent with differences in morphological and chemical characters (G. Deml, personal communication). The affiliation of *Graphiola phoenicis* with the graminicolous smuts was shown from its 5S rRNA nucleotide sequence (Blanz and Gottschalk 1986). The limited similarity of the 5S rRNAs of *Rhodosporidium malvinellum* and *Rhodosporidium toruloides* (Gottschalk and Blanz 1985) was confirmed by Yamada et al. (1989a) from 18S and 26S rRNA partial nucleotide sequences. From these results, they transferred *R. malvinellum* to the new genus *Kondoa* (Yamada et al. 1989a).

Among ascomycetous yeasts, Komiya et al. (1981) determined the 5S sequence of *Schizosaccharomyces pombe*, and Mao et al. (1982) noted that it differed sufficiently from that of *Saccharomyces cerevisiae* to suggest that these two organisms are phylogenetically quite divergent. Similar results were obtained by Walker (1985a) who further showed the ascomycetes to be divided among three groups: (1) *Schizosaccharomyces* and *Protomyces*, (2) budding yeasts, and (3) filamentous fungi. Despite the importance of these phylogenetic studies, the 5S rRNA molecule is losing its prominence and is being replaced by the informationally richer 18S and 26S rRNA molecules which can now be easily sequenced.

3.4. 5.8S rRNA

With about 160 nucleotides, the 5.8S rRNA molecule is not much larger than 5S rRNA. Unlike the latter molecule, 5.8S rRNA contains modified nucleotides as do the 18S and 26S rRNA molecules. Consequently, when enzymatic sequencing is used as was done for 5S rRNA, the modified nucleotides are sometimes difficult to determine. Despite these disadvantages, several 5.8S nucleotide sequences have been analyzed, but only a few phylogenetic comparisons have been deduced from these data (Walker 1985b). More 5.8S rDNA data will become available as the ITS regions of the rDNA tandem repeats are analyzed because the 5.8S rRNA gene is located between the ITS regions.

3.5. Small subunit and large subunit rRNA/rDNA sequences

3.5.1. Close relationships: The compilation of large subunit RNA sequences by Gutell and Fox (1988) demonstrated the 5' end of this molecule to be quite variable and of potential use for detection of closely related species. Peterson and Kurtzman (1991) examined sequence divergence in this region for sibling species pairs from several yeast genera. These data showed that nucleotide differences in region 25S–635 (domain D2, Guadet et al. 1989) are sufficient to separate nearly all

Table 13
Extent of ribosomal RNA sequence divergence among sibling yeast species^a

Species pair	Percent nDNA relatedness ^b	Percent nucleotide differences in region 25S–635 ^c
Heterothallic species		
<i>Saccharomyces cerevisiae</i> × <i>S. pastorianus</i>	58	5.4
<i>Saccharomyces cerevisiae</i> × <i>S. bayanus</i>	10	5.4
<i>Saccharomyces pastorianus</i> × <i>S. bayanus</i>	70	0.0
<i>Pichia mississippiensis</i> × <i>P. amylophila</i>	25	2.0
<i>Pichia bimundalis</i> × <i>P. americana</i>	21	1.0
<i>Issatchenkia scutulata</i> × var. <i>exigua</i>	25	5.1
Homothallic species		
<i>Debaryomyces melissophilus</i> × <i>D. sp. n.</i>	30	0.7
<i>Saturnispora saitoi</i> × <i>S. ahearnii</i>	30	2.0
<i>Williopsis saturnus</i> × var. <i>sargentensis</i>	43	0.0

^a Data from Kurtzman (1984b, 1987b), Kurtzman and Robnett (1991), Kurtzman et al. (1980a,b), Liu and Kurtzman (1991), Peterson and Kurtzman (1990, 1991), Vaughan-Martini and Kurtzman (1985).

^b Conspecific strains generally exhibit in excess of 70% nuclear DNA relatedness. Varietal designations have been accorded those strains showing 40–70% nDNA relatedness unless genetic comparisons demonstrate the absence of interfertility. *I. scutulata* and its variety *exigua* show some intervarietal fertility and, at 25% DNA relatedness, appear to be exceptional because limited fertility would not be expected.

^cCa. 300 nucleotides in region 25S–635 (= region D2).

sibling species (Table 13). One exception is the pair *Saccharomyces bayanus*/*S. pastorianus*. It is believed that the latter species arose as a partial amphidiploid following chance hybridization between *S. cerevisiae* and *S. bayanus*, and that it retains the rDNA of *S. bayanus* (Kurtzman and Robnett 1991, Peterson and Kurtzman 1991, Vaughan-Martini and Kurtzman 1985). *Williopsis saturnus* and its variety *sargentensis*, which show no nucleotide differences in the region sequenced, are insufficiently studied to comment on their apparent lack of divergence (Liu and Kurtzman 1991). Some sibling species pairs show a five-fold difference in substitutions over that of other pairs, but this may not be definitive evidence for proposing unequal rates of nucleotide substitutions among species until the genetic processes that initiate species formation are better understood. With few exceptions, the D2 region is sufficiently variable to recognize ascomycetous and basidiomycetous yeast species, including most sibling pairs. Conspecific strains ordinarily show 0–1% divergence in this region, whereas the distantly related species *Pichia bimundalis* and *Schizosaccharomyces japonicus* var. *versatilis* exhibit ca. 47% substitutions (Peterson and Kurtzman 1991).

3.5.2. Distant relationships:

3.5.2.1. Ascomycetous yeasts: The phylogeny of the ascosporogenous yeasts has been vigorously debated since the time of Guilliermond (1912) and before. Some have viewed the yeasts as primitive fungi while others perceived them to be reduced forms of more evolved taxa. Cain (1972) has been a proponent of this latter idea, arguing that hat- (galeate)-spored genera such as *Pichia* and *Cephaloscypha* are likely to be reduced forms of

the perithecial euscomycete genus *Ceratocystis*. Redhead and Malloch (1977) and von Arx and van der Walt (1987) accepted this argument and commingled yeasts and mycelial taxa in their treatments of the Endomycetales and Ophiostomatales.

Examination of rRNA/rDNA sequence divergence from a limited number of taxa indicated the ascosporeogenous yeasts, with the exception of *Schizosaccharomyces*, to form a monophyletic group (clade) distinct from the filamentous species (Barns et al. 1991, Bruns et al. 1991, Hausner et al. 1992, Hendriks et al. 1992, Kurtzman 1993a, 1994, Nishida and Sugiyama 1993, Walker 1985a, Wilmotte et al. 1993). Kurtzman and Robnett (1994a) analyzed rRNA sequence divergence from type species of all cultivatable ascomycetous yeasts and yeastlike taxa. This work demonstrated the yeasts, as well as yeastlike genera such as *Ascoidea* and *Cephaloscypha* to comprise a clade sister to the “filamentous” ascomycetes (euscomycetes). *Schizosaccharomyces*, *Taphrina*, *Protomyces* and *Saitoella* form a divergent clade basal to the yeast–euscomycete branch. *Eremascus*, which forms asci unenclosed in a fruiting body, aligned with the euscomycete clade. These results substantiate the long-held observation that yeasts cannot be recognized solely on the basis of presence or absence of budding. Such members of the yeast clade as *Ascoidea*, *Eremothecium* (and its synonym *Ashbya*) show no typical budding, whereas *Aureobasidium*, *Phialophora* and certain other genera of euscomycetes are usually dimorphic. Budding is also a common mode of vegetative reproduction among many basidiomycetous genera. Similarly, vegetative reproduction by fission is shared by *Dipodascus* and *Galactomyces*, members of the yeast clade, as well as by the distantly related genus

Schizosaccharomyces. Sexual states of all members of the yeast clade are characterized by asci unenclosed in a fruiting body. This feature is shared by only a few taxa outside the yeast clade such as *Eremascus* and *Schizosaccharomyces*. *Myriogonium* and *Trichomonascus* form unenclosed asci but may be euascomycetes.

The impact of rRNA/rDNA comparisons on the taxonomy of ascomycetous yeasts is just beginning. Additional work is required to evaluate the assignment of species to genera and the relationships among genera. However, major findings to date include: (1) yeasts and yeastlike species are phylogenetically separate from the euascomycetes, (2) the fission yeast genus *Schizosaccharomyces* is phylogenetically distant from the "budding" yeast clade and from the euascomycetes, resulting in the reassignment of the fission yeasts to a separate order, the *Schizosaccharomycetales* (Eriksson et al. 1993, Kurtzman 1993a) and, (3) the demonstration that many phenotypic characters such as ascospore morphology are poor indicators of phylogeny (Kurtzman and Robnett 1991, 1994b, Liu and Kurtzman 1991). In a number of cases, these findings have been used to redefine taxa, and additional details may be found in the treatments of *Debaryomyces*, *Eremothecium*, *Lipomyces*, *Pichia*, *Saturnispora* and *Williopsis*. On the basis of rDNA sequence comparisons, Nishida and Sugiyama (1993) suggested the name Archiascomycetes for the clade comprising *Schizosaccharomyces*, *Saitoella*, *Taphrina*, *Protomyces* and *Pneumocystis*.

3.5.2.2. Basidiomycetous yeasts: Two morphologically distinct teleomorph states are found among the basidiomycetous yeasts (Fell and Kreger-van Rij 1984, Boekhout et al. 1993). In the first, teliospores are formed and germinate to produce a basidium (metabasidium) that bears basidiospores. This type of sexual cycle shows considerable similarity to the rust and smut fungi. The second type of sexual state lacks teliospores. Basidia develop on hyphae or yeast cells and give rise to basidiospores in a manner similar to the Tremellales (jelly fungi). Additionally, taxa may be defined from presence or absence of carotenoids, ballistoconidia, type of hyphal septum (simple or the ultrastructurally more complex dolipore), and cellular xylose, which evidently arises from extracellular polysaccharides (Golubev 1991a).

Guého et al. (1989) presented an overview of phylogeny of basidiomycetous yeasts from measurements of divergence among partial sequences of large and small subunit rRNAs. Three major groups were resolved: (1) teliospore formers with hyphae having simple septal pores, (2) teliospore formers with hyphae having dolipore septa and, (3) non-teliospore formers with hyphae having dolipore septa. Relative to other taxonomic groups, the basidiomycetous yeasts appear to be a sister group to the Agaricales (Berbee and Taylor 1993).

At present, the most extensive phylogenetic comparison of basidiomycetous yeasts is that by Fell et al. (1992)

who examined 117 species assigned to 23 genera. A 247-nucleotide segment in the D2 region was sequenced. Although this region resolves closely related species, it has too few phylogenetically informative sites to accurately assess more distant relationships. Nonetheless, the analysis generally supports the concept that taxa assigned to the Tremellales are characterized by dolipore septa and cellular xylose, whereas taxa placed in the Ustilaginales form teliospores, have simple septal pores, and lack cellular xylose. Some exceptions were noted. The teleomorphic genus *Erythrobasidium* does not form teliospores as do other members of the clade, but *Cystofilobasidium* and *Mrakia*, both members of the Tremellales, do form teliospores.

Ballistoconidia and carotenoids are found among many genera of the basidiomycetous yeasts, suggesting these traits to be ancestral, but not always expressed, thus rendering them of little value for defining taxa. These conclusions were also drawn by Nakase et al. (1993). Heterogeneity of coenzyme Q composition occurs in many currently defined genera and will require additional study before its taxonomic significance is fully understood. rRNA/rDNA sequence analyses demonstrated *Rhodotorula*, *Sporobolomyces*, *Cryptococcus*, and *Bensingtonia* to be polyphyletic, further confirming that commonly used phenotypic characters are insufficient for defining anamorphic genera. Additional comparisons of basidiomycetous taxa can be found in the studies by Blanz et al. (1989), De Wachter et al. (1992), Fell and Kurtzman (1990), Guého et al. (1990), Laaser et al. (1989), Nakase et al. (1991a), Sugiyama and Suh (1993), Suh and Sugiyama (1993b), Van de Peer et al. (1992), Yamada and Kawasaki (1989a), Yamada and Nakagawa (1990), and Yamada et al. (1989a,b, 1990a,b).

A strong start has been made to understand the phylogeny of basidiomycetous yeasts from rRNA/rDNA sequence comparisons, but additional sequencing must be done to better resolve taxa. This will include sequences of greater length as well as inclusion of all known species of a group. For example, the anamorphic genera *Tsuchiyaea* and *Ballistosporomyces*, which were recently defined from differences in partial sequences, may overlap with some earlier described genera (Fell et al. 1992).

4. Reliability of rRNA gene trees to infer phylogeny

Calculations of phylogenetic distances from changes in the sequences of macromolecules require that substitutions occur at a predictable rate and preferably one that is constant as well. Ochman and Wilson (1987) reported that nucleotide substitutions in small (16–18S) subunit rRNAs from both prokaryotes and eukaryotes proceed at the same rate (1%/50 million years). Other workers, however, have presented evidence that rates of nucleotide substitution differ among phylogenetic groups and possibly among species within groups (Britten 1986, Field et al. 1988,

Fig. 17. Phylogenetic analyses of relationships among species of *Debaryomyces* and reference taxa. The trees are derived from maximum parsimony (PAUP) analysis of ca. 600 nucleotides from the 5' end of large subunit rDNAs. Branch lengths are proportional to nucleotide differences, and the numbers given on branches are the percentage of frequencies with which a given branch appeared in 100 bootstrap replications. Values less than 50% are not given. (A) Phylogenetic tree comprised of described *Debaryomyces* species and two reference taxa. (B) Phylogenetic tree as in A, but with eighteen reference taxa. *D. carsonii*, *D. melissophilus* and *Debaryomyces* sp. n. are separated from other members of *Debaryomyces* in this analysis. (C.P. Kurtzman and C.J. Robnett, unpublished data).

Weisburg et al. 1989). Methods for calculating evolutionary relationships based on macromolecular changes have been described (Avice 1989, Felsenstein 1988, Holmquist et al. 1988, Lake 1987, Saitou and Nei 1987, Woese 1987), and some of the algorithms are designed to compensate for disproportional rates of substitution, but there still appears to be uncertainty concerning their reliability (Felsenstein 1988). Evolutionary relationships among the bacteria, for example, are still subject to debate (Achenbach-Richter et al. 1988, Gouy and Li 1989, Lake 1987).

There are presently only a few comparisons among the yeasts that examine congruence between phylogenies from rRNA gene sequences and those determined from other molecules. Sequence analysis of orotidine 5'-monophosphate decarboxylase by Radford (1993) demonstrated the budding yeasts and the euscomycetes to be sister groups as shown from rRNA/rDNA sequences. One unusual aspect of this work was placement of the Mucorales as a sister group to the basidiomycetes. Tsai et al. (1994) showed phylogenetic relationships among species of *Epichloë* (Clavicipitaceae) were the same when analyzed from either rDNA sequences or those from the β -tubulin gene. Relationships among species of *Dekkera* and its anamorph *Brettanomyces* were essentially identical when analyzed from either nuclear rDNA sequences or from

sequences of the mitochondrially encoded cytochrome oxidase subunit II gene (Boekhout et al. 1994).

Another aspect of gene tree reliability is the method used for its construction. Most investigators now analyze data using phylogeny inference programs based on cladistic principles. These programs often include a statistics package to test the robustness of competing phylogenetic trees. Several recent reviews address these important issues (Avice 1989, Felsenstein 1988, Hillis et al. 1994, Saitou and Imanishi 1989).

Although evidence is strong that molecular comparisons give an accurate approximation of the evolutionary history of an organism, use of phylogenetic trees for definition of taxonomic hierarchies should be done cautiously. One impediment to interpretation of these data is the issue of missing taxa. Taxa may be excluded either because they are extinct or they have not been recognized in nature. An indication of missing taxa is the presence of long branches on phylogenetic trees, assuming rates of nucleotide substitutions are reasonably constant for all species compared.

The taxonomy of *Debaryomyces* is an example of the problems encountered when there is incomplete sampling of species. On the basis of nucleotide similarities, Kurtzman and Robnett (1991, 1994b) proposed transfer of *Schwanniomyces occidentalis* and *Wingea robertsiae*

to *Debaryomyces*, and Yamada et al. (1992d) proposed transfer of *Pichia carsonii* and *P. etchellsii* to this genus. A phylogenetic analysis that includes the preceding four species with previously described *Debaryomyces* species suggests that *Debaryomyces* is monophyletic (Fig. 17A). When additional species are included in the analysis, *D. carsonii*, *D. melissophilus* and *Debaryomyces* sp. n. are no longer closely allied with other species in the genus (Fig. 17B). If the circumscription of genera is to be based on monophyly of their assigned species, the preceding three species and other members of their clade represent a new genus. Before such taxonomic changes are made, all known yeasts need to be sequenced and compared, taking into account taxa located on the long branches of phylogenetic trees and their possible effect on genus circumscription.

5. Rapid molecular methods for yeast identification

The specificity of nucleic acid sequences has prompted development of several methods for rapid species identification. Because these techniques can detect single nucleotide changes, they should first be tested on a large variety of genetically defined strains to understand species variation. Aberrant strains may represent different species.

The RFLP technique was discussed earlier in the review and has been used extensively in some laboratories. Bruns et al. (1991) listed some of the factors that

require attention when using RFLPs. Random amplified polymorphic DNA (RAPD) is another methodology that is becoming widely used. The technique is based on amplification of genomic DNA in the presence of one or more short (ca. 10–15-mers) oligonucleotide primers of random sequence. The amplified products are visualized on an agarose gel and strains identified from matching band patterns. Hadrys et al. (1992) discussed details of this procedure noting points of technical difficulty. Poor reproducibility of band patterns may occur, and apparently results from small differences in reagent concentrations and from small variations in thermal cycler temperature control.

Fell (1993) applied a three-primer, PCR-based technique to yeast identification that appears species-specific. The reaction mix includes genomic DNA, two external primers for the D1/D2 region of large subunit rDNA, and a species-specific internal primer. The external primers allow amplification of the ca. 600-nucleotide D1/D2 region, but in the presence of a species-specific primer (third primer), the amplification product is shorter and easily detected on agarose gel. Other molecular technologies for identification include development of species-specific oligonucleotide probes and the sequencing of species-specific regions of DNA. In this latter concept, it is practical to rapidly identify taxa from their sequences in the 600-nucleotide D1/D2 region because many laboratories are beginning to use automated sequencers.

Contents

1. Isolation of yeasts	77
2. Maintenance of yeast cultures	78
3. Procedures for the identification of yeasts	80
4. List of observations and tests included in the standard descriptions	98
5. List of media, reagents and stains	99

1. Isolation of yeasts

Yeasts have been recovered from widely differing aquatic and terrestrial sources, as well as from the atmosphere. Many yeasts occur widely, whereas some appear to be confined to restricted habitats. Yeasts seldom occur in the absence of either molds or bacteria. Consequently, selective techniques are often used for recovery of yeasts, employing media which permit the yeast to grow while suppressing molds and bacteria. The composition of such media is determined by the fact that yeasts are, as a rule, capable of developing at pH levels and water activities which reduce or inhibit the growth of bacteria. Antibiotics may also be used to suppress bacteria. Fungistatic agents for the suppression of molds should be used with caution because such compounds may also inhibit some yeasts.

Cultures are usually incubated at 20–25°C because most yeasts are mesophilic; however, temperatures between 4 and 15°C are essential for psychrophilic taxa. Higher temperatures, in the range of 30–37°C, are often required for yeasts that are strictly associated with warm-blooded sources.

Certain yeasts, such as species of the genera *Cyniclomyces* and *Malassezia*, have exceptional nutritional requirements. The reader should consult the chapters dealing with these taxa for details. The medium formulated by Leeming and Notman (1987) allows species of *Malassezia* to grow well at incubation temperatures between 30 and 35°C.

Anyone interested in the recovery of yeasts from natural substrates is also referred to the informative publications of Beech and Davenport (1969, 1971) and Davenport (1980b), which deal with the isolation of non-pathogenic yeasts. The publications of Buckley (1971) and Staib et al. (1989) may be consulted for methods of isolating yeasts from clinical specimens.

1.1. Use of acidic media (pH 3.5–5.0)

Either hydrochloric acid or phosphoric acid is preferred

for acidifying media. The use of organic acids, such as acetic acid, is not recommended for general isolation purposes. Such acids are only slightly dissociated at pH 3.5–4.0 and the high concentrations of undissociated acids have an inhibitory effect on most yeasts. Notable exceptions are *Zygosaccharomyces bailii*, *Z. bisporus*, *Schizosaccharomyces pombe*, and some strains of *Pichia membranifaciens* and similar species.

1.1.1. Solid media for direct isolation: When yeasts are present in high numbers they may be isolated by plating the material, or suspensions of the material, on either acidified media or media containing antibiotics.

Agar in media with a low pH is hydrolysed when autoclaved. Therefore, the sterilized molten agar is cooled to approximately 45°C before a determined volume of acid is added. The medium and acid are rapidly mixed and immediately poured into petri dishes. The addition of approximately 0.7% (v/v) 1 N hydrochloric acid to YM agar and glucose–peptone–yeast extract agar usually gives the desired pH of 3.7 to 3.8.

Although many yeasts can be recovered at pH 3.7, some species, notably those of the genus *Schizosaccharomyces*, are inhibited by very acid media and are best isolated on moderately acidic media with a pH in the range 4.5 to 5.0.

Dilution-plate techniques may be used for quantitative studies.

1.1.2. Liquid media for enrichment purposes: When yeasts are present in low numbers, their isolation may require enrichment using media and conditions which favor the growth of yeasts over other microorganisms. In such cases, material is put into a liquid medium with a pH of 3.7 to 3.8.

The development of molds can be restricted by excluding air from the culture by pouring sterile pharmaceutical paraffin over the surface of the media to form a layer about 1 cm deep. This procedure favors the development of fermentative strains, but may fail to recover aerobic strains.

An alternative, and preferable, procedure is to incubate the flasks of inoculated media on a rotary shaker (Wickerham 1951). Molds are prevented from sporulating and aggregate in pellets which are outgrown by yeasts. The yeasts may be separated from the molds either by allowing the pellets of mold to settle for a few minutes and then streaking the suspension of yeasts on to agar in petri

dishes, or by removing suspended pellets by aseptically filtering through a loose plug of sterile glass wool. Both fermentative and non-fermentative strains are recovered by this technique.

Wickerham (1969b) described a very useful medium, which he refers to as IM, for isolating yeasts from soil and insect frass. This medium contains Yeast Nitrogen Base plus glucose and six other carbon sources. The pH is not adjusted and drops after inoculation owing to the removal of the ammonium sulfate which is used as a source of nitrogen by the growing organisms.

1.2. Use of media with high concentrations of sugar

Most yeasts can grow on media with concentrations of sugar that are high enough to inhibit the development of many bacteria.

1.2.1. Solid media for direct isolation: A medium such as glucose–peptone–yeast extract agar or YM agar containing glucose at a concentration of 30 to 50% is suitable for recovering osmophilic and osmotolerant yeasts from foodstuffs and juice concentrates of low water activity. The selective action of such media can be enhanced by lowering the pH to around 4.5. Osmotolerant yeasts recovered in this way can usually be successfully subcultured on media containing successively decreasing amounts of sugar, for example 30, 10, 4 and 2%.

1.2.2. Liquid media for enriching cultures: Yeasts may also be isolated by cultivation in liquid media such as glucose–peptone–yeast extract broth and YM broth containing from 30 to 50% glucose. Osmotolerant molds are not inhibited at these sugar concentrations, therefore incubation on a rotary shaker is recommended. Wickerham (1969b) described another useful medium for the isolation of yeasts from soil and insect frass. This medium, which he refers to as D-20, contains Difco Yeast Nitrogen Base, 20% glucose, 0.1% yeast extract and 0.1% malt extract.

1.3. Use of antibiotics and other inhibitory or selective compounds

Several media containing antibiotics have been described for the isolation of yeasts (Davenport 1980b) and these can be employed as a last resort when other means have failed. Such media may have been compounded for the isolation of a particular genus, species, or of yeasts with a particular property. These techniques rely on the use of antibiotics and either other inhibitors or selective carbon and nitrogen sources. Van der Walt and van Kerken (1961a) described isolating species of *Dekkera* using media containing cycloheximide and sorbic acid at pH 4.8. Van Dijken and Harder (1974) used a medium containing methanol as the sole carbon source, plus cycloserine and penicillin G to inhibit the growth of bacteria, for the isolation of yeasts able to utilize methanol. Kwon-Chung et al. (1978) describe a medium for the isolation

of *Filobasidiella neoformans* containing creatinine as nitrogen source and diphenyl to reduce the growth of molds. Another medium for the selective isolation of this species contains Niger seed (*Guizotia abyssinica*), which gives pigmented colonies, and penicillin, streptomycin and gentamicin for the suppression of bacteria (Staib et al. 1989). Beech et al. (1980) reviewed the use of antibiotics such as cycloheximide, aureomycin, chloramphenicol, and penicillin in media for the isolation of yeasts.

1.4. Use of membrane filters

Yeasts may be recovered from liquid substrates (and from solid substrates by first washing them to suspend the yeast cells) by passing the liquid through membrane filters (Mulvany 1969) and then incubating the filters on the surface of a selective agar medium. This technique is particularly useful for recovering yeasts when they are present in very low concentrations.

1.5. Purification of yeast cultures

Isolates are obtained in pure culture from enriched cultures by streaking on a suitable medium, such as glucose–peptone–yeast extract agar and YM agar. Persistent bacterial contamination can be eliminated by acidifying the media or by adding antibiotics. These primary plates are inspected, preferably under low magnification, for the presence of colonies of more than one form. Single, well separated colonies of each form are selected and streaked again. Twice is generally sufficient to obtain pure cultures, but sometimes it may be necessary to streak colonies several times. It must be borne in mind, however, that where two or more forms persistently appear after the replating of a single colony, they may be morphological or sexual variants of a single yeast. In such cases it is necessary to examine the different forms in detail and take into account the possibility that they represent mating types.

2. Maintenance of yeast cultures

Yeast cultures are best maintained on a medium which contains glucose as the only source of carbon as this reduces the risk of changes in growth and fermentative patterns due to the selection of mutants (Scheda 1966). The properties of a strain can change within a few days due to such selection when an unstable strain is cultivated on media which contain malt extract, such as malt agar and YM agar. Many basidiomycetous yeasts do not survive well during prolonged storage on a glucose–peptone medium, although they grow well on it. Potato-dextrose agar is suitable when cultures of such yeasts are to be kept for a long time. The majority of yeasts may be stored at temperatures between 4 and 12°C and subcultured at intervals of 6 to 8 months. Some yeasts, for instance *Arxiozyma* and *Malassezia*, need to be subcultured every month. Strains of species of *Dekkera* and *Brettanomyces* produce excessive amounts of acetic acid; for these it is

best to add 1 or 2% calcium carbonate to the medium to neutralize the acid. Nevertheless, these yeasts still need to be subcultured every two months.

Some ascogenous and basidiosporous yeasts lose their ability to reproduce sexually when maintained by serial cultivation on laboratory media. Some isolates still sporulate well after 50 or more years in cultivation. However, for many strains, ability to sporulate is either impaired or lost within a period that varies from a few weeks to several years. Because of this, it is best to preserve important strains, such as nomenclatural types and reference strains, with one of the more permanent conservation techniques as soon as possible after acquisition. Suitable techniques are: lyophilization (see Kirsop and Kurtzman 1988), L-drying (Mikata and Banno 1989), and freezing in either liquid nitrogen or a mechanical freezer at temperatures between -60° and -135°C . Freezing is the preferred method at the Centraalbureau voor Schimmelcultures at present; cultures of all strains held have been frozen and recovered from liquid nitrogen and many have been successfully kept at -75°C . The preparation of cultures for freezing is simple and quick. The general method as used at the Centraalbureau voor Schimmelcultures is as follows: short lengths of polypropylene drinking straws are sealed at one end, labelled with a black felt-tipped pen (Pentel Permanent Marker), and sterilized in the autoclave at 121°C for 15 min. The strain to be frozen is grown for about 24 h in 3.0 ml of liquid medium on a shaker before adding 1.0 ml of a 60% solution of glycerol in water. An amount of the resulting suspension is pipetted into the straws sufficient to half fill them. The straws are then closed by clamping the open ends in the jaws of a sealing machine for plastic packages. The cultures are then either frozen at approximately -30°C for between 30 and 60 min before being placed in the storage tank under liquid nitrogen, or put directly into a freezer cabinet at -75°C . Sterile plastic ampoules suitable for use in liquid nitrogen are commercially available but are more expensive and take up more storage space.

2.1. Media

- (1) YM broth (yeast extract–malt extract broth). Dissolve 3 g of yeast extract, 3 g of malt extract, 5 g of peptone, and 10 g of glucose in 1 liter of water. The pH reaction of the medium ranges between 5 and 6 depending on the batch of ingredients. The medium is dispensed into containers and autoclaved at 121°C for 15 min. This medium is commercially available as Bacto YM Broth (Difco).
- (2) YM agar (yeast extract–malt extract agar). This medium is prepared by dissolving 20 g of agar in a liter of YM broth. The medium is sterilized by autoclaving at 121°C for 15 min. This medium is commercially available as Bacto YM agar (Difco).
- (3) Malt extract (after Lodder and Kreger-van Rij 1952). Mix 1 kg of malt with 2.6 liters of tap water and

heat to 45°C for 3 h with continuous stirring. Then raise the temperature to 63°C for 1 h. Next filter the mixture through cheese cloth. The filtrate is then filtered through paper and diluted to a density of 15° Balling using a flotation meter. The pH is adjusted to 5.4, if necessary, and the medium is sterilized by autoclaving at 115°C for 15 min. Commercial products in the form of powder or syrup are available from various suppliers.

- (4) Malt agar (malt extract agar). Malt extract is diluted to a density of 10° Balling and 2% (w/v) of agar is added. Malt agar, or wort agar, is available commercially in powder form. The medium is sterilized by autoclaving at 115°C for 15 min.
- (5) Glucose–peptone–yeast extract agar (GPY agar). Add 40 g of glucose, 5 g of peptone, 20 g of agar, and 500 ml of yeast infusion to 500 ml of demineralized water and dissolve. Alternatively, 5 g of powdered yeast extract in 500 ml of demineralized water can be substituted for the yeast infusion.
- (6) Sabouraud's 4% glucose agar. Dissolve 10 g of peptone and 40 g of glucose in 1 liter of demineralized water, adjust the pH to 7.0 and then add 20 g of agar. Sterilize by autoclaving at 121°C for 15 min. Commercial products in dried powder form are available from various suppliers.
- (7) Niger seed agar 1 (Kwon-Chung et al. 1982b). Dissolve 1 g of glucose and 20 g of agar in 800 ml of demineralized water and add 200 ml of Niger seed infusion. Chloramphenicol (40 mg/ml) may be added before sterilizing at 121°C for 15 min, and diphenyl solution (see below) when the medium has been cooled just before pouring into petri dishes.
The Niger seed infusion is prepared by autoclaving 70 g of ground or pulverized seeds of *Guizotia abyssinica* in 350 ml of demineralized water for 10 min at 110°C and filtering the infusion through gauze.
- (8) Niger seed agar 2 (Staib et al. 1989). Pulverize 50 g of Niger seed in a blender, boil in 1 liter of demineralized water for 30 min, filter through paper, and restore the final volume to 1 liter. Dissolve 10 g of glucose, 1 g of potassium dihydrogen phosphate, 1 g of creatinine, and 15 g of agar in this solution. Sterilize by autoclaving at 110°C for 20 min. Add streptomycin (40 E/ml), penicillin (20 E/ml), and diphenyl solution (see below) when the medium has cooled to about 50°C . *Filobasidiella (Cryptococcus) neoformans* produces brown, usually mucoid, colonies after 3–8 days at 25°C .
- (9) Leeming and Notman agar (LNA) for *Malassezia* species. Dissolve 10 g of bacteriological peptone, 0.1 g of yeast extract, 5 g of glucose, 8 g of desiccated ox bile, 1 ml of glycerol, 0.5 g of glycerol monostearate, 0.5 ml of Tween 60, 10 ml of whole-fat cow's milk, and 12 g of agar in 1 liter of

demineralized water. Sterilize by autoclaving at 110°C for 15 min.

- (10) Diphenyl solution. Dissolve 1 g of diphenyl in 100 ml of 95% ethanol. Add 10 ml aseptically to 1 liter of molten medium when it has cooled to approximately 45°C. Diphenyl is used to inhibit the growth of molds.
- (11) Yeast infusion. Yeast infusion is prepared by mixing 1 kg of compressed baker's yeast with 5 liters of demineralized water and heating to 50°C for 24 h. Add the whites of 2 eggs to clarify the liquid, shake well and filter through thick paper. Sterilize by autoclaving at 121°C for 15 min. Alternatively, 5 g of powdered yeast extract dissolved in 1 liter of water may be used.

3. Procedures for the identification of yeasts

Workers should always convince themselves beyond any doubt that they are dealing with pure cultures before proceeding to the determination of the morphological, sexual, biochemical, and physiological properties of the isolates.

3.1. Characteristics of vegetative reproduction

3.1.1. Modes of vegetative reproduction: Vegetative or asexual reproduction occurs in yeasts by budding, by fission, and by the production of conidia on short stalks called sterigmata. Observing how the conidia are formed (conidiogenesis) can provide information which aids the identification of a strain.

Buds may arise either on yeast cells or on hyphal cells. Budding is initiated by the formation of a small evagination or outgrowth at some point on the surface of the cell. The cell remains more or less constant in size during subsequent development, while the bud (blastospore or blastoconidium) increases in size to form a new cell which, usually after some time, separates from the parent (mother) cell. Budding is termed holoblastic or enteroblastic, depending on how the bud is formed in terms of the fine structure of the cell wall. All layers of the wall of the parent cell are involved in the formation of a holoblastic bud, and the bud separates, usually on a narrow base; a scar remains through which no further budding occurs. Von Arx and Weijman (1979) consider holoblastic budding characteristic of the Saccharomycetales and their anamorphic states. When budding is enteroblastic, the first bud arises through a rupture in the wall of the parent cell, through which the inner-most layer evaginates and ultimately grows out to form the outer-most layer of the bud. The site of budding is eventually surrounded by a collarette due to the recurrent formation and abscission of a succession of buds arising from the inner layer of the wall of the cell. Enteroblastic budding is characteristic of basidiomycetous yeasts.

Budding is also classed in terms of the position of the site where it occurs. Budding restricted to one pole

Fig. 18. Monopolar budding (from van der Walt and Yarrow 1984a).

Fig. 19. Bipolar budding (from van der Walt and Yarrow 1984a).

of the cell is termed monopolar (Fig. 18); budding at both poles of the cell is termed bipolar (Fig. 19). When the buds are abstricted on a rather broad base by the formation of a cross wall, the process is referred to as "budding on a broad base" and "bud fission". Recurrent budding leads to the formation of multiple scars or annellations at the poles of the cell (Streiblová 1971). Bipolar budding is characteristic of the apiculate yeasts. Budding from various sites on the cell is termed multilateral or multipolar (Fig. 20).

Budding is also described in terms of the way successive buds are produced. Sympodial budding is on a conidiophore that extends in growth by a succession of apices. A conidium is produced at each apex and the growth continues to the side of the apex; the result is a zigzag appearance (see *Symptodiomyces*, p. 603). Acropetal budding is the formation of successive buds in a chain with the youngest at the apex. Basipetal budding is the formation of successive buds with the oldest at the apex.

Reproduction by fission is the duplication of a vegetative cell by means of a septum growing inwards from the cell wall to bisect the long axis of the cell. The newly formed fission cells, which are arthroconidia (arthrospores), elongate and the process is repeated. Recurrent fission by a cell may give rise to transverse multiple scars or annellations (Streiblová 1971). This

Fig. 20. Multilateral budding (from van der Walt and Yarrow 1984a).

Fig. 21. Fission (from van der Walt and Yarrow 1984a).

Fig. 22. Conidia on stalks (from van der Walt and Yarrow 1984a).

manner of reproduction is characteristic of the genus *Schizosaccharomyces* (Fig. 21).

Reproduction by the formation of conidia borne on stalk-like tubular structures is uncommon among the yeasts. It entails the formation by a cell of one or more tubular protuberances, each of which gives rise to a terminal conidium (Fig. 22). On maturation the conidium is disjointed at a septum either in the mid-region of the tube (e.g., *Sterigmatomyces*) or close to the bud (e.g., *Fellomyces*). The conidia are not forcibly discharged.

Yeasts may also reproduce by the formation of more or less filamentous structures consisting of either pseudo-hyphae or true hyphae (see section 3.1.2.2) and the formation of forcibly discharged spores or ballistospores (see section 3.1.2.6).

3.1.2. Characteristics of vegetative cells:

3.1.2.1. The morphology of vegetative cells: Cells can be globose, subglobose, ellipsoidal, ovoidal, obovoidal, cylindrical, botuliform, bacilliform, elongate, apiculate, ogival, lunate, or triangular. Definitions and illustrations of the various possibilities can be found in *Ainsworth and Bisby's Dictionary of the Fungi* (Hawksworth et al. 1983, 1995). The shape may reflect the mode of reproduction and, in some cases, it is a characteristic of particular genera or species. Some examples are: the lemon-shaped cells of the apiculate yeasts *Hanseniaspora* and *Wickerhamia*, the bottle-shaped cells of *Malassezia*, the triangular cells of *Trigonopsis*, and the lunate cells of *Metschnikowia lunata* and *Candida peltata*.

Methods

(1) Growth in liquid media. The morphology of cells is examined in cultures grown in liquid media; the most generally used are: glucose-peptone-yeast extract broth, malt extract, and YM broth. Cells from a young actively growing culture are inoculated into 30 ml of medium in a 100-ml, cotton-plugged Erlenmeyer flask and incubated for 2–3 days. Some workers use tubes with a diameter of 16 mm containing 5 ml of medium. Incubation is normally at 25°C, but some strains may require other temperatures. The culture is then examined, noting the shape of the cells, their mode of reproduction, whether they are single, in pairs, or aggregated in large clumps. The length and breadth of at least 20 cells are measured and the extreme values noted.

The characteristics of the culture are noted when the cells are examined and again after 4 weeks, usually at either room temperature or 20°C. The growth of yeasts in liquid media can result in the formation of a compact, coherent, flocculent or mucoid sediment, a ring, floating islets or a pellicle. The pellicle, if formed, can be dry, moist, dull, glistening, smooth, wrinkled, or creeping up the sides of the flask. It is either formed rapidly and is present at the first inspection or it is not present until the second inspection and, even then, it may not completely cover

the surface of the medium. Should the yeast form true hyphae copiously, these may produce a thick tenacious growth. This sometimes results in the contents of the flask or tube becoming a mucoid mass. Liquid media are unsuitable for cultivating some yeasts, notably *Malassezia* and *Oosporidium* species.

(2) Growth on solid media. Solid media are sometimes used as well as, or as an alternative to, liquid media for the examination of the morphology of cells. The most commonly used media are glucose-peptone-yeast extract, malt, morphology, and YM agars. A slant or, if morphology agar is used, either a Dalmau plate or an agar-covered slide, is inoculated with cells from a young actively growing culture. (See the next section for the preparation of Dalmau plates and slides.) The slants, plates or slides are incubated for 1–7 days and then the characteristics of the culture are noted. The cell morphology, as described in the previous section, is also examined in some laboratories.

The following features of the appearance of cultures are recorded:

Texture: whether mucoid, fluid or viscous, butyrous, friable, or membranous. Mucoid growth is frequently associated with encapsulation of cells as a result of the production of extracellular polysaccharides; membranous growth generally results from profuse formation of filaments.

Color: any distinctive colors, such as yellow, orange and red are recorded. The presence of red, orange or yellow non-diffusible carotenoid pigments is characteristic of certain genera, for instance, *Phaffia*, *Rhodospiridium*, and *Sporidiobolus*. Other yeasts, such as *Metschnikowia pulcherrima*, certain *Kluyveromyces* species, and some adenine-requiring mutants of *Saccharomyces*, produce diffusible, non-carotenoid Bordeaux-red pigments. The majority of yeasts, however, produce growth which ranges in color from whitish through cream to buff.

Color charts are not used by the majority of yeast taxonomists and so the color terminology used in descriptions of yeasts is not consistent. The adoption of a standard terminology such as used in *A Mycological Colour Chart* (Rayner 1970) is strongly recommended.

Surface: whether glistening or dull, smooth, rough, sectoried, folded, ridged, or hirsute. Strains which are smooth when first isolated sometimes become rough when kept on agar. This change is, in some cases, accompanied by a change in texture from butyrous to membranous. Changes of this kind have often been observed at the CBS Culture Collection in strains of *Candida albicans* and *C. tropicalis* which had been maintained on malt agar and glucose-peptone-yeast extract agar for several years. The smooth form could usually be recovered by incubating subcultures at a

temperature considerably higher than that normally used, i.e., 37 or 40°C.

Elevation: whether the growth is flat or raised.

Margin: whether the edge of the streak or colony is smooth, entire, undulating, lobed, erose, or fringed with filaments.

Media

- (1) Malt extract. See p. 79.
- (2) 2% (w/v) Glucose-peptone-yeast extract broth. Dissolve 20 g of glucose, 10 g of peptone, and 5 g of yeast extract in 1 liter of demineralized water. Sterilize by autoclaving at 121°C for 15 min.
- (3) 2% (w/v) Glucose-peptone-yeast extract agar. Prepare as in (2) and add 20 g of agar per liter of medium. Sterilize by autoclaving at 121°C for 15 min.
- (4) Leeming and Notman agar. See p. 79.
- (5) *Cyniclomyces* medium. Dissolve 10 g of yeast autolyzate (p. 90), 40 g of glucose, 10 g of proteose peptone, and 20 g of agar in 1 liter of demineralized water. Sterilize by autoclaving at 121°C for 15 min. Melt the agar just before use, cool to approximately 45°C, then adjust the pH with 1 N HCl to between 3.5 and 4.5 (approximately 4.5 ml is required for each 100 ml of medium), and pour into petri dishes. Yeast infusion can be substituted for the water and yeast autolyzate.
- (6) Malt agar. See p. 79.
- (7) Malt (extract) agar-2% calcium carbonate. Finely powdered calcium carbonate is sterilized by dry heat (160–180°C) for 2 h and 20 g is added to 1 liter of malt agar. Sterilize by autoclaving at 121°C for 15 min. When preparing slants and plates, the medium must be gently agitated until the agar is on the point of setting, otherwise most of the calcium carbonate will settle to the bottom of the tube or dish.
- (8) Morphology agar. The composition of this chemically defined medium is given in Table 14 (p. 99). This medium, marketed by Difco Laboratories as Bacto Yeast Morphology Agar, should be prepared according to the instructions on the container.

3.1.2.2. Filamentation: Mature buds can either become detached as discrete cells or remain attached to the parent cell and give rise to either agglomerations or chains of cells. The tendency of some yeasts to form chains of cells results in the formation of pseudohyphae. A pseudohypha is, therefore, defined as a filament composed of a chain of cells which has been formed by budding.

Pseudohyphae may be either rudimentary, in which case they consist of cells of similar size and shape, or they may be differentiated into elongated cells, each of which may produce blastospores in a regular and more or less characteristic arrangement. The arrangement of blastospores was used for the differentiation of certain genera in earlier taxonomic systems (see van der Walt 1970a). The form of pseudohyphae can be markedly affected by cultural conditions (van der Walt 1970a).

An unusual type of pseudohypha is restricted to some species of *Dekkera* and is called blastese. This

term describes the so-called germination of blastospores in which the germ-tube results in slender filamentous aseptate elongations (Langeron and Guerra 1939, 1940). This term has been broadened to include the formation of pseudohyphae consisting of a single filamentous cell which does not form septa, but which sometimes branch.

Some yeasts produce true septate branching hyphae under suitable conditions. True septate hyphae elongate by continuous growth of the hyphal tip followed by the formation of septa. Septation lags behind the growth of the hyphal tip to such a degree that the terminal cell, measured from tip to first septum, is normally longer than the preceding cell, measured from first to second septum (Wickerham 1951). The fine structure of hyphal septa varies among taxa. Light microscopy does not reveal much detail of the hyphal septa of filamentous yeasts except the presence of visible pore bodies.

Since budding and fission sometimes occur concurrently, it is frequently difficult to distinguish true hyphae, pseudohyphae, and intermediate forms. Wickerham (1951) applied three criteria to recognize types of hyphae. He based these criteria on observations of the terminal cells of the filaments. Firstly, true hyphae usually have refractive straight septa that can generally be differentiated by their greater thickness and refractivity from the edges of vacuoles. There is little or no constriction at the septum. The terminal cells are considerably longer than the cells immediately preceding them. Secondly, pseudohyphae do not have discernible septa, and the ends of intercalary cells are curved and not refractive. There are marked constrictions where the cells join. The terminal cell is, as a rule, shorter than or nearly as long as the adjacent cell. It is rare to find a pseudohypha with a terminal cell that is distinctly longer than the adjacent cell. Thirdly, only a small proportion of cells are separated by septa in intermediate forms.

Hyphae of some yeasts break up or disarticulate to form one-celled arthrospores (also called arthroconidia) (Fig. 23). Arthrospores formed in this way on solid media are frequently arranged in a characteristic zigzag fashion.

Hyphae may show modifications apart from simple branching. They include the formation of lateral conidia on differentiated conidiogenous cells. The presence of conidia on denticles is a characteristic of *Stephanoascus* species and *Pichia burtonii*. Conidiogenous cells showing repetitive monopolar budding are a characteristic of *Ambrosiozyma cicatricosa*.

Hyphae of some species form clamp connections. Clamps arise by outgrowths on the hypha at cell division and connect the two cells that result from the division. Their purpose is to ensure that daughter nuclei, that form during nuclear division, are both transferred to the new cell. One daughter nucleus migrates through the clamp and the other through the hypha. Some strains have incomplete clamps, i.e., the clamp does not connect to the new hyphal cell. This occurs when the nuclei fail to divide. Clamps are characteristic of the dikaryotic

Fig. 23. Arthrospores (from van der Walt and Yarrow 1984a).

phase of basidiomycetous taxa. Hyphae are sometimes joined by a process in which there is the fusion of branches of the same or different hyphae, this is called anastomosis. Anastomosing hyphae are a characteristic of *Ambrosiozyma platypodis*.

Methods. The media most commonly employed in routine testing for the formation of filaments are: corn meal (maize) agar, morphology agar, and potato-dextrose agar. Some clinical laboratories use rice agar.

(1) Slide cultures. A petri dish containing a U-shaped glass rod supporting two glass microscope slides is sterilized by dry heat at 160–180°C for 2 h. The agar is melted and poured into a second petri dish. The glass slides are quickly removed from the glass rod with a flame-sterilized pair of tweezers and dipped into the molten agar, after which they are replaced on the glass rod. The layer of agar on the back of the slide is wiped off after the agar has solidified. In many laboratories the molten agar is poured onto the glass slides to form a thin layer.

After the surface of the agar has dried, the yeast is lightly inoculated in either one or two lines along each slide and a sterile cover slip is placed over part of each line. A little sterile water is poured into the petri dish to prevent the agar from drying out. The culture is then incubated for up to 21 days at either room temperature or another temperature suitable for the strain. The culture is examined microscopically at intervals of a few days for the formation of filaments along the edges of the streak, both under and around the cover slip.

(2) Dalmau plates. Agar is poured into petri dishes, which are then put aside for a day or two to allow the surface to dry. The yeast is inoculated as a single streak near one side of the plate (for example from the ten o'clock position to the two o'clock position), and as two points

near the other side of the plate (for example at the four and eight o'clock positions). A sterile cover slip is placed over the center of the streak and another over one of the point inoculations. The cultures are incubated and examined in the same way as slide cultures.

Media

- (1) Corn meal (maize) agar. Heat 42 g of maize in 1 liter of demineralized water at 60°C for 1 h, filter through paper then restore the volume to 1 liter by adding water. Add and dissolve 12 g of agar. Sterilize at 121°C for 15 min. Commercial products are available from various suppliers.
- (2) Potato-dextrose agar. An infusion of potatoes is prepared by soaking 300 g of washed, peeled, and finely grated or homogenized potato in 900 ml of water overnight in a refrigerator. The resulting infusion is filtered through cheese cloth and autoclaved at 110°C for 1 h.

Dissolve 20 g of glucose and 20 g of agar in 230 ml of potato infusion and 770 ml of demineralized water. Sterilize by autoclaving at 121°C for 15 min. Commercial products are available from various suppliers.

- (3) Rice agar. Simmer 20 g of *unpolished* rice in 1 liter of water for 45 min, filter, and add water to restore the volume to 1 liter. Add and dissolve 20 g of agar. Sterilize by autoclaving at 121°C for 15 min. Commercial products are available but the results obtained with them are usually inferior to those obtained with the medium freshly prepared with rice infusion.
- (4) Morphology agar, see p. 82.

3.1.2.3. Formation of asexual endospores: Asexual endospores are not commonly formed, but they have been observed in strains of the genera *Trichosporon*, *Candida*, *Cryptococcus*, *Oosporidium*, *Cystofilobasidium*, and *Leucosporidium*. Endospores are vegetative cells which are formed within discrete cells and hyphae. Unlike chlamydo-spores and ascospores, endospores cannot be stained selectively. They are usually observed in old cultures on YM agar, malt agar, potato-dextrose agar, and corn meal agar kept at room temperature.

No special media have been devised to stimulate the development of endospores. The publication by do Carmo-Sousa (1969b) should be consulted for a more detailed discussion of endospores.

3.1.2.4. Formation of chlamydo-spores: The chlamydo-spore has been defined as a thick-walled non-deciduous, intercalary or terminal, asexual spore formed by the rounding off of a cell or cells (Ainsworth 1971). The asexual nature of the chlamydo-spore distinguishes it from the teliospore of the Sporidiales and Ustilaginales from which the basidium is produced.

As chlamydo-spores are generally rich in lipids, they are well adapted to maintain vitality through periods of dormancy. Mature chlamydo-spores have particular

affinities for certain dyes and, in contrast to normal vegetative cells, are markedly acid-fast on staining, a characteristic shared by ascospores (van der Walt 1970a). It can be observed in older cultures that these cells shed their outer layers just before or during germination.

Chlamyospores are characteristic of *Candida albicans* and *Metschnikowia* species, but are also occasionally noticed in old cultures of other taxa on agar, including some *Trichosporon* and *Cryptococcus* species. However, chlamyospores fulfill a dual function in the genus *Metschnikowia* as they germinate giving rise either to budding diploid cells or to asci.

The production of chlamyospores by *Candida albicans* is best observed in slide cultures on rice agar; corn meal agar also gives good results with some strains. Some laboratories add Tween 80 (1%) to these media.

3.1.2.5. Formation of germ tubes by *Candida albicans*: The formation of germ tubes is accepted by many medical laboratories as a reliable means of rapidly identifying *Candida albicans* (Stenderup and Thomsen 1964, Ahearn et al. 1966, Joshi and Gavin 1974). A germ tube is a thin filamentous outgrowth without a constriction at its point of origin on the cell. The formation of germ tubes is influenced by temperature, inoculum, medium, and strain. Ogletree et al. (1978) evaluated the various techniques of inducing their formation.

Method. A simple method of testing for germ tubes is to suspend cells from a 24-hour-old culture (10^5 – 10^6 cells per ml) in either normal blood serum or egg albumin. The cells are examined microscopically after incubation at 37°C for 1–3 h.

3.1.2.6. Formation of ballistospores: The formation of forcibly discharged asexual spores, known as ballistospores or ballistoconidia, is a specialized mode of reproduction which is encountered in some basidiomycetous genera, such as *Sporidiobolus*, *Bullera*, and *Sporobolomyces*. Ballistospores are produced on sterigmata that protrude from vegetative cells (Fig. 24) and are discharged into the air by the so-called droplet mechanism (Kluyver and van Niel 1924).

Methods. Ballistospores are generally detected as a mirror image of the culture formed by the discharged spores on the lid of an inverted petri dish. Suitable media are: corn meal agar, malt agar, morphology agar, and potato-dextrose agar. Do Carmo-Sousa and Phaff (1962) described the following procedure. Inoculate a petri dish containing 10 ml of corn meal agar in two lines at right angles across the diameter. The dish is inverted over the bottom of another petri dish containing malt agar on which a sterile slide has been placed. One of the lines is positioned over the slide and the halves of the two dishes are taped together. The culture is incubated at 18 to 20°C. Discharged spores germinate to form colonies on the bottom dish and are collected on the glass slide, which can be removed for examination under the microscope.

Fig. 24. Ballistospores (from van der Walt and Yarrow 1984a).

Media

- (1) Malt agar, see p. 79.
- (2) Potato-dextrose agar, see p. 83.
- (3) Corn meal agar, see p. 83.
- (4) Morphology agar, see p. 82.

3.2. Characteristics of sexual reproduction

Many yeasts reproduce sexually, resulting in an alternation of generations with the formation of characteristic cells in which reduction division takes place. In the ascogenous yeasts, the site of meiosis is the ascus where the haploid generation of ascospores is formed by so-called 'free-cell' formation, i.e., the process by which the cytoplasm surrounding the meiotic nuclei becomes enveloped by a wall. In the basidiomycetous yeasts, reduction division is restricted to either the teliospore or the basidium on which the haploid basidiospores are formed externally.

A yeast that forms either asci or basidia has been referred to as either a perfect yeast or as having a perfect state. A yeast that does not form either asci or basidia has been referred to as an imperfect yeast or as an imperfect state. In current mycological parlance the perfect state is termed the teleomorphic state or *teleomorph*, the imperfect state is termed the anamorphic state or *anamorph*, and the combined states are termed the *holomorph*. The teleomorph and anamorph of the same yeast can have different names, for instance *Pichia jadinii* (teleomorph) and *Candida utilis* (anamorph) are states of the same yeast. The holomorph has the same name as the teleomorph, i.e., *Pichia jadinii* in this example. However, only the teleomorph of many species has been named, the anamorph has not been named separately in an imperfect genus.

3.2.1. Characteristics of ascospore formation: Ascogenous yeasts can be either homothallic or heterothallic, and the vegetative phase is normally either diploid or haploid or a mixture of the two. The existence of higher degrees of ploidy has also been reported.

In haploid homothallic yeasts, plasmogamy, karyogamy, and meiosis occur within the zygote, which is generally formed by two vegetative cells fusing. This diplophase is transient, being restricted to the diploid zygote within which the ascospores are formed. Such a life cycle is termed haplontic.

One mode of diploidization involves a haploid vegetative cell which undergoes mitosis and forms a bud. The bud remains attached to the parent cell which is converted into an ascus in which usually 1 to 4 ascospores

Fig. 25. Ascus formed by parent–bud (mother–daughter) cell conjugation. Fig. 26. Conjugated ascus. Fig. 27. Ascus with abortive conjugation tube. Fig. 28. Unconjugated ascus. (From van der Walt and Yarrow 1984a.)

are formed (Fig. 25). Asci bearing such vestigial buds are found in the genus *Debaryomyces*, and some species of the genera *Torulasporea* and *Pichia*. Kreger-van Rij and Veenhuis (1975a, 1976b) and Kreger-van Rij (1977a) maintain that the bud is abstricted, with subsequent dissolution of the cross wall which separates the two cells, before the two daughter nuclei fuse. Van der Walt et al. (1977) take the view that abstriction of the bud is not a prerequisite of the process. This mode of ascus formation is referred to as conjugation between a cell and its bud (mother–daughter cell conjugation) or bud-meiosis. As the process involves the fusion of two sister nuclei, it does not constitute heterogamy. Strains of species in which diploidization is effected exclusively by this process would be predominantly inbreeding because conjugation between a cell and its bud does not involve the fusion of independent cells. A process comparable to cell–bud conjugation appears to operate in the genus *Nadsonia*, where karyogamy is effected by the fusion of the nuclei of a bud and its parent. The contents of the zygote move into a third bud at the opposite pole. The second bud, which is abstricted by a septum, becomes the ascus.

Diploidization may also be brought about by the fusion of two independent haploid cells. The cells themselves may fuse giving rise to amoeboid conjugated asci as in *Schizosaccharomyces*. Alternatively, the cells may form elongated copulatory processes, or conjugation tubes, which fuse to give dumbbell-shaped asci (Fig. 26) as in *Zygosaccharomyces*. Occasionally the conjugation tubes fail to fuse. Cells bearing such abortive conjugation tubes nevertheless sometimes convert into asci with 1 or 2 spores (Fig. 27). In this event, it is presumed that the haploid nuclei of such cells undergo mitosis and the sister nuclei fuse in a manner comparable to that in conjugation between a parent cell and its bud. The process constitutes somatogamous autogamy because the protuberance is not abstricted from the cell. Asci bearing either vestigial buds or abortive conjugation tubes may be formed concomitantly, for instance in *Debaryomyces* and *Torulasporea*.

In homothallic yeast strains with a diploid vegetative phase, a single diploid vegetative cell may undergo reduction division and become an unconjugated ascus (Fig. 28) as in the genus *Saccharomyces*. The diploid condition is soon restored, either by germinating ascospores

conjugating within the ascus, or by daughter nuclei fusing autogamously at the conclusion of the first mitotic division within a germinating ascospore (Winge and Laustsen 1937). The latter process has been referred to as direct diploidization or autodiploidization. The haploid phase is of very short duration in such a cycle and is restricted to the ascospore stage. A life cycle characterized by these features is referred to as diplontic.

When some zygotes, in the case of the haplontic cycle, proceed to reproduce mitotically, or when, in the case of the diplontic cycle, diploidization of the ascospores is delayed, the result is a vegetative phase consisting of both diploid and haploid cells. Such a mixed vegetative phase then gives rise to conjugated as well as unconjugated asci.

The diploid cells of heterothallic strains are normally heterozygous for the mating-type genes and bisexual. The existence of unisexual diploid strains has been reported (Wickerham 1958, Oshima and Takano 1972). The asci remain unconjugated and unisexual haploid ascospores of both mating types are formed if the diplophase is stable. Ascospores of opposite mating type either conjugate within the ascus giving rise to the diplophase, as in *Saccharomyces*, or the ascospores germinate giving haploid vegetative cells which can be of opposite mating types. Normally the diplophase can only be restored if conjugation of haploid cultures of opposite mating type occurs, as in *Pichia*. Active cultures of mating types are not invariably stable and may revert to sporulating cultures as a result of mutation of the mating-type alleles (Hawthorne 1963, Takano and Oshima 1967, 1970). Some species have both heterothallic and homothallic strains; *Pichia membranifaciens* and *Saccharomyces cerevisiae* are examples. Heterothallism may also be associated with sexual agglutination, as in *Pichia canadensis* (*Hansenula wingei*) and *Saccharomyces kluyveri* (Wickerham 1956, 1958), in which cells of opposite mating types agglutinate when mixed. Agglutination in *Pichia canadensis* has been shown to be mediated by complementary glycoproteins present on the surface of cells of the opposite mating types (Brock 1959, Taylor 1965, Crandall and Brock 1968).

Winge and Roberts (1954) reported the formation of binucleate ascospores in yeasts which normally remain haploid in single-spore cultures. Wickerham (1958) reported the formation of triploids and tetraploids in

Fig. 29. Representative ascospores found among the yeasts: (a) hat-shaped, *Pichia anomala*; (b) spheroidal and smooth, *Saccharomyces cerevisiae*; (c) saturn-shaped and smooth, *Williopsis saturnus*; (d) spheroidal and roughened, *Debaryomyces hansenii*; (e) saturn-shaped and roughened, *Debaryomyces occidentalis*; (f) elongated with terminal appendage, *Eremothecium coryli*; (g) needle-shaped, *Metschnikowia reukaufii*.

Saccharomyces kluyveri by the conjugation of unisexual diploid cells with unisexual haploid and diploid cells of the opposite mating type.

The mycelial phase of filamentous yeasts may be either haploid or diploid, and this determines how the ascus is formed. The fusion of two hyphae of opposite sex, or anastomoses of lateral branches of two such hyphae, precedes ascus formation in the case of the haploid heterothallic species *Stephanoascus ciferrii*. The asci of yeasts with diploid hyphae are borne either in characteristic clusters (as in *Ambrosiozyma monospora*), or in terminal chains (as in *Ambrosiozyma platypodis*), or hyphal units can be converted into intercalary asci (as in *Saccharomycopsis capsularis*).

The form of the asci can characterize a genus; for instance, in *Lipomyces* the asci are sac-like appendages or structures, in *Metschnikowia* they are long and clavate. Asci are either persistent, as in *Saccharomyces* and *Zygosaccharomyces*, rupturing only when the spores germinate, or evanescent, as in *Kluyveromyces* and *Clavispora*, the wall lysing and freeing the ascospores. Liberated ascospores tend to aggregate in masses.

Ascospores vary in the number present in the asci, in shape, in size, in ornamentation, and in color. The number of ascospores in an ascus can be one or many, though two to four are the most common. Asci with either one or two ascospores are normal in *Lodderomyces*, and some species of *Debaryomyces*. Asci with more than eight spores are usually characteristic of *Lipomyces* and some species of *Kluyveromyces*, although they have occasionally been observed in strains of some species of *Pichia* and *Saccharomyces cerevisiae*.

The shape of ascospores varies widely and includes globose, ellipsoidal, cylindrical, reniform, crescentic, clavate, hat-shaped (galeate), cap-shaped, saturnoid, walnut-shaped, falcate, needle-shaped, and spindle-shaped with whip-like appendages (Fig. 29). The surface may be smooth or rough. However, surface ornamentation, brims and ledges may be reduced to such an extent that they cannot be detected by light microscopy. The morphology of the ascospores is given particular diagnostic value in the keys. By way of example, cap-shaped ascospores are diagnostic of the genus *Wickerhamia*, and spindle-shaped ascospores of *Eremothecium coryli*. However, it should not be forgotten that variation in the shape of ascospores has been observed within a species. An example is *Pichia ohmeri*, where both hat-shaped and globose ascospores have been found depending on the strains paired.

The ascospores may be pigmented in genera such as *Lipomyces*, *Nadsonia*, *Pichia*, *Saccharomycopsis*, and *Debaryomyces* and, as a result, sporulating cultures assume an amber, brown, or reddish-brown color. Ascospores are generally acid-fast, a notable exception being the spores of *Schizosaccharomyces*. However, the spores of some species of this genus stain blue with Lugol's iodine owing to the presence of amyloid substances.

Ascospore germination is generally induced under conditions which restrict vegetative growth. However, it is sometimes important that cells should be well nourished and growing vigorously on a rich medium when transferred to such conditions, though some strains sporulate without any special preparation. A variety of media have been specially formulated to induce sporulation, probably the most commonly used are: malt agar, acetate agar, Gorodkova agar, V8 vegetable juice agar, YM agar, corn meal agar, and carrot wedges. Most of these media do not contain much carbohydrate and as a consequence they support little vegetative growth.

Some genera appear to sporulate best on a particular medium: acetate agar has been recommended for *Saccharomyces* (Adams 1949, Fowell 1952, Kleyn 1954, McClary et al. 1959), and dilute V8 agar for *Metschnikowia* (Pitt and Miller 1968); many strains of *Pichia* sporulate on malt agar. Some strains of *Zygosaccharomyces rouxii* are reported to sporulate best on media containing 2% sodium chloride (Wickerham and Burton 1960). Sporulation of many strains of the genus *Lipomyces* is favored by dilute media at low temperatures (15–20°C). Temperature can affect ascus formation markedly. Temperatures between 20 and 25°C are suitable for most yeasts. Nevertheless, strains of *Debaryomyces hansenii* generally sporulate best at 20°C or slightly lower, and many strains of the genus *Metschnikowia* require temperatures between 12 and 17°C.

Some yeasts sporulate rapidly, i.e., within 48 hours, especially when first isolated; others may require much longer, up to 6 weeks or more. The ability to sporulate sometimes declines when a strain is maintained in the laboratory, and may even be lost altogether. This occurs rapidly in some isolates, perhaps after 2 or 3 subcultures, whereas other strains may be kept for many years without any apparent decline in their ability to form spores.

Methods. The strain to be examined is brought to active growth by cultivating it on a rich medium at a suitable temperature for 24–48 h. Special pre-sporulation

media have been formulated for this, such as Lindgren's medium (Lindgren 1949) and grape juice, although a general cultivation medium such as glucose-peptone-yeast extract agar serves just as well in most cases. Tubes of sporulation media are lightly inoculated from this culture and incubated at suitable temperatures as mentioned above. Preparations of material from the cultures are examined under the microscope after 2 or 3 days, 1 week, and then at weekly intervals for at least 6 weeks. Either water mounts or stained heat-fixed preparations can be used. If asci are not found after this time, the strain is either unable to sporulate or is a mating type that needs to be mated with a strain of the opposite sex.

Staining procedures. A heat-fixed preparation is flooded with a solution of 0.5% malachite green and 0.05% basic fuchsin and heated to steaming for 1 min, washed thoroughly in flowing water and blotted dry. Wickerham (1951) recommends flooding a heat-fixed preparation with a 5% solution of malachite green, heating to 80°C for 3–5 min, washing for 30 seconds, and counter staining with a 0.5% solution of safranin for 10 seconds.

Media

- (1) Lindgren's pre-sporulation medium. This medium contains 10 ml of beet-leaf extract (100 g per 100 ml of boiling water), 10 ml of beet-root extract (100 g per 100 ml of boiling water), 35 ml of canned apricot juice, 16.5 ml of grape juice, 2 g of dried baker's yeast, 2.5 ml of glycerol, 1 g of calcium carbonate, and 3 g of agar. Water is added to give a final volume of 100 ml. The medium is sterilized by autoclaving at 121°C for 15 min.
- (2) Grape juice pre-sporulation medium. Freshly expressed juice of any variety of grape is diluted to a density of 8–10° Balling (using a flotation meter). It is sterilized in flowing steam or by autoclaving at 110°C for 10 min.
- (3) Acetate agar 1 (Fowell 1952). Dissolve 5 g of sodium acetate trihydrate in 1 liter of water and adjust the pH to between 6.5 and 7.0 before adding and dissolving 20 g of agar. Sterilize by autoclaving at 121°C for 15 min.
- (4) Acetate agar 2 (McClary et al. 1959). Dissolve 1 g of glucose, 1.8 g of potassium chloride, 8.2 g of sodium acetate trihydrate, 2.5 g of yeast extract, and 15 g of agar in 1 liter of demineralized water. Sterilize by autoclaving at 121°C for 15 min.
- (5) Corn meal agar, see p. 83.
- (6) Gorodkova agar. Dissolve 1 g of glucose, 5 g of sodium chloride, 10 g of peptone, and 20 g of agar in 1 liter of tap water. Sterilize by autoclaving at 121°C for 15 min. A variant of this medium which is used in some laboratories contains 2.5 g glucose, and 10 g of meat extract is substituted for the peptone.
- (7) Gypsum blocks and wedges. Mix 8 parts of gypsum (calcium sulfate hemihydrate) with 3 parts of water. Cast the paste into cylindrical or wedged-shaped cylindrical forms 3–4 cm high. After they have set, the blocks are placed in suitable sterile glass dishes with lids and heated to 110–120°C for at least 2 h. Before use, either sterile water or a solution of mannitol and phosphate is added to a depth of about 1 cm. The mannitol and phosphate solution is prepared by adding 2 ml of a 5% solution of K_2HPO_4 to 18 ml of a 1% solution of mannitol. The gypsum may also be prepared in tubes. Gypsum and water are mixed to a creamy paste which is poured into test tubes through a funnel. The tubes are plugged with cotton-wool, slanted and the gypsum allowed to harden for 24–48 h at 50°C. The slants are sterilized by autoclaving at 121°C for 15 min.
- (8) 5% Malt extract agar (Wickerham 1951). Dissolve 20 g of agar in 1 liter of distilled water, then add 50 g of powdered malt extract (Difco). Sterilize by autoclaving at 115°C for 15 min. As little heat as possible should be used when melting the sterile medium.
- (9) Oatmeal agar. Boil 40 g of oatmeal in 1 liter of water for 1 h and then filter through cheesecloth. Add enough water to restore the volume to 1 liter and then add 15 g of agar. Sterilize by autoclaving at 121°C for 15 min.
- (10) Potato-dextrose agar, see p. 83.
- (11) Restricted growth (RG) medium (Herman 1971a). Dissolve 0.2 g of yeast extract, 0.2 g of peptone, 1.0 g of glucose, and 20 g of agar in 1 liter of demineralized water. Sterilize by autoclaving at 121°C for 15 min.
- (12) Rice agar, see p. 83
- (13) Vegetable juice agar 1: V8 agar (Wickerham et al. 1946b). Suspend 5 g of compressed baker's yeast in 10 ml of water and add to 350 ml of canned V8 juice, adjust the pH to 6.8 and heat in a boiling water bath for 10 min. The pH is again adjusted until a cooled sample has a pH of 6.8. This hot medium is then mixed with a hot solution of 14 g of agar in 340 ml of water. Sterilize by autoclaving at 121°C for 15 min. The canned vegetable juice, which contains a blend of tomatoes, carrots, celery, beet, parsley, lettuce, spinach, and watercress, can be obtained at many food shops and is marketed under the name "V8 Vegetable Juice" by Campbell Soup Company, Camden, NJ, USA.
- (14) Vegetable juice agar 2 (Mrak et al. 1942a). Either mince or finely grate equal weights of washed unpeeled carrots, beet roots, cucumbers, and potatoes and mix with an equal weight of water. Autoclave the mixture at 115°C for 10 min and express it through cheesecloth. The extract has a pH of approximately 5.7. Add 2% (w/v) dried baker's yeast and 2% (w/v) agar to the extract. Sterilize by autoclaving at 121°C for 15 min.
- (15) Dilute V8 agar (Pitt and Miller 1968). Mix a can of V8 juice with an equal volume of demineralized

water and adjust the pH to 5.5 with sodium hydroxide before filtering through Whatman No. 1 paper. The filtrate is then diluted 1:2, 1:9, 1:19 as required and solidified with 2% (w/v) agar. Sterilize by autoclaving at 121°C for 15 min.

- (16) Vegetable wedges. Wedges of either carrot, potato, beet, cucumber or turnip can be used. The vegetables are thoroughly cleaned by washing and then long cylinders about 1 cm in diameter are cut out of them with either a cork borer or apple corer. The cylinders are cut obliquely to make wedges, rinsed in cold water and put into a glass tube with a little water to prevent drying. Sterilize by autoclaving at 115°C for 10 min.
- (17) Water (aqueous) agar. Dissolve 20 g of agar in 1 liter of demineralized water. Sterilize by autoclaving at 121°C for 15 min.
- (18) YM agar, see p. 79
- (19) YM-2% sodium chloride agar. This medium is prepared by adding 20 g of sodium chloride to 1 liter of YM agar.
- (20) Yeast extract-2% glucose agar. Dissolve 5 g of yeast extract, 20 g of glucose, and 20 g of agar in 1 liter of demineralized water. Sterilize by autoclaving at 121°C for 15 min.
- (21) Yeast infusion agar. Dissolve 15 g of agar in 1 liter of yeast infusion. Sterilize by autoclaving at 121°C for 15 min.

3.2.2. Characteristics of basidiospore formation:

The basidiomycetous yeasts occur as either a budding haplophase, a dikaryotic hyphal phase, or a self-sporulating diplophase. Septate dikaryotic hyphae with clamp connections are characteristic of the sexual states of basidiomycetous yeasts, but they are not always formed (Fig. 30).

Sexual reproduction in the basidiomycetous yeasts is either heterothallic or homothallic. The incompatibility system in the heterothallic species can be either bipolar or tetrapolar and the dikaryotic hyphae are produced by one of the conjugants after a pair of compatible cells have mated. The dikaryotic hyphae eventually form large inflated, frequently lipid-rich, clamped cells in which karyogamy occurs. These cells have been interpreted as probasidia because of this function. They are intercalary, lateral, or terminal, and are sometimes thick walled. Two kinds of homothallism are found in the homothallic or self-fertile strains, which are termed primary and secondary homothallism (Fell 1974). The hyphae are uninucleate and lack clamp connections in strains with primary homothallism, whereas they are dikaryotic and have clamps in those with secondary homothallism. The manner in which the large lipid-rich cells subsequently develop into basidial structures differs widely between taxa.

Fig. 30. Conjugated cells producing dikaryotic hypha with a clamp connection.

Fig. 31. Telomorphs of basidiomycetous yeasts: (a) germinating teliospore with septate metabasidium bearing basidiospores, *Rhodosporeidium toruloides*; (b) non-teliospore species with bulbous basidium bearing basidiospores, *Filobasidiella neoformans*.

The terminology of the basidium has not been standardized (see Donk 1973b). The thick-walled cells found in the ustilaginaceous genera *Rhodosporeidium* and *Leucosporeidium* have been referred to as teliospores, teleutospores, and ustospores (Fig. 31a). These spores are of various shapes, ranging from globose, through ovoidal to angular, and are sometimes pigmented as in *Rhodosporeidium toruloides*. The teliospore forms a germ tube, called a metabasidium or promycelium, after maturing and passing through a period of dormancy. The diploid nucleus in *Leucosporeidium scottii* migrates into the promycelium where it undergoes reduction division and the four haploid nuclei are distributed throughout the promycelium. However, in *Rhodosporeidium toruloides*, meiosis occurs in the teliospore and the four haploid nuclei migrate into the promycelium. The promycelium then forms transverse septa which separate the haploid nuclei. Each nucleus then divides mitotically and one of these nuclei migrates into a bud that usually develops laterally on each of the promycelial cells. These haploid sessile buds are termed sporidia or basidiospores. The genetic factors controlling compatibility segregate during meiosis, with the result that the sporidia give rise to yeast phases of different mating types in heterothallic strains. In some strains of *Mrakia frigida* and *Cystofilobasidium* spp., the promycelium does not become septate and the sporidia develop terminally (Fell and Phaff 1970).

Both terminal and lateral basidia are formed on hyphae with clamp connections in *Filobasidium*. Thin-walled cells, slightly broader than the hyphae bearing them, elongate to form long slender non-septate metabasidia which taper apically. The tip is inflated and bears 6-8 sessile basidiospores arranged in a characteristic petal-like whorl (Fig. 31b). The basidiospores give rise to yeast phases of opposite mating types. In the genus

Filobasidiella, the basidia generally arise in groups either terminally or laterally on septate dikaryotic hyphae. The basidia are slender non-septate elongations with swollen apices with up to 20 haploid basidiospores in acropetal chains that arise from each of 4 sites on an apex. Karyogamy and meiosis occur in the swollen apices (Kwon-Chung 1980). The sessile basidiospores give rise to yeast phases of opposite mating types.

Methods. The heterothallic basidiomycetous yeasts are more often isolated as budding haploid yeast phases than as the sexual phase. Therefore, compatible strains need to be mated to obtain the dikaryotic clamp-bearing hyphal phase. A loopful of cells of each test strain is thoroughly mixed in as small an area as possible on an agar plate or slide. The cultures are incubated and examined at frequent intervals under low magnification (60–100×) for clamped hyphae growing into the agar around colonies where mating has occurred. Cultural conditions such as temperature may have an appreciable effect on the results of the mating tests. Media such as 5% malt extract agar, corn meal agar, hay infusion agar, and sucrose–yeast extract agar are used (see Banno 1967, Fell et al. 1969, 1973, Fell and Statzell-Tallman 1980b, Kwon-Chung 1976a, 1977b).

The basidia of *Filobasidium* and *Filobasidiella*, as well as the teliospores of some ustilaginaceous species, will mature and develop further on the media on which the dikaryotic mycelium is produced. The teliospores of other ustilaginaceous yeasts fail to germinate under these conditions and special treatments have been developed for them. Usually bits of agar containing spores are soaked in demineralized water at low temperatures, sometimes for as long as 3 months, before being put on water agar. The descriptions of the individual species should be consulted for further details.

Media

- (1) Corn meal agar, see p. 83.
- (2) Hay infusion agar. Autoclave 50 g of decomposing hay in 1 liter of demineralized water for 30 min at 121°C and then filter. Dissolve 2 g of potassium monohydrogen phosphate and 15 g of agar in the filtrate and adjust the pH to 6.2. Sterilize by autoclaving at 121°C for 15 min.
- (3) 5% Malt extract agar, see p. 87
- (4) Sucrose–yeast extract agar. Dissolve 1 g of potassium dihydrogen phosphate, 0.5 g of magnesium sulfate heptahydrate, 0.1 g of calcium chloride, 0.1 g of sodium chloride, 0.5 g of yeast extract, 20 g of sucrose, 5 µg of biotin, and 40 g of agar in 1 liter of demineralized water. Sterilize by autoclaving at 121°C for 15 min.

3.2.3. Methods of isolating mating types: When dealing with strains whose perfect state or teleomorph is not known and when testing for interfertility, it is necessary to isolate mating types from haploid and diploid heterothallic species. A strain that does not produce a

sexual state might be a mating type and should be tested to determine whether or not it has the ability to mate by mixing it with other non-sporulating strains of the same species. The more strains that are tested in this way the greater the chance of detecting compatible mating types. Approximately equal amounts of young actively growing cells of the test strains are mixed on the surface of sporulation media, either as agar slants or in petri dishes. The cultures are examined under the microscope for zygotes and sexual structures at intervals of about 3 days for up to 12 weeks. If sexual activity is detected, the strains are then mixed in pairs to determine which are compatible. More details can be found in the publications of Wickerham (1952, 1960, 1965a,b, 1969a), Wickerham and Burton (1952, 1954a,b, 1962), Phaff and Yoneyama (1961), and Slooff (1964).

Mating types of diploid heterothallic species are obtained by isolating single ascospores and basidiospores. This is most rapidly and reliably achieved by employing a micromanipulator when the strain produces enough sexual spores to be easily found and picked out. When the strain produces only very few ascospores, one must resort to the method of heat treatment as described by Wickerham and Burton (1954a), in which a suspension of cells from a sporulating culture are heated and samples are taken at frequent intervals and spread on agar plates. A temperature should be chosen at which vegetative cells are killed within about 5 min, after which only ascospores remain viable and the colonies arising on plates near the end of a series are derived from ascospores only. The most suitable temperature varies with the species, but generally lies in the range of 52 to 65°C.

3.3. Physiological and biochemical characteristics

Physiological properties primarily serve to describe and identify yeast species and, to a very minor extent, genera. The tests most used for routine identification purposes are fermentation of and growth on carbon sources, growth on nitrogen sources, requirements for vitamins, growth at various temperatures and on media with a high content of sugar or sodium chloride, hydrolysis of urea, and resistance to antibiotics. There is not a single standardized method for many of these tests. The results of such tests are frequently dependent on the techniques employed, therefore whichever procedure is chosen, it should be scrupulously adhered to and young vigorously growing cultures should be used as inocula.

3.3.1. Utilization of carbon compounds: There appear to be no exceptions to the rule that when a yeast strain ferments a carbohydrate it is also able to grow on it. However, the reverse does not hold true: many yeasts grow aerobically on sugars they cannot ferment. It is essential that only pure, high-grade carbohydrates are used in the preparation of the media used in these tests.

3.3.1.1. Fermentation of carbohydrates: Yeasts vary in their ability to ferment sugars as measured by

the production of carbon dioxide. Yeasts of the genera *Kluyveromyces*, *Saccharomyces*, and *Zygosaccharomyces*, for example, ferment, at least, glucose vigorously, whereas others, such as *Rhodosporidium* and *Sterigmatomyces*, do not noticeably ferment any sugars. Species ranging from non-fermentative to strongly fermentative are found in other genera.

Several tests have been devised to detect the production of carbon dioxide from carbohydrates (van der Walt 1970a). Durham tubes containing 2% solutions of sugar have been found to be the most useful for routine purposes. The basal medium in which the sugars are dissolved must contain adequate nutrients, so that conditions are suitable for the synthesis of the enzyme systems involved in the transport and hydrolysis of the carbohydrates. The basal medium must be free of contamination with fermentable sugars, such as trehalose in yeast infusion, because such contamination may lead to falsely positive results. The fermentation of D-glucose, D-galactose, sucrose, maltose, lactose, raffinose, and α - α -trehalose are generally tested for routine identification; other compounds such as inulin, starch, melibiose, cellobiose, and D-xylose are sometimes used.

Methods. The ability to ferment sugars is tested in Durham tubes containing 2% (w/v) solutions of sugar (except in the case of raffinose where 4% is usually used because some strains use only part of the molecule). Durham tubes are test tubes with a small inverted tube inserted to collect any gas that may be produced.

The tubes of test media are inoculated with cells from a culture which is 24–48 hours old, either in suspension or on the tip of an inoculating needle. The tests are incubated at 25°C for up to 28 days. The tubes are shaken and inspected at frequent intervals for accumulation of gas in the insert and, if used, a change of color in the indicator. The results are scored as follows, depending on the time taken to fill the insert with gas and the amount accumulating:

- +, strongly positive, insert filled within 7 days;
- l, delayed positive (latent), insert rapidly filled, but only after more than 7 days;
- s, slowly positive, insert slowly filled after more than 7 days;
- w, weakly positive, the insert is not fully filled with gas (e.g., less than $\frac{1}{3}$ full is often considered weak, whereas greater than $\frac{1}{3}$ full is positive);
- , negative, no accumulation of gas in the insert;
- v, variable, some strains are positive, others are negative

Media

- (1) Yeast autolyzate. Mix equal parts of compressed baker's yeast and water in a flask. A thin layer of toluene may be added. Incubate at 50–55°C for three days, stirring occasionally. Boil for a few minutes and allow to cool. Adjust the pH to 6.0 by adding 1N KOH. The supernatant is clarified either by adding egg white or by filtering using suction. The clear filtrate represents full strength yeast

autolyzate. Commercial products are available and should be prepared according to the manufacturers instructions.

- (2) Yeast infusion, see p. 80.
- (3) Fermentation basal medium. Wickerham (1951) formulated the following medium. Dissolve 4.5 g of powdered yeast extract and 7.5 g of peptone in 1 liter of demineralized water. Add bromothymol blue to give a sufficiently dark green color. Bromothymol blue stock solution is 50 mg/75 ml distilled water. Add 4 ml stock solution per 100 ml fermentation basal medium. Put 2-ml amounts of basal medium into tubes 150×12 mm in size, which contain small (approximately 50×6 mm) inverted tubes. Sterilize at 121°C for 15 min. Add 1 ml of concentrated, filter-sterilized sugar solution aseptically to give a final sugar concentration of 2% (w/v).

Alternatively, dissolve 2 g of sugar (4 g in the case of raffinose) in either yeast infusion or a 1.0% (w/v) solution of powdered yeast extract or autolyzate. Dispense 5–6 ml amounts of medium into 150×12 mm plugged test tubes containing a small inverted tube (Durham insert) approximately 50×6 mm in size. Sterilize by autoclaving at 121°C for 15 min. When cool after autoclaving, the insert should be full of medium, because air in the inverted tubes is displaced during autoclaving. Some laboratories use screw-capped bottles instead of plugged tubes, because they have the advantage that they can be stored longer without drying but the disadvantage of being less easy to inoculate.

3.3.1.2. Assimilation of carbon compounds: The so-called assimilation tests are in fact tests of the ability of a yeast to grow aerobically on a particular carbon compound supplied as the sole source of energy. The tests can be done either on solid media or in liquid media. However, the use of liquid media is advocated when preparing descriptions of strains and species.

The method employing tubes of liquid media was described by Wickerham and Burton (1948) and Wickerham (1951). The results are improved by agitating the tubes during incubation (Barnett and Ingram 1955, Ahearn et al. 1960, Barnett et al. 1990). Some workers incubate the tests for a period of three weeks, others for four weeks. These long incubations allow the yeast to adapt to utilize some compounds. The tests on solid media can be done in two ways. The first is the auxanographic method of Beijerinck (1889a) in which the yeast is suspended in agar in pour plates and the test sugars are spotted at intervals around the circumference. The second way is to incorporate the test compound into a nutrient agar base in petri dishes and inoculate the test yeast as either a streak or a dot on the surface. This technique was used by Shifrine et al. (1954) and Beech et al. (1955) for screening many isolates on a single plate and can be used with replica-plating. The disadvantage of these agar plates is that they tend to dry within a few days and therefore do not

detect delayed growth on carbon sources. However, they have the advantage that the results can be read after 2–4 days and that any contaminating organisms can easily be seen, which makes them very suitable for the preliminary screening of many isolates.

In the present volume, 36 carbon compounds are used in the description of each species, namely:

- Hexoses: D-glucose, D-galactose, L-sorbose;
- Disaccharides: cellobiose, lactose, maltose, melibiose, sucrose, α - α -trehalose;
- Trisaccharides: melezitose, raffinose;
- Polysaccharides: inulin, soluble starch;
- Pentoses: D-arabinose, L-arabinose, D-ribose, L-rhamnose, D-xylose;
- Alcohols: *meso*-erythritol, galactitol, D-glucitol, glycerol, *myo*-inositol, D-mannitol, ribitol, ethanol, methanol;
- Organic acids: citric acid, DL-lactic acid, succinic acid, D-gluconic acid;
- Glycosides: α -methyl-D-glucoside, salicin;
- Other compounds: D-glucosamine hydrochloride, *N*-acetyl-D-glucosamine, hexadecane.

Additional compounds are sometimes used when they are needed to discriminate between species of a particular genus; these include: 2-keto-D-gluconate, 5-keto-D-gluconate, saccharate, arbutin, D-glucuronate, xylitol, and L-arabinitol.

3.3.1.2.1. Assimilation tests in liquid medium. (See Wickerham and Burton 1948, Wickerham 1951, Barnett and Ingram 1955, Ahearn et al. 1960).

Method. It is reiterated that only pure high-grade chemicals should be used to prepare the media, as appreciable amounts of impurities may be present in some products, for instance D-glucose in maltose, and D-galactose in L-arabinose.

The tests are done in rimless test tubes (180 mm by 16 mm), either with plugs or caps. Each tube contains a standard 5 ml amount of liquid nitrogen base medium with one test substrate, except those for the negative controls, which have no carbon source added, and those for the positive controls, which contain glucose.

Suspensions of cells from young actively growing cultures are used to inoculate the tubes of test media. For this purpose the yeast is cultivated on any convenient medium such as glucose–peptone–yeast extract agar for 24–48 h, or longer if it is particularly slow growing, at a temperature at which the strain grows well. Material is taken from this culture aseptically with a sterile platinum needle or loop and dispersed in about 3 ml of liquid, taking care to avoid carrying over any of the nutrient medium. Some laboratories make suspensions in sterile distilled (or demineralized) water, others use sterile yeast nitrogen base. A white card with black lines approximately 0.75 mm wide drawn on it is held behind the tube. The suspension is diluted aseptically until the lines become visible through the tube as dark bands; this is the same as a 2+ reading as in evaluating growth tests. Each of

the tubes containing the test media is inoculated with 0.1 ml of the suspension. Some laboratories dissolve the test sugars in demineralized water instead of basal medium and dispense 4.5 ml of this solution into test tubes. In this case, 2.5 ml of the suspension of yeast in nitrogen base is pipetted aseptically into 25 ml of basal medium and each tube is then inoculated with 0.5 ml of the resulting suspension. Soluble starch and inulin are sometimes prepared at single strength and sterilized by filtration.

Wickerham (1951) described a special medium to starve the inoculum. This medium is the same nitrogen base used in the tests but contains only 0.1% (w/v) of glucose. Cells from a culture grown for 24–48 hours on agar are inoculated into 10 ml of this medium in a test tube and then incubated for a further 48 hours. The culture is then diluted with basal medium until the density when measured in a photometer is equal to that imparted by either 10×10^6 cells per ml of *Saccharomyces cerevisiae* NRRL Y-567 (= ATCC 9763 = CBS 2978) or 15×10^6 cells per ml of *Candida utilis* NRRL Y-900 (= ATCC 9950 = CBS 5609 = IFO 0988). Cells at these concentrations in test tubes with a diameter of 16 mm transmit about 55% of light passing through a blue filter (420 nm) in a Lumitron photometer. The cell suspension may be diluted using a card with black lines as described above if a photometer is not available. Each tube of test medium is inoculated with 0.1 ml of the final suspension.

The tubes of inoculated test media are incubated at either 25°C or 28°C, usually for 3 weeks, though some workers extend this to 4 weeks. Strains of some species fail to grow or grow only poorly at these temperatures (see descriptions of individual species) and a suitable temperature must be used; 15°C is suitable for most psychrophilic yeasts. It is the practice in some laboratories for the tubes to be stationary, perhaps tilted to improve aeration by exposing a larger surface of liquid. However, better aeration and mixing are obtained if the tubes are agitated, giving more reliable and quicker results. This is achieved either by putting the tubes on a rotary shaker or a Rollordrum (New Brunswick Scientific Co.) or by rocking them. The angle of rocking should be as wide as possible without causing wetting of plugs or caps. T-tubes (Monod tubes) can be agitated far more energetically than test tubes (Monod et al. 1951, Barnett et al. 1990). They can be rocked to an angle of up to 90° each side of the horizontal or shaken on a reciprocating shaker. The great disadvantages of T-tubes are that they are expensive to buy and troublesome to clean, handle and store.

Results are read after 1 week and after 3 weeks; in some laboratories also after 2 weeks and 4 weeks. The degree of growth is assessed by eye by placing the tubes, after they have been shaken well to thoroughly disperse the yeast, against a white card on which lines 0.75 mm thick have been drawn approximately 5 mm apart with India ink. The result is scored as 3+ if the lines are completely obscured; as 2+ if the lines appear as diffuse bands; as 1+ if the lines are distinguishable as such but have blurred edges;

as negative if the lines are distinct and sharp edged. In those cases where the outcome is doubtful, growth may be checked by inoculating 0.1 ml of the culture into a tube of fresh test medium. After reading, several tubes of culture are tested for a starch reaction as described in a later section (p. 95).

The results are presented in the descriptions as follows:

+, positive, either a 2+ or a 3+ reading after 1 week, or 2 weeks in some laboratories;

l, delayed positive (latent), either a 2+ or 3+ reading develops rapidly, but after 2 weeks or longer;

s, slow positive, a 2+ or 3+ reading develops slowly over a period exceeding 2 weeks;

w, weakly positive, a 1+ reading;

–, negative;

(+), seldom positive (if a particular result is seldom observed, it is sometimes given in parentheses);

Various combinations may be also used, such as:

v, variable: some strains are positive, others negative;

+/w, positive or weak: all strains grow, but some of them grow weakly;

w/–, weak or negative.

Media

(1) Inoculation medium of Wickerham (Wickerham 1951). Dissolve 6.7 g of Bacto Yeast Nitrogen Base and 1 g of glucose in 100 ml of demineralized water. This 10-fold concentrated solution is filter sterilized and stored in a refrigerator. The final medium is prepared by aseptically pipetting 1-ml amounts of this basal medium into 9 ml of sterile demineralized water.

(2) Nitrogen base medium for carbon assimilation tests in liquid medium. The composition of Bacto Yeast Nitrogen Base is given in Table 14 (p. 99). A 10-fold concentrated solution of nitrogen base medium is prepared by dissolving 6.7 g of Bacto Yeast Nitrogen Base and the amount of the carbon compound equivalent to 5 g of glucose (with warming if necessary) in 100 ml of demineralized water. Filter sterilize and store refrigerated. Tubes of test media are prepared by aseptically pipetting 0.5 ml of the concentrate into 4.5 ml of sterile water in a 16×180 mm test tube.

3.3.1.2.2. Assimilation tests on agar medium. The ability to grow on various carbon sources in an agar medium may be tested either in tubes, or on agar plates by replica plating, or in auxanogram plates.

Methods

(1) Tube method. Each tube of a set containing the various carbon sources in a basal agar medium is inoculated with one drop of a suspension of cells from a young actively growing culture. The tubes are incubated at a suitable temperature and the results assessed by inspecting the cultures after 1, 2, and 3 weeks. The amount of growth on each of the test media is compared with that on a negative control consisting of the basal medium without any carbon source.

The tubes of test media are prepared by aseptically adding 0.5 ml of a 10-fold concentrated filter-sterilized solution of the test compound to 4.5 ml of sterile molten basal medium in 16×180 mm test tubes. The tubes are slanted after their contents have been carefully mixed and the agar is allowed to set.

(2) Replica plating. A set of plates, each containing one carbon source in basal agar medium, is inoculated by transferring cells from many young colonies simultaneously by “printing”. The results are read by inspecting the plates and comparing the colonies with those of a negative control provided by a plate containing the basal medium without a carbon source.

The various strains to be tested are spot inoculated with a needle onto a plate of a suitable agar medium such as glucose–peptone–yeast extract agar. The plates are incubated for 24–48 hours. The size of the petri dishes determines how many strains can be put on this master plate. The dishes are marked to orientate them and the young discrete colonies are printed to each of the plates in the test set. This is achieved by picking up the colonies on a disk of sterile filter paper, or velveteen cloth, attached to the end of a wooden or metal cylinder by pressing it first on to the master plate and then on to each of the test plates in turn. Ridgeway Watt (1979) described an automatic device for replica plating.

(3) Auxanograms. Petri dishes of basal agar medium in which yeast cells are suspended are seeded with carbon sources at various points around the periphery. The results are read by inspecting the plates for an opaque zone of growth around the point where a carbon source was applied.

The basal agar medium is melted and cooled to between 40 and 45°C. A suspension of young cells in water is either added to a tube of medium, mixed and then poured into a petri dish or, alternatively, pipetted into a petri dish into which the agar medium is then poured, the plate is gently swirled to mix the contents. The petri dishes are left on a level surface for the agar to set and then allowed to stand for a few hours to allow the surface of the agar to dry. Some laboratories consider this drying step unnecessary. Three to six carbon sources can be tested on each petri dish depending on its size. The bottom of the petri dish is marked around the periphery to locate and identify the carbon sources and a small amount of each compound is deposited as aseptically as possible on the surface of the agar. The plates are examined every two days for up to a week.

Media.

(1) Basal agar medium 1 (Lodder and Kreger-van Rij 1952). Dissolve 5 g of ammonium sulfate, 1 g of potassium dihydrogen phosphate, 0.05 g of magnesium sulfate tetrahydrate, and 20 g of high-grade agar in 1 liter of demineralized water. Add either 2.0 g of

yeast extract or 10 ml of 100-fold concentrated stock vitamin solution. Dispense the medium into tubes or bottles and sterilize at 121°C for 15 min.

- (2) Basal agar medium 2. Dissolve 6.7 g of Bacto Yeast Nitrogen Base and 20 g of high-grade agar in 1 liter of demineralized water. Dispense into tubes or bottles and sterilize at 121°C for 15 min.
- (3) Vitamin stock solution (van der Walt and van Kerken 1961a). Dissolve 0.2 mg of biotin, 40 mg of calcium pantothenate, 0.2 mg of folic acid, 200 mg of inositol, 40 mg of niacin, 20 mg of *p*-aminobenzoic acid, 40 mg of pyridoxine hydrochloride, 20 mg of riboflavin, and 100 mg of thiamine in 1 liter of demineralized water and sterilize by filtration. The sterile solution is stored frozen at -10°C or lower.

3.3.1.2.3. Splitting of arbutin. The test for splitting of arbutin is an alternative to the growth test for determining whether or not a yeast can utilize arbutin. The aglucone moiety, hydroxyquinone, gives a brown color with any soluble ferric salts in the medium when a yeast strain hydrolyses arbutin.

Method. A slant of arbutin agar is inoculated with cells from a young actively growing culture and incubated at 25°C, or other suitable temperature. If arbutin is split, the agar develops a dark brown color, usually within 2 to 7 days.

Medium. Arbutin agar. Dissolve 0.5 g of arbutin, 1 g of powdered yeast extract, and 2 g of agar in 100 ml of demineralized water. Sterilize by autoclaving at 121°C for 15 min. After sterilization, 2 ml of a sterile 1% solution of ferric ammonium citrate is added aseptically to and mixed with the molten agar before it is dispensed into tubes or petri dishes. The tubes are slanted and the agar is allowed to set.

3.3.1.3. Assimilation of nitrogen compounds: Yeasts are capable of utilizing a wide variety of nitrogen sources. However, the utilization of nitrate, nitrite, ethylamine hydrochloride, cadaverine dihydrochloride, L-lysine, imidazole, glucosamine, creatine, and creatinine as sole source of nitrogen are the most commonly used tests. The ability to utilize nitrate was an important criterion in defining some genera, for instance the genus *Pichia* was distinguished from the former genus *Hansenula* by its inability to grow with nitrate as the sole source of nitrogen. At present, the presence or absence of this ability is mainly used as a taxonomic criterion at the species level. The methods for testing growth are similar to those described for growth on sources of carbon, using liquid or solid media, with carbon base instead of nitrogen base.

Yeasts, which grow with nitrate as the sole source of nitrogen, are also able to grow on nitrite but the reverse does not always apply. For instance, some strains of *Debaryomyces hansenii* utilize nitrite but not nitrate. Nitrite can be toxic to the yeast because nitrous acid is formed at pH values below 6, therefore media should be adjusted initially to pH 6.5, and nitrite used in low concentrations. Because of this toxicity, auxanograms are

particularly suitable for testing the utilization of nitrite and of ethylamine, which also can be inhibitory at high concentrations. The use of the auxanographic method is also preferred by van der Walt (1970a) for testing the utilization of creatine and creatinine.

3.3.1.3.1. Assimilation in liquid medium. (See Wickerham 1946, 1951.)

Method. The medium used for testing the ability to utilize the various nitrogen sources is similar in composition to that used in the tests for growth on carbon compounds (Table 14, p. 99).

Tubes of test media are inoculated either with 0.1 ml of a suspension of cells in water or saline as for the carbon tests, or with a light inoculum on the tip of a needle, and incubated in the same way. A certain amount of growth is apparent after the tubes have been incubated for 3–7 days, even though the nitrogen sources may not have been utilized. This is due to reserves of nitrogen carried by the cells of the inoculum. Therefore, a second tube is inoculated with a loopful (4 mm diameter) of cells from the first. If this second tube gives a 2+ to 3+ score (as for carbon tests, see p. 91) the strain is considered capable of utilizing the nitrogen source.

An alternative method of testing for the utilization of nitrate in liquid medium is to use a chemical test for nitrate as described by Nickerson (1944a). Four tubes of assimilation medium are incubated and tested after about 3, 5, 10 and 15 days. One of the tubes will give a positive reaction for nitrite if the yeast utilizes nitrate. A few drops of reagent 1 and reagent 2 are added to test the culture (the composition of the reagents is given in the *Media and reagents* description below). The development of a distinct pink or red color indicates the presence of nitrite produced as a result of the partial utilization of nitrate. However, the absence of color may indicate that the nitrate has been completely consumed. Therefore, to test for nitrate in the medium, a small pinch of zinc powder is added to the tube in which the previously described test has just been done. Any nitrate still present is reduced to nitrite in the presence of the zinc and the characteristic pink color will develop after a few minutes.

Media and reagents.

- (1) Carbon base. The stock medium is prepared at a 10-fold concentration by dissolving 11.7 g of Bacto Yeast Carbon Base, together with the required amount of the nitrogen source, in 100 ml of demineralized water. The following amounts of nitrogen sources are used: 0.78 g of potassium nitrate, 0.26 g of sodium nitrite, 0.64 g of ethylamine hydrochloride, 0.68 g of cadaverine dihydrochloride, and 0.56 g of L-lysine (van der Walt and Yarrow 1984a). The solution is sterilized by filtration and stored in a refrigerator until required. The final medium is prepared by aseptically pipetting 0.5 ml of the concentrated medium into 4.5 ml of sterile demineralized water. Tubes for negative controls are prepared by adding filter-sterilized basal medium without nitrogen source.

- (2) Reagent 1. Dissolve 8 g of sulfanilic acid in either 1 liter of 5 N acetic acid (1 part glacial acetic acid to 2.5 parts of water) or 1 liter of dilute sulfuric acid (1 part concentrated acid to 20 parts of water).
- (3) Reagent 2. Dissolve 5 g α -naphthylamine in 1 liter of either 5 N acetic acid or of dilute sulfuric acid (1:20), or dissolve 6 ml of dimethyl- α -naphthylamine in 1 liter of 5 N acetic acid.

3.3.1.3.2. Auxanographic method. (See Lodder and Kreger-van Rij 1952.)

Method. A procedure similar to that described for the carbon tests is used (p. 92), but the basal medium lacks a nitrogen source and contains glucose as carbon source. Three nitrogen sources are tested on each plate by spotting them around the periphery, and either ammonium sulfate or peptone is used as a positive control. Sodium nitrite and ethylamine hydrochloride should be used sparingly; overdosing of the plates is best avoided by dipping an inoculating needle into saturated solutions of the salts and then touching the surface of the seeded plate with the tip. After the nitrogen sources have been introduced, the plates are incubated at a suitable temperature and inspected after 2 and 4 days for zones of growth around the sites of the nitrogen sources.

Media

- (1) Basal medium I (Lodder and Kreger-van Rij 1952). Dissolve 20 g of glucose, 1 g of potassium dihydrogen phosphate, 0.5 g of magnesium sulfate (heptahydrate), and 20 g of high quality agar in 1 liter of distilled water. Sterilize by autoclaving at 121°C for 15 min.
- (2) Basal medium II. Dissolve 11.7 g of Bacto Yeast Nitrogen Base and 20 g of high quality agar in 1 liter of distilled water. Sterilize by autoclaving at 121°C for 15 min.

3.3.1.4. Growth in vitamin-free medium and vitamin requirements: The ability to grow in a glucose/mineral medium devoid of all vitamins was introduced as a diagnostic property by Wickerham (1951) and extended to include the requirements for individual vitamins by van Uden and Farinha (1958) and van Uden and do Carmo-Sousa (1959).

Method. The vitamins generally employed are: *myo*-inositol, calcium pantothenate, biotin, thiamine hydrochloride, pyridoxine hydrochloride, niacin, folic acid, and *p*-aminobenzoic acid. These tests are useful for discriminating between some species, for instance, *Pichia cactophila* can readily be distinguished from *Pichia membranifaciens* by the test for growth in media without pyridoxine.

The determination of requirements for vitamins is based on whether or not a yeast can grow in a complete mineral medium devoid of either all, one or a pair of vitamins. A tube of vitamin-free medium is inoculated by needle with cells from a young vigorously growing culture and the tube is incubated at a suitable temperature with agitation for 2 or 3 days. Generally the yeast grows considerably in this first tube owing to reserves being carried over within

the cell. A second tube of vitamin-free medium, and a complete set of tubes lacking individual vitamins when individual requirements are being tested, are inoculated with 1 drop of cell suspension from the first tube. The cultures are incubated and inspected after 3 and 7 days for evidence of growth.

Media

- (1) Vitamin-free medium. The composition of this medium is given in Table 14 (p. 99). A 10-fold concentrated stock medium is prepared by dissolving 16.7 g of Bacto Vitamin-Free Yeast Base in 100 ml of distilled water, which is warmed slightly to effect complete solution of the ingredients.

3.3.1.5. Growth in media of high osmotic pressure:

Yeasts from substrates with high sugar and salt contents are usually resistant to high osmotic pressures. Many yeast species grow well in glucose concentrations up to 40% by weight, whereas few species grow at sugar concentrations between 50 and 70%. The ability to grow with high concentrations of sugar is generally tested by growth on agar media containing 50% and 60% (w/w) glucose.

Method. Wickerham (1951) introduced the use of a liquid medium containing 5% glucose and 10% sodium chloride. Kurtzman (1990c) formulated a medium containing 16% NaCl and 5% glucose to distinguish *Zygosaccharomyces rouxii* from *Z. mellis*.

Culture media in cotton-plugged tubes and petri dishes tend to dry up quite rapidly in dry climates as the result of evaporation. Such water losses can affect the results of tests and can be reduced by incubating the tubes either in plastic bags inflated with air or with self-sealing plastic caps (Kimble P.M. Cap Closures, Kimble Inc., Toledo, OH, USA), which permit gaseous exchange but prevent water loss. A strip of plastic film is sometimes used to seal petri dishes, but this can have an adverse effect on growth by preventing aeration.

Media

- (1) 50% Glucose agar. First dissolve 13 g of agar and then 500 g of glucose in 500 g of either yeast infusion or a 1% solution of yeast extract. Dispense into tubes and sterilize at 110°C for 10 min before slanting. Overheating leads to a noticeable browning because the sugar becomes caramelized; any media showing browning must be discarded.
- (2) 60% Glucose agar. First dissolve 22.5 g of agar and then 600 g of glucose in 400 g of either yeast infusion or a 1% solution of yeast extract. Dispense into tubes and sterilize at 110°C for 10 min before slanting. Overheating leads to a noticeable browning because the sugar becomes caramelized; any media showing browning must be discarded.
- (3) 10% Sodium chloride plus 5% glucose medium (Wickerham 1951). Dissolve 100 g of sodium chloride, 50 g of glucose, and 6.7 g of Bacto Yeast Nitrogen Base in 1 liter of demineralized water. Dispense 5-ml amounts into tubes and sterilize at 121°C for 15 min.

3.3.1.6. Growth at 37°C and at other temperatures: The strains of most yeast species grow best at temperatures between 20 and 28°C. However, some yeasts, and particularly those from restricted and specific habitats, require higher or lower temperatures. Yeasts from polar regions grow poorly at 20°C but grow well between 4°C and 15°C (Sinclair and Stokes 1965). In contrast, yeasts from mammals, such as *Cyniclomyces guttulatus*, require a temperature of 35–37°C to grow well, and 30–35°C is reported to be the optimum for *Malassezia furfur* by Leeming and Notman (1987).

Method. Some laboratories test for growth at various temperatures in liquid medium, whereas others test on an agar medium. When testing in liquid medium, a tube of either glucose–nitrogen base medium (as used for assimilation tests) or glucose–peptone–yeast extract broth is inoculated in the usual way and incubated at the chosen temperature. The result is recorded after 1 and 3 weeks (Wickerham 1951). When testing on agar medium, a slant of glucose–peptone–yeast extract agar is inoculated with cells of a young culture and incubated at the chosen temperature for 4 days and then inspected for growth.

Media

- (1) 2% (w/v) Glucose–peptone–yeast broth, see p. 82.
- (2) Glucose–peptone–yeast extract agar (GPY agar), see p. 79.
- (3) Glucose–nitrogen base. Dissolve 5 g of glucose and 6.7 g of Bacto Yeast Nitrogen Base in 1 liter of demineralized water. Sterilize by autoclaving at 121°C for 15 min.

3.3.1.7. Acid production from glucose: Yeasts produce traces of volatile and non-volatile acids in culture, however, it is only when large amounts of acetic acid are produced that acid formation has diagnostic value (Custers 1940, van der Walt 1970a). Custer's chalk medium, which contains glucose (5%) and calcium carbonate (0.5%), is used for the test and the result is determined by the calcium carbonate going into solution. Production of acid on this medium has limited use in taxonomy. It is considered characteristic of *Dekkera* and *Brettanomyces*. However, acid production is quite weak in some strains.

Some yeasts which produce citric acid, such as some *Candida* species, also give a weakly positive reaction in this test. Because of this, a weak reaction to the production of acid has to be regarded as an equivocal result.

Method. The strains to be tested are streaked onto slants or a plate of Custer's chalk medium and incubated at 25°C. The cultures are inspected at frequent intervals for up to 2 weeks for clearing of the medium around the streaks. This results from the chalk being dissolved by any acid that may have been formed.

Medium

- (1) Custer's chalk medium. Dissolve 50 g of glucose, 5 g of finely powdered calcium carbonate, 5 g of yeast extract powder, and 20 g of agar in 1 liter of demineralized water. Sterilize by autoclaving at 121°C

for 15 min. Cool tubes to around 45°C and agitate the medium gently to resuspend the chalk and then slant in a cool place so that the agar gels quickly before the chalk can settle.

3.3.1.8. Formation of extracellular amyloid compounds (starch formation): Aschner et al. (1945) and Mager and Aschner (1947) studied the production of extracellular starch-like material by encapsulated yeasts. They found that under suitable conditions several yeasts formed extracellular polysaccharides, which give a blue to greenish-blue color with iodine solution. One of the conditions required was that the pH of the medium be maintained below 5.0. However, some species, such as those of *Leucosporidium*, give a positive result to the starch test at pH values above 5.0.

Methods

- (1) Testing in liquid culture at pH 5.6 (Wickerham 1951, 1952). Cultures for the carbon growth tests which contained sugars or polyhydric alcohols are tested for the presence of amyloid compounds. Some cultures are tested after incubation for 7 days and, if these give a negative result, others are tested after the next reading. Some laboratories prefer to use a medium containing 1% glucose. The test is done by adding one or two drops of dilute Lugol's iodine and mixing it with the culture by shaking the tube. A positive result is indicated by the development in the culture of a color varying from dark blue to green. The strain may be re-tested by cultivating it in yeast nitrogen base medium with 3% glucose if the result is doubtful.

The relatively large amount of glycogen synthesized by some yeasts interferes with the test, especially if iodine solutions stronger than 0.02 N are used. The brown color typical of glycogen may mask a weak starch reaction. The tubes should be allowed to stand at room temperature for several hours when this occurs, after which time the brown color of the glycogen reaction will have disappeared and the blue color of the starch reaction remains.

- (2) Testing on solid media. One or more strains are inoculated onto agar medium in petri dishes. The cultures are incubated for 1–2 weeks, then flooded with dilute Lugol's iodine, and inspected for formation of a blue to green color.

Media

- (1) Medium I (Lodder and Kreger-van Rij 1952), ammonium sulfate–glucose agar. Dissolve 2 g of ammonium sulfate, 2 g of potassium dihydrogen phosphate, 1 g of magnesium sulfate heptahydrate, and 20 g of glucose in 1 liter of demineralized water. Adjust the pH to 4.5. Dissolve 40 g of agar in 1 liter of demineralized water. The two portions of the media are autoclaved at 121°C for 15 min. They are put together aseptically and 20 ml of either a 20% solution of yeast extract or a 100-fold concentrated vitamin solution are added. The two solutions are mixed gently while the agar is still molten and dispensed aseptically into petri dishes.

- (2) Medium II. Dissolve 10 g of glucose, 6.7 g of Bacto Yeast Nitrogen Base, and 15 g of agar in 1 liter of demineralized water. Sterilize by autoclaving at 121°C for 15 min.
- (3) Lugol's iodine solution (Gram's modification). Dissolve 1 g of iodine and 2 g of potassium iodide in 300 ml of demineralized water.

3.3.1.9. Hydrolysis of urea: Seeliger (1956) tested the hydrolysis of urea by some ascogenous and anascogenous species on Christensen's urea agar. Hydrolysis is generally absent in ascogenous species, whereas it is marked in the basidiomycetous genera such as *Cryptococcus* and *Rhodotorula* (Abadie 1967, Hagler and Ahearn 1981). The ascogenous yeasts *Schizosaccharomyces pombe*, *Yarrowia lipolytica* and *Lipomyces* species are exceptions. Booth and Vishniac (1987) established the presence of urease and, probably, its role as the major enzyme concerned in the utilization of urea by yeasts. Urease catalyses the hydrolysis of urea, giving ammonia and carbamate which, itself, hydrolyses to form carbonic acid and another molecule of ammonia (Andrews et al. 1984). The overall reaction leads to an increase in pH. The test can be done on solid medium (Seeliger 1956) or in liquid medium (Barnett et al. 1990).

3.3.1.9.1. Testing on solid medium. *Method.* Cells from a young culture are inoculated onto a slant of Christensen's urea agar (Christensen 1946) and a control tube of the basal medium without urea and incubated at 25°C. The cultures are inspected daily for up to 4 days and the result is recorded as positive when a deep pink color develops in the tube of test medium but not the control.

Medium. Christensen's urea agar. Dissolve 1 g of peptone, 5 g of sodium chloride, 2 g of dihydrogen phosphate, and 12 µg of phenol red in 1 liter of demineralized water and adjust the pH to 6.8. Add and dissolve 20 g of agar and dispense 4.5-ml amounts into 16 mm diameter plugged glass tubes. Autoclave at 121°C for 15 min, then add 0.5 ml of a filter-sterilized 20% solution of urea. After mixing, slant the tubes and allow the agar to set. This medium is available in powdered form commercially.

3.3.1.9.2. Testing in liquid medium. *Method.* Difco Bacto Urea R Broth is dissolved in sterile demineralized water and amounts of 0.5 ml are dispensed into tubes aseptically. These tubes can be stored in a freezer for up to 6 months. A loopful of cells from a one- or two-day-old culture is suspended in the broth and incubated at 37°C (irrespective of whether the yeast can grow at this temperature). The tubes are examined every half hour for a change of color to red, which indicates hydrolysis of urea. Many yeasts which give a positive result produce the color change within half an hour, most do so within two hours and all within four hours.

3.3.1.10. Splitting of fat: Lipase activity has been reported in several species, including *Yarrowia lipolytica*, *Candida rugosa*, *Zygoascus hellenicus*, and *Trichosporon*

pullulans. Several methods have been proposed for detecting lipolytic activity, although this property is employed mainly as a confirmatory test. These methods use substrates such as tributyrin, olive oil, tallow, Tween 40, 60, and 80, as well as partial glyceryl esters of higher fatty acids (Bulder 1955, Sierra 1957, Tuynenburg-Muys and Willemse 1965). Tuynenburg-Muys and Willemse compared the various methods and concluded that for routine purposes none was better than that developed by Eijkman (1901). They did, however, recommend the use of partial glycerol esters of higher fatty acids, which have a higher melting point than beef tallow.

Method. Melt and filter fresh beef suet, then sterilize the tallow by autoclaving it at 121°C for 15 min. Pipette approximately 0.5 ml of molten fat into a slightly warmed sterile petri dish and then tilt it from side to side so that the fat spreads evenly over the bottom. Remove any surplus fat with a pipette. Put the dish in a refrigerator for an hour or two to allow the fat to harden. Melt 18–20 ml of either YM agar (p. 79) or Gorodkova agar (p. 87) and let it cool to about 40°C, pour over the fat and allow to set. The plates are inoculated by streaking the test strains across the plate, cutting slightly into the agar medium with the needle, and incubated at 25°C. The plates are inspected daily for the formation of an opaque zone, formed by calcium salts of the liberated fatty acids, which is usually apparent along the streak within a week.

3.3.1.11. Cycloheximide resistance: Whiffen (1948) was the first to report that yeasts varied in their sensitivity to the antibiotic cycloheximide (Acti-dione). Her results, based on the study of 22 species, indicated that yeasts could be divided into 3 categories:

- (1) markedly sensitive, inhibited by 1 µg/ml, e.g., *Saccharomyces cerevisiae*;
- (2) moderately sensitive, inhibited by 25 µg/ml, e.g., *Schizosaccharomyces pombe*;
- (3) tolerant, not inhibited by concentrations as high as 1000 µg/ml, e.g., *Kluyveromyces lactis*.

Method. The test is done in liquid Bacto Yeast Nitrogen Base with D-glucose, as for the assimilation tests, with cycloheximide added to give a final concentration of either 0.1% or 0.01% (w/v). The results are read and scored in the same way as for the carbon assimilation tests (p. 91).

3.3.1.12. Tolerance of 1% of acetic acid: Sand (1973) and Pitt (1974) showed that yeasts could be distinguished on the basis of their resistance to benzoic and acetic acids. A test was described by Yarrow (1984d) for growth on a medium containing 1% acetic acid to discriminate *Zygosaccharomyces rouxii* from *Z. bailii*, and *Z. bisporus*.

Method. A 4-mm loopful of the same cell suspension as used to inoculate the assimilation tests is either spotted onto or streaked across an agar plate (several strains can be tested in one petri dish). The plates are incubated at 25°C and examined after 3 and 6 days for the development of colonies.

Medium. Acetic-acid (1%) agar. Dissolve 10 g of glucose, 1 g of tryptone, 1 g of powdered yeast extract, and 2 g of agar in 100 ml of demineralized water and autoclave at 121°C for 15 min. Cool the sterilized medium to between 45°C and 50°C, add 1 ml of glacial acetic acid, mix rapidly and pour into petri dishes.

3.3.1.13. Gelatin liquefaction: The ability to liquefy gelatin is of limited diagnostic value because few yeasts are strongly proteolytic. This property is used as a confirmatory test for species that liquefy gelatin rapidly and completely, within about a week.

Method. Stelling-Dekker (1931), Lodder (1934), and Lodder and Kreger-van Rij (1952) used a medium containing malt extract and 20% gelatin, whereas Wickerham (1951) preferred to use a synthetic medium containing 10% gelatin. The use of the synthetic medium is preferred for reasons of standardization. When the test is done in tubes, each tube is inoculated with the same amount of inoculum as each tube of assimilation medium. When done on plates, the surface of the medium is inoculated with a needle or a multi-point inoculator. The cultures are examined regularly for up to 3 weeks for signs of liquefaction.

Medium. Dissolve 100 g of gelatin, 5 g of glucose, and 6.7 g of Bacto Yeast Nitrogen Base in 1 liter of demineralized water, dispense into either tubes or bottles (from which the medium can be poured into petri dishes when required). Sterilize by autoclaving at 121°C for 15 min. The medium in tubes is allowed to gel with the tubes in a vertical position.

3.3.1.14. Diazonium Blue B color reaction: Van der Walt and Hopsu-Havu (1976) studied 70 yeast strains representing 26 ascomogenous and 4 basidiomycetous genera and reported that all the strains of basidiomycetous yeasts, as well as those anamorphs which had cell walls with a fine structure typical of basidiomycetes, gave a dark-red color reaction when a buffered solution of Diazonium Blue B (DBB) was applied to the cultures. Ascomogenous yeasts did not give this reaction.

The mechanism of the reaction has not yet been elucidated. Nevertheless, this test is employed to determine whether an asexual yeast belongs to a basidiomycetous or an ascomycetous genus. The synonymy in the chemical nomenclature of the reagent and related compounds has been discussed by Barnett et al. (1990).

3.3.1.14.1. Reaction on solid media. **Method.** The strains being tested are cultivated on YM agar. Van der Walt and Hopsu-Havu (1976) incubated the cultures for 3 weeks, however, Hagler and Ahearn (1981) reduced this period to 5–7 days followed by 16 h at 55–60°C. Hagler and Mendonça-Hagler (1991) reduced the time needed for this test even further by incubating the cultures on carbon base–urea agar at 25°C for 3 days followed by incubation overnight at 55°C. The plates are allowed to cool to room temperature after incubation before the cultures are tested. One or two drops of freshly prepared chilled DBB reagent are applied to the surface of each colony, taking care to

ensure good contact between the reagent and the yeast. The result is recorded as positive if a dark-red to violet-red color develops within 1–2 min at room temperature.

Media and reagent.

- (1) YM agar, see p. 79.
- (2) Carbon base–urea agar. Dissolve 11.7 g of Bacto Yeast Carbon Base, 0.2 g of acid fuchsin, and 20 g of agar in 900 ml of demineralized water. Sterilize by autoclaving at 121°C for 15 min. Add 100 ml of a filter-sterilized 20% solution of urea to the molten medium, mix and dispense into either tubes or petri dishes.
- (3) DBB reagent. The DBB reagent is prepared by dissolving 15 mg of Diazonium Blue B salt (Brentamine Blue B, ICI plc; Fast Blue Salt B, Farbwerke Hoechst AG) in 15 ml of chilled 0.25 M tris(hydroxymethyl)aminomethane (Tris) buffer, pH 7.0. The salt is unstable under warm and damp conditions, but 15-mg portions of the dye can be stored in sealed tubes at 4°C. The freshly prepared reagent is kept in an ice bath and used before it turns dark yellow (within about 30 min).

3.3.1.14.2. Reaction in liquid medium. **Method.** The strains to be tested are cultivated in 5 ml of nitrogen base with 0.5% glucose (pH 7.0) for 3 days with agitation at a suitable temperature. Slow-growing strains may have to be cultivated for longer to obtain sufficient material for the test. The cells are collected in a centrifuge and the supernatant is poured off. The cells are then suspended in 0.5 ml of 0.05 N KOH and the tube is placed in boiling water for 10 min. The suspension is cooled to ambient temperature and mixed well with 2.5 ml of 95% ethanol. The cells are sedimented by centrifuging briefly and the supernatant is poured away. The cells are suspended in 0.3 ml of DBB reagent. The test is scored positive if a violet color develops within a few seconds. The color is retained by the cells for several hours if 0.1 ml of 95% ethanol is added immediately after the color has formed. Some workers scale this test down and use one fifth of the amounts of medium and reagents given above.

3.3.1.15. Canavanine–Glycine–Bromothymol blue (CGB) agar for identifying the varieties of *Filobasidiella neoformans* (*Cryptococcus neoformans*): *Filobasidiella neoformans* variety *neoformans* can be distinguished from the variety *bacillispora* within 2–5 days by incubating cultures on CGB agar at 25°C. Isolates of the variety *bacillispora* hydrolyze glycine and are resistant to L-canavanine. The pH of the medium rises and the color of the bromothymol blue indicator turns to blue when the glycine is hydrolyzed. Most isolates of the variety *neoformans* do not hydrolyze glycine, and the few which do are sensitive to the canavanine so the medium remains greenish-yellow in color (Kwon-Chung et al. 1982b, Min and Kwon-Chung 1986).

Method. A loopful of cells from a young culture is streaked onto CGB agar in either a tube or a petri dish and incubated at 25°C for up to 5 days. The color of the

medium does not change if the strain is *Filobasidiella neoformans* var. *neoformans*, but turns blue if the strain is the variety *bacillispora*.

Medium. Canavanine–glycine–bromothymol blue (CGB) agar. The complete medium is prepared by cooling 900 ml of bromothymol agar (c, below) to about 55°C and adding 100 ml of stock solution A (a, below).

- (a) Stock solution A. Dissolve 300 mg of L-canavanine sulfate, 100 g of glycine, 10 g of potassium dihydrogen phosphate, 10 g of magnesium sulfate heptahydrate, and either 10 drops of Bejectal with vitamin C (Abbott Laboratories, Chicago, IL, USA) or 10 mg of thiamine hydrochloride in 1 liter of demineralized water, adjust the pH to 5.6 and filter sterilize.
- (b) Bromothymol blue solution. Dissolve 0.4 g of sodium bromothymol blue in 100 ml of demineralized water and filter sterilize.
- (c) Bromothymol blue agar. Dissolve 20 g of agar in 880 ml of demineralized water and add 20 ml of bromothymol blue solution. Sterilize by autoclaving at 121°C.

3.3.1.16. Melanin synthesis on DOPA medium:

The formation of melanin-like pigments from various *ortho*- and *para*-diphenols is used for rapid presumptive identification of *Filobasidiella neoformans*. A variety of substrates may be used: extracts of the seeds of *Guizotia abyssinica* (Niger seed), catechol, chlorogenic acid, protocatechuic acid, norepinephrine, dopamine, hydroxymetaniamine, dihydroxymetaniamide, and dihydroxyphenylalanine (DOPA) (Staib 1962, Chaskes and Tyndall 1975, 1978, Nurudeen and Ahearn 1979).

Method. Cells from a young culture are streaked onto DOPA agar in either a tube or a petri dish and incubated at a temperature of 20–30°C for up to 72 h. Colonies of *Filobasidiella neoformans* are black on this medium.

Medium

- (1) DOPA solution. Dissolve 0.04 g of dihydroxyphenylalanine (DOPA), 1 g of asparagine, 1 g of L-glutamine, and 1 g of glycine in 200 ml of demineralized water. Adjust the pH to 5.5 with 1 M potassium hydrogen phosphate (about 2.5 ml is needed) and filter sterilize the solution.
- (2) Basal medium. Dissolve 4 g of potassium dihydrogen phosphate, 2.5 g of magnesium sulfate heptahydrate, 10 mg of thiamine hydrochloride, 20 µg of biotin, 0.5 g of glucose, and 25 g of agar in 800 ml of demineralized water. Adjust the pH to 5.5 with approximately 7 ml of 1 M potassium hydrogen phosphate and sterilize by autoclaving at 121°C for 15 min. Cool the agar medium to 55°C and mix with the DOPA solution before pouring into petri dishes or test tubes. The complete medium should be stored at 4°C and used within one week of preparation.

3.3.1.17. Tetrazolium indicator medium (TTC medium): Media containing tetrazolium salts are used in some medical laboratories as an aid in isolating and presumptively identifying some species (Pagano et al.

1957, Mendel et al. 1960, Yamane and Saitoh 1985). *Candida tropicalis* produces dark red to maroon colonies owing to the reduction of the tetrazolium salt, whereas yeasts which are incapable of reducing the tetrazolium salt, such as *Candida albicans*, produce pale pink to whitish colonies.

Method. Cells are either streaked or spotted onto the agar. The plate is incubated for 24–48 h and then inspected for colored colonies.

Medium

- (1) TTC stock solution. Dissolve 1 g of 2,3,5-triphenyltetrazolium chloride in 10 ml of demineralized water. Sterilize by filtration and store at 4°C in a dark glass bottle.
- (2) Basal medium. Dissolve 10 g of mycological peptone, 10 g of glucose, and 15 g of agar in 1 liter of demineralized water. Sterilize by autoclaving at 121°C for 15 min. Melt the agar just before use and cool to 45–50°C, then add 0.1 ml of the stock TTC solution, to give a final concentration of 100 µg per ml, and pour into petri dishes. The final pH of the medium is 7.0.

3.3.1.18. Staining nuclei: Although several methods have been recommended for staining the nuclei of yeast cells, none surpass the Feulgen–Giemsa technique of Ganesan and Swaminathan (1958) as modified by Robinow (1961). This method, if followed carefully, gives good preparations and has been applied for chromosomal counts. The method involves the hydrolysis of albumin-mounted cells in 1 N HCl at 60°C, followed by washing in a buffer and the application of the Giemsa stain. It should be kept in mind that not only is the time allowed for hydrolysis critical but also that it varies for different yeasts. It is therefore necessary to determine the best time to allow for hydrolysis. The publications of Robinow (1961) and McCully and Robinow (1972a,b) should be consulted for further details.

4. List of observations and tests included in the standard descriptions

Acetic acid (1%) tolerance test	96
Acid production from glucose	95
Assimilation of carbon compounds	90

Chapter 12

Identification of coenzyme Q (ubiquinone) homologs

Y. Yamada

Contents

1. Introduction	101
2. Methods	101

1. Introduction

The yeasts and yeastlike fungi have coenzyme Q or ubiquinone as a respiratory component. The coenzyme Q homologs of these organisms are recognized to be Q-5 through Q-10 (Yamada and Kondo 1973, Yamada et al. 1976b, 1981). The chemical structure of the isoprenoid quinone is designated as 2,3-dimethoxy-5-methyl-6-multiprenylⁿ-1,4-benzoquinone (Fig. 32). A dihydrogenated isoprenoid side-chain coenzyme Q homolog, Q-10(H₂) was found in basidiomycetous yeasts (Yamada et al. 1973c, Nakase and Suzuki 1986d). Of the four procedures described below, the usage of high performance liquid chromatography gives a qualitative as well as quantitative analysis in the identification of isoprenoid quinones. The coenzyme Q homologs are useful for classifying yeasts and yeastlike fungi at the generic level (Yamada and Kondo 1972b, Yamada et al. 1976a).

Fig. 32. Diagrammatic representation of coenzyme Q. The coenzyme Q homologs are expressed as Q-*n*, with *n* denoting a specified number of isoprene units in a side chain, e.g., Q-6, Q-10. If there are 2 hydrogen atoms saturating the isoprene units in the side chain the formula becomes Q-*n*(H₂), e.g., Q-10(H₂).

2. Methods

2.1. Growth conditions and extraction of coenzyme Q

The yeasts and yeastlike fungi are aerobically grown in a glucose/peptone/yeast extract medium (2/0.4/0.3%, w/v, 500 ml) on a rotary shaker for 24–72 h (Yamada and Kondo 1973, Yamada et al. 1989c). The cells harvested by centrifugation are suspended in 150 ml of water/methanol (1:2, v/v), containing 20 g NaOH and 5 g pyrogallol. The hydrolysis of the yeast cells is performed by heating for

30 min in a 95°C water bath (or a mantle heater). After cooling with tap water for 25 min, the coenzyme Q is extracted by vigorous shaking with 100 ml of hexane, followed by centrifugation for 2 min at 3000 rpm. This procedure is repeated two times. The pooled hexane extracts are shaken three times with 30 ml of water in a separatory funnel for removal of the NaOH. After evaporation to dryness under reduced pressure, the residue is treated with 30 ml of acetone. The yellow-colored acetone solution is concentrated to a small volume (1 ml) *in vacuo*.

2.2. Purification of coenzyme Q

The purification of coenzyme Q is carried out by preparative thin-layer chromatography (0.5 mm silica gel 60F₂₅₄ layers on 20×20 cm glass plates, E. Merck) using benzene for development. A yellow band (R_f 0.3–0.5), corresponding to the yellow spot of a reference standard (Q-6 and/or Q-10), also visualized as a dark band under a short-wave UV light (wave length, 254 nm), is scraped off. The yellow silica gel powder is transferred to a filter paper in a funnel, and the yellow substance is extracted with a small volume of acetone (2 ml). The yellow solution is concentrated to a very small volume (150 μl) *in vacuo*. The isoprenoid quinones can be crystallized in ethanol at –20°C.

2.3. Identification of coenzyme Q homologs

2.3.1. Reversed-phase paper chromatography: A filter paper strip (12×40 cm, Whatman No. 1 or Toyo No. 50) is impregnated with 3.0% silicon oil (w/w, KF-54, Shin'etsu Chem. Co.) in chloroform (Yamada and Kondo 1973, Yamada et al. 1989c). Three samples can be spotted inside on the paper strip using the known reference standards (Q-6 through Q-10) on both sides. The paper strip is developed with ethanol/ethyl acetate/water (5:3:1, v/v/v). Likewise, another filter paper strip is impregnated with 2.5% white vaseline (w/w, U.S. Pharm.) in toluene. In the latter case, the solvent system is *N,N*-dimethylformamide/water (97:3, v/v). After developing and drying the paper strips, the coenzyme Q homologs are located as yellowish-brown spots on the chromatograms by oxidation with 0.3% KMnO₄ (w/v) in water. The remaining KMnO₄ is eluted from the paper strips with tap water.

2.3.2. Reversed-phase thin-layer chromatography:

The samples are spotted on a reversed-phase thin-layer plate (HPTLC RP-18F_{254S}, 10×10 cm, 0.2 mm, E. Merck), which is then developed with acetone/acetonitrile (4:1, v/v) (Collins and Jones 1981). The spots of the coenzyme Q homologs are visualized under a short-wave UV light (wave length, 254 nm) or by spraying 50% H₂SO₄ (v/v), followed by heating the plate in an oven at 120–150°C for 2–5 min.

2.3.3. High performance liquid chromatography:

The separation of the coenzyme Q homologs is performed on a Novapak C₁₈ column (3.9×150 mm, Waters). Other usable columns are: Zorbax ODS (4.6×150 mm, Du Pont); Cosmosil 5C₁₈ (4.6×150 mm, Nacalai); μ Bondapak C₁₈ (3.9×300 mm, Waters). The mobile phase is methanol/isopropanol (7:3 and/or 1:1, v/v), and the flow rate is 1.0 ml/min (or 1.5–2.0 ml/min) (Collins and Jones 1981, Tamaoka et al. 1983, Billon-Grand 1985, Nakase and Suzuki 1985a). Detection is done at 275 nm. The

sample peaks are compared with those of known reference standards (Q-6 through Q-10).

2.3.4. Mass spectroscopy:

The samples are vaporized at the ion source with a direct inlet system operating at 140–170°C (Yamada et al. 1969, Yamada and Kondo 1973). Mass spectra of the coenzyme Q homologs show intense fragment ion peaks at *m/z* 197 and 235. Besides these characteristic ion peaks, several small fragment ion peaks are found at M-15 and M-69, M-69-68, M-69-68-68 and so on, which indicate the expulsion of a methyl group and the successive loss of isoprene units in the side chain, respectively. The molecular ions (M⁺) are: at *m/z* 522 (Q-5), 590 (Q-6), 658 (Q-7), 726 (Q-8), 794 (Q-9) and 862 (Q-10). The dihydrogenated isoprenoid side-chain ubiquinone 10, Q-10(H₂) has the molecular ion peak at *m/z* 864. These molecular ion peaks are often observed at M⁺ + 2, which indicates the presence of reduced coenzyme Q.

Chapter 13

Analysis of carbohydrate composition of cell walls and extracellular carbohydrates

H. Roeijmans, H. Prillinger, C. Umile, J. Sugiyama, T. Nakase and T. Boekhout

Contents

1. Introduction	103
2. Methods	104

1. Introduction

Cell wall composition is a useful marker to indicate taxonomic and phylogenetic affiliations among fungi (Bartnicki-Garcia 1968, 1970, Weijman and Golubev 1987, Dörfler 1990, Prillinger et al. 1990a,b, 1991a,b, 1993). Bartnicki-Garcia (1970) divided the fungi into eight groups using combinations of the two most dominant cell wall carbohydrates present. Weijman and Golubev (1987) distinguished six categories of yeasts and yeastlike fungi using qualitative and semi-quantitative analyses of cell walls. The following groups were recognized:

- (1) Saccharomycetes (Endomycetes) pro parte (e.g., Saccharomycetaceae), characterized by high mannan, low chitin content, and absence of galactose;
- (2) the remaining Saccharomycetes (Endomycetes) (e.g., Dipodascaceae, Nadsoniaceae) have high mannan content, intermediate chitin content, and contain galactose;
- (3) the "red yeasts" (Sporobolomycetaceae, Sporidiobolaceae): variable mannan content, intermediate chitin content, and contain fucose or rhamnose;
- (4) the smuts (Ustilaginales): low mannan content, but high chitin content;
- (5) the remaining basidiomycetes (i.e., Filobasidiaceae and Cryptococcaceae): low mannan content, but with chitin and xylose present; and
- (6) the Euascomycetes: low mannan content, but contain chitin and rhamnose.

Prillinger et al. (1993) differentiated seven cell wall types among the yeasts and yeastlike fungi using both quantitative and qualitative analyses. Their typology is a refinement of that of Weijman and Golubev (1987). Three cell wall types occur within the ascomycetous yeasts:

- (1) *Saccharomyces*-type with mannose and glucose present;
- (2) *Schizosaccharomyces*-type with galactose, glucose and mannose present;
- (3) *Protomyces*-type with glucose predominant, rhamnose and mannose present, and galactose commonly present.

The presence of glucose, mannose and galactose is

found in different orders of Ascomycetes (Saccharomycetales, Schizosaccharomycetales, *Saitoella*, and different orders of filamentous Ascomycetes) indicating that the phylogenetic value of galactose is rather low (Prillinger et al. 1994). Four cell wall types occur within the basidiomycetous yeasts:

- (1) *Microbotryum*-type with mannose dominant, glucose present, fucose usually present, and rhamnose sometimes present;
- (2) *Ustilago*-type with glucose dominant, and mannose and galactose present;
- (3) *Dacrymyces*-type with xylose present, and glucose and mannose present in equal amounts, traces of galactose may be present, but extracellular amyloid compounds are usually absent;
- (4) *Tremella*-type with glucose predominant, xylose, mannose, and galactose present, and extracellular amyloid compounds are often present.

The latter four types agree with the cell wall typology of the Basidiomycetes given by Dörfler (1990). From these data it is apparent that cell wall biochemistry is an important tool in the taxonomy and phylogeny of yeasts and yeastlike organisms.

Four main methods have been applied to analyze the carbohydrate composition of the yeast cell wall:

- (1) Gas chromatographic analysis of acid hydrolyzates of whole cells with derivatization using capillary columns (Weijman 1976, Weijman and Golubev 1987) or packed columns (Sugiyama et al. 1985);
- (2) gas chromatographic analysis of acid hydrolyzates of purified cell walls with derivatization (Dörfler 1990, Prillinger et al. 1990a,b, 1991a,b, 1993);
- (3) high performance liquid chromatographic (HPLC) analysis of acid hydrolyzates of whole cells without derivatization (Suzuki and Nakase 1988a); and
- (4) high performance anion-exchange chromatography with pulsed amperometric detection (HPAE-PAD) of cell wall neutral sugars without derivatization (Prillinger et al. 1993).

Weijman's method is summarized as follows: cells are hydrolyzed with 1 N HCl for 12 h at 100°C. During hydrolysis monomers are formed. Neutral polysaccharides are hydrolyzed completely at low concentrations of HCl (1 N), whereas chitin is converted to glucosamine at high concentrations of HCl (5 N). After hydrolysis,

the solubilized components are trimethylsilylated (TMS) prior to gas-liquid chromatography. Sugiyama's method differs in that dried cells are hydrolyzed in 2.5 N trifluoroacetic acid (TFA) at 100°C for 15 h, followed by reduction of the neutral sugars to their corresponding alditols by borohydride and acetylation of the alditol derivatives by acetic acid anhydride. The final residues are trifluoroacetylated, followed by gas chromatographic analysis. In Prillinger's method cell walls are isolated and purified before further processing. In order to accurately detect xylose, Suzuki and Nakase (1988a) developed a method using HPLC analysis of whole-cell hydrolyzates without derivatization. In brief, whole cells are hydrolyzed with TFA and directly analyzed using HPLC.

2. Methods

2.1. Analysis of whole-cell hydrolyzates using trimethyl-silylation (Weijman 1976, Weijman and Golubev 1987)

Yeast cells are grown in 100 ml yeast extract-peptone-glucose (YPG) broth in 300 ml Erlenmeyer flasks on a rotary shaker at 150 rpm and 24°C (psychrophilic species at 17°C). After 5–7 days, the cells are harvested by centrifugation (9000g), washed with 0.9% NaCl and washed again with deionized water. The pellet is freeze-dried and powdered. Fifteen mg dried cells are hydrolyzed in 6 ml 1 N HCl or 5 N HCl under nitrogen in glass tubes with a screwcap for 12 h at 100°C in a sandbath. To detect xylose, the cells are hydrolyzed with 2 N trifluoroacetic acid for 3 h at 100°C. After cooling, the hydrolyzates are filtered through Whatman No. 1 filter paper and 1 ml of the filtrate is dried in a rotary evaporator. An additional 100 µl Tri-Sil (Pierce) is used to silylate the sample. The reaction mixture is vigorously shaken and allowed to stand for 15 min. One µl is injected into the gas chromatograph-mass spectrometer (GC-MS), which is equipped with a wall coated open tubular (WCOT) capillary column of 25 meters, coated with CP Sil 5CB with a film thickness of 0.13 µm and an inside diameter of 0.32 mm. The column is programmed from 125 to 175°C with a rate of 10°C min⁻¹ and an isothermal period of 5 min. Helium is used as the carrier gas at a flow rate of 30 ml min⁻¹. Electron Impact (EI) at 70 eV is used for ionization and a quadrupole serves as a massfilter.

2.2. Analysis of whole-cell hydrolyzates using trifluoroacetic acid (TFA) and reduction of sugars to their alditol derivatives (Sugiyama et al. 1985)

Yeast cells are grown in liquid Wickerham's basal nitrogen medium supplemented with 15 ml 1% glucose at 25°C for 3–5 days on a test tube shaker. Cells are harvested by centrifugation, and washed with deionized water. The pellet is freeze-dried and powdered. About 30 mg of the dry cell powder is hydrolyzed in 5 ml 2.5 N trifluoroacetic acid (TFA) at 100°C for 15 h in a sealed tube. The

remaining acid is removed by drying over a rotary evaporator. Fifty mg of sodium borohydride in 10 ml distilled water is added to the residue. The reaction mixture is allowed to stand overnight to reduce the sugars to alditols. Excess sodium borohydride is removed by adding dropwise 5% hydrochloric acid in methanol and by evaporating to dryness. Insoluble material and low-polar materials are removed by membrane filtration (0.45 µm, Gelman Sciences, Inc., Ann Arbor, MI, USA), followed by reversed-phase chromatography (Sep-Pak C, Waters Associates, Milford, MA, USA). After drying, 2 ml of methanol are added. The solution is dried in a rotary evaporator to remove the borate complex. This step is repeated several times. To 10 mg of the residue, 0.1 ml of trifluoroacetic anhydride and 0.1 ml of *N*-methylbis-trifluoroacetamide are added. The reaction mixture is kept in a sealed tube and left overnight. One to 2.5 µl of the sample is injected in a gas chromatograph equipped with a hydrogen flame ionization detector. The U-shaped glass column (4 m × 3 mm i.d.) is packed with Chromosorb W (HP) 80–100 mesh coated with 2% silicone OV-105, 800 mesh. Nitrogen is used as the carrier gas at a flow rate of 35 ml min⁻¹. The column temperature is 140°C, and the injector temperature is 150°C. Carbohydrates are identified on the basis of sample coincidence with the relative retention times for the trifluoroacetyl derivatives of the neutral monosaccharide standards.

2.3. Analysis of whole cell hydrolyzates without derivatization using HPLC (Suzuki and Nakase 1988a)

Yeast cells are grown in a 500-ml Erlenmeyer flask containing 200 ml YM broth supplemented with 2% glucose on a rotary shaker at 150 rpm and 25°C (17°C for psychrophilic species). After 4–5 days the cells are harvested by centrifugation (5000 rpm) and washed twice with deionized water. Fifty to 100 mg of acetone dried cells are suspended in 2 ml 2 M trifluoroacetic acid (TFA) in a test tube (13 × 100 mm) with a teflon-sealed screw cap, and kept at 100°C for 3 h in a metal block bath. After cooling, the hydrolyzate is filtered through paper and evaporated to dryness. The residue is dissolved in 0.5 ml water, neutralized with small amounts of Amberlite IRA 410 (OH form), filtered with a disposable filter unit (e.g., Shodex DT ED-13), and then subjected to HPLC. HPLC was performed using two different column systems, namely:

- (1) with water (HPLC grade) as the mobile phase at a flow rate of 0.8 ml min⁻¹ at 80°C; and
- (2) with acetonitrile-water (80:20, v/v, HPLC grade) as the mobile phase at a flow rate of 0.8 ml min⁻¹ at 75°C.

A refractive index detector is used to detect the carbohydrates. Neutral sugars and sugar alcohols are identified by comparing their retention times with those of standard neutral sugars and sugar alcohols.

2.4. Isolation and purification of cell walls (Prillinger et al. 1993)

Yeast cells are grown in 5×100 ml YPG broth on a rotary shaker at 150 rpm for 3–5 days, harvested by centrifugation (3000 rpm), washed with deionized water until the supernatant is clear, and frozen at –20°C until further use.

For disruption, cells are suspended in distilled water (1:1, v/v), and disrupted in a French Press (20 000 PSI) until no intact yeast cells are present under the light microscope. Recently, Messner et al. (1994) have shown that disintegration of yeast cells by a Vibrogen Cell Mill (Tübingen, Germany) and 0.5 mm glass beads (yeast pellet/distilled water/glass beads = 1/1/3, w/w) is superior to the disruption with a French Press. Disrupted cells are washed with ice-cold distilled water until the supernatant is clear. To remove cytoplasmic remnants, the cell walls are thoroughly washed twice with 1% Na-desoxycholate (pH 7.8) with intensive stirring. After each Na-desoxycholate purification the cell walls are rinsed three times with distilled water. In the case of capsuled yeasts, all the capsular material, which may form a second slimy layer above the cell wall pellet, should be removed. Yeast cells without capsules (i.e., those not having a positive starch test with Lugol's solution) are lyophilized and powdered with a pestle and mortar and further processed.

2.5. High performance anion-exchange chromatography with pulsed amperometric detection (HPAE-PAD) of cell wall neutral sugars without derivatization (Prillinger et al. 1993)

Acid hydrolysis of purified cell walls and removal of TFA

are performed according to the method of Sugiyama et al. (1985) (see above). Usually a mixture of 2 mg of powdered cell wall suspended in 2 ml 2 N TFA is hydrolyzed for 2 h at 120°C using teflon-sealed Pyrex test tubes. A standard mixture of monosaccharides containing 90 µg of each neutral sugar is treated in the same way. After blowing off the TFA, samples and standards are resolved in 10 ml distilled water. Monosaccharides are separated on a Dionex CarboPac PA-1 column (4.6×250 mm), equipped with a guard column, using a flow rate of 1 ml min⁻¹ at room temperature. Elute with NaOH as follows: 10 mM NaOH for 3.9 min isocratic, followed by a step gradient to 100% deionized water for 30 min, and reequilibration to the initial conditions for 10 min. The system used for monosaccharide analysis consisted of a Dionex (Sunnyvale, CA) Gradient Pump Module GPM 2 and a Pulsed Amperometric Detector PAD 2. A Dionex Eluant Degas Module is used to sparge and pressurize the eluants with helium. Eluant 1 is 100 mM NaOH (preparation of a 50% NaOH stock solution with ultrapure distilled water), and eluant 2 is 18 MOhm deionized water. Sample injection is via a Dionex High Pressure Injection Valve equipped with a 10 µl sample loop. To ensure a carbonate free eluant, an anion trap column ATC-1 was installed before the injection valve. Detection of the separated monosaccharides is by a PAD, equipped with a gold working electrode. The following pulse potentials are used: $E_1 = 0.1 \text{ V}$ ($t_1 = 300 \text{ ms}$); $E_2 = 0.6 \text{ V}$ ($t_2 = 120 \text{ ms}$); $E_3 = -0.6 \text{ V}$ ($t_3 = 60 \text{ ms}$). The response time of the PAD 2 is set to 1 s. Resulting data are integrated and plotted using Dionex A1-450 software.

Chapter 14

Determination of ethanol production

Ann Vaughan-Martini and Alessandro Martini

Contents

1. Introduction	107
2. Method	107
3. Media	107

1. Introduction

Several yeast species are capable of forming ethanol by fermentation of monosaccharides and oligosaccharides. The quantitative expression of this property is, however, quite variable among fermenting yeasts, ranging from less than 1–2% (w/v) to 14% and higher in some strains of the *sensu stricto* group of the genus *Saccharomyces* (p. 358).

Tolerance to concentrations of ethyl alcohol higher than 12–13% (w/v) is a technological character highly appreciated in the case of yeasts utilized as fermentation starters in the wine industry. Screening surveys for this property (fermenting power) have been done on a large number of strains isolated from grapes, fermenting grape musts and wines (Kunkee and Goswell 1977) by using a simple method that allows a rough evaluation of ethanol yields from the gravimetric estimation of the CO₂ formed in a liquid fermentation medium containing an excess of glucose (24% w/v).

The test is carried out at 25°C in Erlenmeyer flasks plugged with a special glass device (Müller valve) that

Fig. 33. Müller valve assembly for determining ethanol production from fermentation.

causes the CO₂ produced by fermentation to pass through concentrated sulfuric acid (Fig. 33). This acts as a water trap to eliminate weight loss as water vapor.

2. Method

Cells from a 24 h preculture grown with agitation (150 rpm) at 25°C are centrifuged, washed twice and re-suspended in sterile, deionized water. 200-ml Erlenmeyer flasks with 100 ml of synthetic medium are inoculated to a final concentration of 5×10^6 cells per ml and closed with the Müller valve previously filled with sulfuric acid. A zero time weight value is taken before incubating in static culture at 25°C. Flasks are weighed daily until values are stationary. Relative ethanol production (as volume percent) is calculated by multiplying the weight loss (as grams of CO₂) by 1.25.

3. Media

Although grape must adjusted to 24% glucose concentration has been used by some authors (Capriotti 1954, Rosini et al. 1982b), more reliable results are obtained with the following synthetic medium (Ciani and Rosini 1987): 13.7 g/l Bacto Yeast Nitrogen Base (Difco, Detroit, MI, USA); glucose 24% (w/v), pH adjusted to 3.0. Sterilization is preferably done by Tyndalization which involves the exposure of the medium to steam on three consecutive days. The medium is steamed for 30 min on the first day, incubated at room temperature overnight, steamed for a further 30 min on the second day, reincubated and steamed again for 30 min on the third day. The first day's exposure kills non-spore-forming organisms, i.e., vegetative forms; subsequent incubation, provided the medium is favorable, allows germination of bacterial endospores, which are killed during the second or third steaming.

Classification of the ascomycetous taxa

This Page Intentionally Left Blank

Chapter 15

Discussion of teleomorphic and anamorphic ascomycetous yeasts and a key to genera

C.P. Kurtzman

Contents

1. Introduction	111
2. Diagnostic descriptions of presently accepted ascomycetous genera	113
3. Key to the genera of ascomycetous yeasts	119

1. Introduction

Historically, ascomycetes have been placed in two taxonomic classes, or as subclasses in some treatments, the Hemiascomycetes and the Euascomycetes. Hemiascomycetes are characterized by asci that are not enclosed within a fruiting body (ascocarp), whereas Euascomycetes usually form asci within or upon fruiting bodies. Budding yeasts, fission yeasts and yeastlike genera such as *Ascoidea*, *Cephaloascus*, and *Taphrina* are assigned to the Hemiascomycetes, but taxonomic treatments of yeasts typically exclude the yeastlike taxa.

Earlier proposals for classification of the ascomycetous yeasts have been summarized by Lodder (1970) and Kreger-van Rij (1984a). Those systems were mostly based on type of vegetative cell division, ploidy and morphology of ascospores. Another aspect of classification is whether the ascomycetous yeasts represent primitive organisms, as is suggested by their appearance, or whether they are reduced forms derived from various more advanced fungal lineages. Cain (1972) proposed that yeasts represent reduced forms, citing the hat-shaped (galeate) ascospores common to *Pichia* (*Hansenula*), *Cephaloascus*, and *Ceratomyces* as evidence of an adaptation that would have occurred just once in evolutionary history. Redhead and Malloch (1977) accepted this proposal and further argued for the derived status of various yeastlike ascomycetes, which they assigned to existing families of mycelial fungi. Von Arx and van der Walt (1987) also agreed with the concept that ascospore shape is of phylogenetic significance and suggested additional relationships between yeasts and euascomycete families.

In the last few years, the system of classification for yeasts, as well as for other fungi, has been revolutionized by the introduction of phylogenetic analysis of molecular sequences. A majority of the studies have focused on rRNA gene sequences, but comparisons of other molecules have given similar results (Kurtzman 1994). Details of these studies are discussed in the chapter on

rRNA/rDNA sequence comparisons as well as in many of the chapters on individual genera. These studies (Barns et al. 1991, Berbee and Taylor 1993, Hausner et al. 1992, Hendriks et al. 1992, Kurtzman 1993a,c, 1994, Kurtzman and Robnett 1994a; Nishida and Sugiyama 1993, Walker 1985a) have demonstrated the following: (1) budding yeasts and yeastlike taxa such as *Ascoidea* and *Cephaloascus* are members of the same clade and this clade is a sister group to the euascomycetes, some of which are dimorphic and have a yeast phase; (2) with few exceptions (e.g., *Eremascus*), euascomycetes form asci within or upon a fruiting body, whereas members of the yeast clade do not; (3) *Schizosaccharomyces*, *Taphrina*, *Protomyces*, *Saitoella* and *Pneumocystis* form a divergent group of taxa basal to the other ascomycetes; (4) ascospore shape, presence or absence of hyphae and pseudohyphae, presence or absence of budding, and most assimilation reactions are not predictive of phylogenetic relationships.

The classification system used for ascomycetous taxa in this edition of *The Yeasts, A Taxonomic Study*, is given in Table 15. The class "Archiascomycetes" was proposed by Nishida and Sugiyama (1993) for those basal taxa now represented by *Schizosaccharomyces*, *Taphrina*, *Protomyces*, *Saitoella* and *Pneumocystis*. Although genetic distances within this clade are uncertain, it has been divided into four orders. The Taphrinales and the Protomycetales appear closely related and may prove synonymous. Eriksson (1994) recently described the order Pneumocystidales for placement of the genus *Pneumocystis*. Prillinger et al. (1990a), noting the many differences that previously had been observed between *Saccharomyces* and *Schizosaccharomyces*, introduced the order Schizosaccharomycetales. However, Prillinger et al. (1990a) indicated a possible basidiomycetous affinity for this new order. Because of this questionable link to the basidiomycetes and the earlier uncertainty concerning the relationship of *Schizosaccharomyces* with *Dipodascus* and *Geotrichum*, the order Schizosaccharomycetales was emended by Kurtzman (1993a) to reflect its ascomycetous nature and phylogenetic scope. Eriksson et al. (1993) examined the molecular and organismal differences between *Saccharomyces* and *Schizosaccharomyces* and also proposed the order Schizosaccharomycetales. Because Prillinger et al. (1990a) first made the proposal for ordinal rank, Schizosaccharomycetales Prillinger et al.

^a Authority names for genera are given in the individual chapters.

^b A question mark preceding the genus name indicates that family assignment is uncertain.

^c Placement in the class Hemiascomycetes is uncertain.

^d The genus *Endomyces* and the family Endomycetaceae are uncertain, see discussion, this chapter.

ex Kurtzman is accepted over Schizosaccharomycetales O.E. Eriksson et al.

With the preceding changes, the class Hemiascomycetes has become phylogenetically circumscribed to include just the budding yeasts and such yeastlike genera as *Ascoidea* and *Cephaloascus*. Previously, all of these taxa were placed in the order Endomycetales. However, the identity of the Endomycetales has been in doubt because typification of *Endomyces*, the type genus, is based only on the drawings of Brefeld (von Arx 1972), rather than on a preserved specimen of collected type material. In an effort to preserve nomenclatural stability, Redhead and Malloch (1977) designated as neotype a specimen found on *Agaricus melleus* that appeared to match the description of *Endomyces decipiens*, the type species. Kurtzman and Robnett (1995) determined the 5' end large subunit rDNA sequences from living cultures that had been identified as *Endomyces decipiens* and *Endomyces scopularum*. The strain identified as *E. decipiens* proved to be a member of the *Dipodascus albidus* clade, whereas *E. scopularum* was shown to be a euscomycete. Sequence analysis of the dried neotype of *E. decipiens*, although technically possible, will not resolve the taxonomic issue because of the uncertainty of which species is depicted in Brefeld's drawing. Because it is unknown whether *E. decipiens* is a member of the yeast clade or a euscomycete, or whether either of the living cultures that were sequenced were correctly identified, the order accepted for the budding and related yeasts is the Saccharomycetales as typified by the genus *Saccharomyces*.

Family assignments for members of the Saccharomycetales are generally uncertain because there are insufficient molecular data available to resolve most intergeneric relationships. Present assignments have been made using a combination of molecular and morphological similarities, but these assignments will change as more molecular data become available. To denote the uncertainty, many of the genera listed in Table 15 are preceded by a question mark. It should also be emphasized that at present there are insufficient molecular phylogenetic analyses to adequately circumscribe many of the genera. Consequently, most genus descriptions should be considered only as diagnostic groupings to aid in species identification. For example, the phylogenetically divergent genus *Pichia* is accepted with present species assignments only because proposals for its division into phylogenetically defined groups (genera) appear inadequate. Once additional information is available, some of the recently proposed genera, which are presently treated as synonyms, may be adopted. In another example, rDNA sequence comparisons suggest *Blastobotrys*, *Arxula* and *Sympodiomyces* to be congeneric and to represent the anamorphic states of *Stephanoascus* (Kurtzman and Robnett 1995). It should also be noted that rDNA-sequence comparisons have shown the genus *Oosporidium* to be a dimorphic euscomycete (Kurtzman

and Robnett 1995). A history of each genus is given in individual chapters.

2. Diagnostic descriptions of presently accepted ascomycetous genera

2.1. Teleomorphic genera

2.1.1. *Ambrosiozyma*:

Vegetative reproduction: Multilateral budding; pseudo-hyphae and true hyphae with blastoconidia. True hyphae have plugged septal pores that are usually visible under the light microscope as small dots.

Sexual reproduction: Asci are generally attached to hyphae, often in clusters, and they usually become deliquescent at maturity. Asci form 1–4 hat-shaped ascospores.

Physiology: Sugars are fermented, often slowly or weakly. Nitrate is assimilated by some species. Pellicles are not formed on liquid media. Extracellular starch-like compounds are not produced. Inositol is not assimilated. Urease production and gelatin liquefaction are not determined.

2.1.2. *Arxiozyma*:

Vegetative reproduction: Multilateral budding; pseudo-hyphae may form but true hyphae are absent.

Sexual reproduction: Asci are unconjugated, persistent, and form 1–2 roughened, spheroidal ascospores.

Physiology: Sugars are fermented. Nitrate is not assimilated. Pellicles are not formed on liquid media. Extracellular starch-like compounds are not produced. Inositol is not assimilated. Urease production is not determined. Gelatin liquefaction is variable.

2.1.3. *Ascoidea*:

Vegetative reproduction: Budding cells and pseudohyphae are occasionally present; true hyphae are abundant and often form blastoconidia which may be sessile or borne on denticles.

Sexual reproduction: Asci are formed laterally or terminally on true hyphae and are ellipsoidal or acicular. Characteristically for this genus, new asci form percurrently inside older asci. Ascospores are hat-shaped or ellipsoidal, 16–160 per ascus, and are released through a terminal opening in the ascus.

Physiology: Sugars are not fermented. Nitrate may be assimilated. Pellicle formation on liquid media is not determined. Extracellular starch-like compounds are not produced. Inositol may be assimilated. Urease may be weakly produced. Gelatin liquefaction is not determined. The DBB reaction is ordinarily negative, but occasionally weak for *A. africana*.

2.1.4. *Babjevia*:

Vegetative reproduction: Multilateral budding; pseudo-hyphae are rudimentary; true hyphae are infrequently formed.

Sexual reproduction: Buds develop into asci while remaining attached to the parent cell. Several asci are usually

attached to a single parent cell, and the asci produce 4–30 hyaline, globose to ellipsoidal ascospores.

Physiology: Sugars are not fermented. Nitrate is not assimilated. Pellicles are not formed on liquid media. Extracellular starch-like compounds are sometimes produced. Inositol is not assimilated. Urease production and gelatin liquefaction are not determined. Cultures are not mucoid as is common for *Lipomyces*.

2.1.5. *Cephaloascus*:

Vegetative reproduction: Multilateral budding; pseudohyphae and true hyphae, often with blastoconidia which may be borne on distinct denticles.

Sexual reproduction: Erect ascophores are formed which may be smooth or roughened and hyaline or with a brownish pigment. Clusters of asci form at the apex of each ascophore to give a brush-like appearance. The asci, which become deliquescent, generally form 4 hat-shaped ascospores.

Physiology: Sugars may be fermented. Nitrate is not assimilated. Pellicles are formed on liquid media. Extracellular starch-like compounds are not produced. Inositol is not assimilated. Urease production is not determined. Gelatin is not liquified.

2.1.6. *Citeromyces*:

Vegetative reproduction: Multilateral budding; neither pseudohyphae nor true hyphae are formed.

Sexual reproduction: Asci are persistent and contain 1 or, infrequently, 2 roughened, spheroidal ascospores.

Physiology: Sugars are fermented. Nitrate is assimilated. Pellicles are not formed on liquid media. Extracellular starch-like compounds are not produced. Inositol is not assimilated. Urease production is not determined. Gelatin is not liquified.

2.1.7. *Clavispora*:

Vegetative reproduction: Multilateral budding; pseudohyphae may be formed, but true hyphae are not.

Sexual reproduction: Asci form following pairing of complementary mating types. The asci, which become deliquescent, produce 1–4 clavate ascospores.

Physiology: Sugars are fermented. Nitrate is not assimilated. Pellicles are not formed on liquid media. Extracellular starch-like compounds are not produced. Inositol is not assimilated. Urease production is not determined. Gelatin is not liquified.

2.1.8. *Coccidiascus*:

Vegetative reproduction: Cells are spheroidal to ovoidal; pseudohyphae and true hyphae are not formed.

Sexual reproduction: Asci are thick-walled and contain 2 elongated ascospores that are closely intertwined to form a helix.

Physiology: Unknown. The taxon is known only from the tissue of *Drosophila*.

2.1.9. *Cyniclomyces*:

Vegetative reproduction: Cells are long-ovoidal to cylindrical with budding at the poles or on broad shoulders

at the poles. Poorly differentiated pseudohyphae are present, but true hyphae are not formed.

Sexual reproduction: Asci are persistent and form 1–4 ovoidal to cylindrical ascospores.

Physiology: Sugars are weakly fermented. Nitrate is not assimilated. Pellicles are not formed on liquid media. Extracellular starch-like compounds are not produced. Inositol is not assimilated. Urease production is not determined. Gelatin is not liquified. Growth occurs only between 30–40°C. Amino acids, B-vitamins, and an increased level of atmospheric CO₂ are required for growth.

2.1.10. *Debaryomyces*:

Vegetative reproduction: Multilateral budding; pseudohyphae may be formed but true hyphae are absent.

Sexual reproduction: Conjugation between a cell and its bud usually precedes ascus formation, but conjugation between independent cells may occur. Asci produce 1–4 ascospores that may be spheroidal or ellipsoidal and smooth or roughened, spheroidal and roughened with a prominent equatorial ring, or smooth and lenticular. Asci are persistent or deliquescent.

Physiology: Sugars are fermented by some species. Nitrate is not assimilated. Pellicles may be formed on liquid media. Extracellular starch-like compounds are not produced. Inositol is not assimilated. Urease production and gelatin liquefaction are not determined.

2.1.11. *Dekkera* (*Anamorph Brettanomyces*):

Vegetative reproduction: Multilateral budding; cells are spheroidal to ellipsoidal, and some have an ogival shape. Pseudohyphae may form, but true hyphae are not produced. Single cells may profusely elongate and branch to give the appearance of a non-septate mycelium.

Sexual reproduction: Asci, which are unconjugated and become deliquescent, produce 1–4 ascospores that are hat-shaped or somewhat spheroidal with tangential brims.

Physiology: Sugars are fermented, and fermentation is usually stimulated by oxygen. Nitrate is assimilated by some strains. Pellicles may be formed on liquid media. Extracellular starch-like compounds are not produced. Inositol is not assimilated. Urease is not produced. Gelatin liquefaction is not determined. Acetic acid is often produced. Growth is slow and generally short-lived.

2.1.12. *Dipodascopsis*:

Vegetative reproduction: Budding cells may be present. Pseudohyphae are absent, but true hyphae are abundant.

Sexual reproduction: Asci are acicular or cylindrical and form laterally on hyphae after fusion of gametangia. Ascospores are hyaline, ellipsoidal to reniform, and 32–128 are formed in each ascus. The spores are released following dissolution of the ascus apex.

Physiology: Sugars are not fermented. Nitrate is not

assimilated. Pellicle formation on liquid media is not determined. Extracellular starch-like compounds are produced. Inositol is assimilated. Urease production and gelatin liquefaction are not determined.

2.1.13. *Dipodascus* (Anamorph *Geotrichum*):

Vegetative reproduction: Arthroconidia and true hyphae are formed.

Sexual reproduction: Asci are acicular, cylindrical, ellipsoidal or subglobose and form after fusion of hyphal gametangia. Ascospores are hyaline and ellipsoidal; 4–128 are formed in each ascus. The spores are released following dissolution of the ascus apex.

Physiology: Fermentation of sugars is weak or absent. Nitrate is not assimilated. Pellicle formation on liquid media is not determined. Extracellular starch-like compounds are not produced. Inositol is not assimilated. Urease production and gelatin liquefaction are not determined.

2.1.14. *Endomyces*:

Vegetative reproduction: Pseudohyphae and true hyphae are present and may produce blastoconidia.

Sexual reproduction: Asci are subglobose to clavate and may arise following conjugation of hyphal gametangia. Asci form 4–6 hat-shaped ascospores and deliquesce at maturity.

Physiology: Unknown. All known species appear to be obligate parasites of mushrooms (Agaricales).

2.1.15. Endomycete-like genera: See individual descriptions in chapter 31.

2.1.16. *Eremothecium*:

Vegetative reproduction: Multilateral budding and pseudohyphae are absent or present. True hyphae are formed.

Sexual reproduction: Asci are unconjugated, fusiform to cylindrical, become deliquescent, and produce 8–32 acicular to fusiform ascospores. Ascospores may have a central septum, and those of some species have a tapered, terminal extension of the cell wall.

Physiology: Sugars are fermented by some species. Nitrate is not assimilated. Pellicles may be formed on liquid media. Extracellular starch-like compounds are not produced. Inositol is not assimilated. Urease production is not determined. Gelatin is liquified by some species. Visible amounts of riboflavin are produced by some species.

2.1.17. *Galactomyces* (Anamorph *Geotrichum*):

Vegetative reproduction: Arthroconidia and true hyphae are produced.

Sexual reproduction: Asci are subspheroidal and arise following conjugation of hyphal gametangia. Asci produce 1 ascospore that is broadly ellipsoidal, sometimes with a faintly roughened surface, and a pale golden-brown color. Asci deliquesce at maturity.

Physiology: Sugars may be weakly fermented. Nitrate is not assimilated. Pellicle formation on liquid media is not determined. Extracellular starch-like compounds are

not produced. Inositol is not assimilated. Urease production and gelatin liquefaction are not determined.

2.1.18. *Hanseniaspora* (Anamorph *Kloeckera*):

Vegetative reproduction: Bipolar budding; pseudohyphae may form but true hyphae are absent.

Sexual reproduction: Asci are unconjugated and form 1–4 ascospores that may be hat-shaped, or spheroidal and smooth, or rough and with or without an equatorial ledge. Asci may be persistent or deliquescent.

Physiology: Sugars are fermented. Nitrate is not assimilated. Pellicles are not formed on liquid media. Extracellular starch-like compounds are not produced. Inositol is not assimilated. Urease is not produced. Gelatin liquefaction is not determined.

2.1.19. *Issatchenkia*:

Vegetative reproduction: Multilateral budding; pseudohyphae are present, but true hyphae are not formed.

Sexual reproduction: Asci are unconjugated unless directly arising from the pairing of complementary mating types. Asci are persistent and form 1–4 spheroidal ascospores that may appear roughened under the light microscope.

Physiology: Glucose is fermented. Nitrate is not assimilated. Pellicles form early on liquid growth media. Extracellular starch-like compounds are not formed. Inositol is not assimilated. Urease production is not determined. Gelatin may be liquified.

2.1.20. *Kluyveromyces*:

Vegetative reproduction: Multilateral budding; pseudohyphae may be present, but true hyphae are not produced.

Sexual reproduction: Asci may or may not be conjugated and produce 1–4, or exceptionally, much greater than 4 ascospores that are smooth, reniform, bacilliform, ellipsoidal or spheroidal. Ascospores are liberated at maturity.

Physiology: Sugars are fermented. Nitrate is not assimilated. Pellicles may form on liquid media. Extracellular starch-like compounds are not produced. Inositol is not assimilated. Urease production is not determined. Gelatin is not liquified.

2.1.21. *Lipomyces*:

Vegetative reproduction: Multilateral budding; pseudohyphae are absent or rudimentary; true hyphae are absent.

Sexual reproduction: Buds, and occasionally the parent cells, develop into asci which produce 4–20 smooth or roughened ellipsoidal ascospores that are amber or brown in color. Asci generally deliquesce.

Physiology: Sugars are not fermented. Nitrate is not assimilated. Pellicles may be formed on liquid media. Extracellular starch-like compounds are produced. Inositol may be assimilated. Urease production and gelatin liquefaction are not determined. Cultures are often quite mucoid.

2.1.22. *Lodderomyces*:

Vegetative reproduction: Multilateral budding; pseudohyphae are present but true hyphae are not produced.

Sexual reproduction: Asci are unconjugated, persistent and produce 1–2 long ellipsoidal ascospores.

Physiology: Sugars are fermented. Nitrate is not assimilated. Pellicles are not formed on liquid media. Extracellular starch-like compounds are not produced. Inositol is not assimilated. Urease production is not determined. Gelatin is not liquified.

2.1.23. *Metschnikowia*:

Vegetative reproduction: Multilateral budding; pseudohyphae are usually present but true hyphae are not produced.

Sexual reproduction: Asci are unconjugated, persistent, and elongate with one end usually enlarged. Asci produce 1–2 needle-shaped ascospores that have no terminal appendages.

Physiology: Sugars are fermented. Nitrate is not assimilated. Pellicles are formed infrequently on liquid media. Extracellular starch-like compounds are not formed. Inositol is not assimilated. Urease is not produced. Gelatin is not liquified.

2.1.24. *Nadsonia*:

Vegetative reproduction: Bipolar budding; pseudohyphae and true hyphae are not formed.

Sexual reproduction: Asci develop following conjugation between a cell and its bud. Either the bud, an opposing bud, or the cell becomes the ascus, which is persistent and forms 1–2 spheroidal ascospores that may be visibly roughened.

Physiology: Sugars may or may not be fermented. Nitrate is not assimilated. Pellicles are formed on liquid media. Extracellular starch-like compounds are not formed. Inositol is not assimilated. Urease is not produced. Gelatin is not liquified.

2.1.25. *Pachysolen*:

Vegetative reproduction: Multilateral budding; pseudohyphae may be poorly developed or absent; true hyphae are not produced.

Sexual reproduction: An ascus develops on the end of a refractile tube which arises from a vegetative cell that may or may not be conjugated. Asci produce 4 hat-shaped ascospores that are released through deliquescence of the ascus wall.

Physiology: Glucose and D-xylose are fermented. Nitrate is assimilated. Pellicles may form on liquid media. Extracellular starch-like compounds are not formed. Inositol is not assimilated. Urease production is not determined. Gelatin is not liquified.

2.1.26. *Pichia*:

Vegetative reproduction: Multilateral budding; pseudohyphae and true hyphae may be present.

Sexual reproduction: Asci may be conjugated or unconjugated, and persistent or deliquescent; 1–4, rarely 8,

ascospores are produced that may be hat-shaped, hemispheroidal, or spheroidal and with or without a subequatorial ledge.

Physiology: Sugars are fermented by some species. Nitrate is assimilated by some species. Pellicles may form on liquid media. Extracellular starch-like compounds are not formed. Inositol is assimilated by one species. Urease production is not determined. Gelatin may be liquified.

2.1.27. *Protomyces*:

Vegetative reproduction: Budding is multilateral, but predominantly at the polar regions of cells. True hyphae are formed within the tissue of parasitized plants.

Sexual reproduction: Asci are formed within plant host tissue and produce up to several hundred ellipsoidal ascospores that appear to be forcibly discharged.

Physiology: Sugars are not fermented. Nitrate is assimilated by some species. Pellicles may form on liquid media. Extracellular starch-like compounds are generally formed. Inositol is not assimilated as a carbon source. Urease production is not determined. Gelatin may be weakly liquified.

2.1.28. *Saccharomyces*:

Vegetative reproduction: Multilateral budding; pseudohyphae may be present, but not true hyphae.

Sexual reproduction: Asci are persistent, generally unconjugated, and form 1–4 smooth, ellipsoidal ascospores.

Physiology: Sugars are fermented. Nitrate is not assimilated. Pellicles are not formed on liquid media. Extracellular starch-like compounds are not formed. Inositol is not assimilated. Urease production is not determined. Gelatin is not liquified.

2.1.29. *Saccharomycodes*:

Vegetative reproduction: Bipolar budding; pseudohyphae are absent or poorly developed; true hyphae are not formed.

Sexual reproduction: Asci are unconjugated, persistent, and produce 1–4 smooth, spheroidal ascospores with a minute subequatorial ledge.

Physiology: Sugars are fermented. Nitrate is not assimilated. Pellicles are not formed on liquid media. Extracellular starch-like compounds are not formed. Inositol is not assimilated. Urease is not produced. Gelatin may be weakly liquified.

2.1.30. *Saccharomycopsis*:

Vegetative reproduction: Multilateral budding and arthroconidia; pseudohyphae are present; true hyphae are abundant and often produce blastoconidia.

Sexual reproduction: Asci are usually unconjugated, generally deliquescent, and often attached to hyphae, or sometimes free and spindle-like. The asci produce 1–4, rarely 8, ascospores that may be hat-shaped, reniform with terminal appendages, spheroidal or ellipsoidal, and may have one or more ledges. Surfaces may be smooth or roughened.

Physiology: Sugars may or may not be fermented. Nitrate is not assimilated. Pellicles may be formed on liquid media. Extracellular starch-like compounds are not formed. Inositol may be assimilated. Urease production is not determined. Gelatin is not strongly liquified.

2.1.31. *Saturnispora:*

Vegetative reproduction: Multilateral budding; pseudo-hyphae may be produced but true hyphae are not.

Sexual reproduction: Asci are persistent or deliquescent and may be unconjugated or show conjugation between a cell and its bud or between independent cells. Asci produce 1–4, rarely 8, smooth, spheroidal ascospores that have an equatorial ledge.

Physiology: Glucose is fermented. Nitrate is not assimilated. Pellicles may be formed on liquid media. Extracellular starch-like compounds are not formed. Inositol is not assimilated. Urease production is not determined. Gelatin may be weakly liquified. D-xylose is not assimilated.

2.1.32. *Schizosaccharomyces:*

Vegetative reproduction: Cells divide by fission. True hyphae may develop and often fragment into arthrospores.

Sexual reproduction: Asci are usually unconjugated, deliquescent, and produce 2–8 spheroidal, ellipsoidal or reniform ascospores.

Physiology: Sugars are fermented. Nitrate is not assimilated. Pellicles are not formed on liquid media. Extracellular starch-like compounds are produced. Inositol is not assimilated. Urease production and gelatin liquefaction are not determined.

2.1.33. *Sporopachydermia:*

Vegetative reproduction: Multilateral budding; pseudo-hyphae and true hyphae are not formed.

Sexual reproduction: Asci are deliquescent and may or may not be conjugated. The asci produce 1–4 spheroidal, subglobose, ellipsoidal or bacilliform ascospores.

Physiology: Glucose fermentation is absent or weak. Nitrate is not assimilated. Pellicles are not formed on liquid media. Extracellular starch-like compounds are not produced. Inositol is assimilated as a sole carbon source. Urease production is not determined. Gelatin is not liquified.

2.1.34. *Stephanoascus:*

Vegetative reproduction: Multilateral budding; pseudo-hyphae and true hyphae are produced. Blastoconidia may form on the true hyphae.

Sexual reproduction: Asci are globose with an apical cap cell, persistent, and develop following fusion of hyphal gametangia. Ascospores are oblate to hat-shaped, and 2–4 are formed in an ascus.

Physiology: Sugars are not fermented. Nitrate is not assimilated. Pellicle formation on liquid media is not determined. Extracellular starch-like compounds are

not produced. Inositol is assimilated by some species. Urease is not produced. Gelatin liquifaction is not determined.

2.1.35. *Torulasporea:*

Vegetative reproduction: Multilateral budding; pseudo-hyphae may be formed but true hyphae are not.

Sexual reproduction: Asci are persistent and may be unconjugated or show conjugation between a cell and its bud or between independent cells. Cells with tapered protuberances resembling conjugation tubes may also be present. Asci contain 1–4 spheroidal ascospores that are either roughened or smooth.

Physiology: Sugars are fermented. Nitrate is not assimilated. Pellicles are not formed on liquid media. Extracellular starch-like compounds are not produced. Inositol is not assimilated. Urease production is not determined. Gelatin is not liquified.

2.1.36. *Wickerhamia:*

Vegetative reproduction: Bipolar budding; pseudohyphae and true hyphae are not formed.

Sexual reproduction: Asci are unconjugated, deliquescent, and form 1–2, rarely 16, ascospores that somewhat resemble a baseball cap in shape.

Physiology: Sugars are fermented. Nitrate is not assimilated. Pellicles are not formed on liquid media. Extracellular starch-like compounds are not produced. Inositol is not assimilated. Urease is not produced. Gelatin is not liquified.

2.1.37. *Wickerhamiella:*

Vegetative reproduction: Multilateral budding; pseudo-hyphae and true hyphae are not formed.

Sexual reproduction: Asci are conjugated and form 1 roughened, asymmetrical, elongated ascospore. Asci deliquesce at the terminus and appear corrugated following spore release.

Physiology: Sugars are not fermented. Nitrate is assimilated. Pellicles are not formed on liquid media. Extracellular starch-like compounds are not produced. Inositol is not assimilated. Urease production is not determined. Gelatin is not liquified.

2.1.38. *Williopsis:*

Vegetative reproduction: Multilateral budding; pseudo-hyphae may form but true hyphae are absent.

Sexual reproduction: Asci may be persistent or deliquescent and are unconjugated, or show conjugation between a cell and its bud or between independent cells. Asci produce 2–4 smooth, spheroidal or ellipsoidal ascospores that have an equatorial ledge.

Physiology: Glucose is fermented. Nitrate may or may not be assimilated. Pellicles are often formed on liquid media. Extracellular starch-like compounds are not produced. Inositol is not assimilated. Urease production is not determined. Gelatin may be liquified. D-xylose is assimilated.

2.1.39. Yarrowia:

Vegetative reproduction: Multilateral budding; occasional formation of arthroconidia. Pseudohyphae and true hyphae are produced.

Sexual reproduction: Asci are unconjugated and slowly deliquesce at maturity. Asci form 1–4 ascospores that may be spheroidal, hemispheroidal, hat-shaped, or somewhat angular.

Physiology: Sugars are not fermented. Nitrate is not assimilated. Pellicles are formed on liquid media. Extracellular starch-like compounds are not produced. Inositol is not assimilated. Urease is strongly produced. Gelatin is strongly liquified. Lipases are produced.

2.1.40. Zygoascus:

Vegetative reproduction: Multilateral budding; pseudo-hyphae and true hyphae are formed.

Sexual reproduction: Asci are globose, persistent, and arise following conjugation between hyphal cells. Asci produce 1–4 ascospores that are hemispheroidal to hat-shaped.

Physiology: Sugars are fermented. Nitrate is not assimilated. Pellicles may be formed on liquid media. Extracellular starch-like compounds are not produced. Inositol is assimilated. Urease is not produced. Gelatin liquefaction is not determined.

2.1.41. Zygosaccharomyces:

Vegetative reproduction: Multilateral budding; pseudo-hyphae may be formed but true hyphae are not.

Sexual reproduction: Asci are persistent and may be unconjugated or show conjugation between a cell and its bud; asci predominantly form by conjugation between independent cells, often with both cells producing ascospores. Ascospores are smooth, spheroidal to ellipsoidal, with 1–4 per ascus.

Physiology: Sugars are fermented. Nitrate is not assimilated. Pellicles are not formed on liquid media. Extracellular starch-like compounds are not produced. Inositol is not assimilated. Urease production is not determined. Gelatin is not liquified.

2.1.42. Zygozoma:

Vegetative reproduction: Multilateral budding; pseudo-hyphae and true hyphae are not formed.

Sexual reproduction: Asci, which become deliquescent, arise from evaginations on single cells or from the bridge of conjugating cells, and produce 4 to numerous smooth, elongate ascospores that show an amber color.

Physiology: Sugars are not fermented. Nitrate is not assimilated. Pellicles are not formed on liquid media. Extracellular starch-like compounds are produced. Inositol may be assimilated. Urease production and gelatin liquefaction are not determined.

2.2. Anamorphic genera**2.2.1. Aciculoconidium:**

Vegetative reproduction: Multilateral budding; pseudo-hyphae and true hyphae with blastoconidia are present.

Diagnostic of the genus is the presence of blastoconidia, each with a needle-shaped terminus and a rounded base.

Physiology: Sugars are fermented. Nitrate is not assimilated. Pellicle formation on liquid media is not determined. Extracellular starch-like compounds are not produced. Inositol is not assimilated. Urease is not produced. Gelatin liquifaction is not determined.

2.2.2. Arxula:

Vegetative reproduction: Budding cells as well as arthroconidia are formed. Pseudohyphae and true hyphae are produced, the latter giving rise to blastoconidia that sometimes form on short denticles.

Physiology: Sugars are not fermented. Nitrate is assimilated. Pellicles may be formed on liquid media. Formation of extracellular starch-like compounds is not determined. Inositol is assimilated. Urease production and gelatin liquefaction are not determined.

2.2.3. Blastobotrys:

Vegetative reproduction: Multilateral budding; pseudo-hyphae and true hyphae are abundant. Diagnostic of the genus is production of blastoconidia on pedicels or denticles.

Physiology: Sugars are fermented by some species. Nitrate is not assimilated. Pellicle formation on liquid media is not determined. Inositol is assimilated by some species. Formation of extracellular starch-like compounds, urease production and gelatin liquefaction are not determined.

2.2.4. Botryozyma:

Vegetative reproduction: Multilateral budding; pseudo-hyphae are produced but true hyphae are absent. Diagnostic for this genus is the presence of terminal pseudohyphal cells that are dichotomously branched.

Physiology: Sugars are not fermented. Nitrate is not assimilated. Pellicles are not formed on liquid media. Extracellular starch-like compounds are not produced. Inositol is not assimilated. Urease production and gelatin liquefaction are not determined.

2.2.5. Brettanomyces (Teleomorph Dekkera):

Vegetative reproduction: Multilateral budding; cells are spheroidal to ellipsoidal, and some have an ogival shape. Pseudohyphae may form, but true hyphae are not produced.

Physiology: Sugars are fermented, and fermentation is usually stimulated by oxygen. Nitrate is assimilated by some strains. Pellicles may be formed on liquid media. Extracellular starch-like compounds are not produced. Inositol is not assimilated. Urease is not produced. Gelatin liquefaction is not determined. Acetic acid is often produced. Growth is slow and generally short-lived.

2.2.6. Candida:

Vegetative reproduction: Multilateral budding; cells are globose, ellipsoidal or cylindroidal, and occasionally

- 3(2). a Growth is butyrous and yeastlike *Schizosaccharomyces*: p. 391
 b Growth is predominantly mycelial; not exclusively yeastlike → 4
- 4(3). a Ascospores are not produced *Geotrichum*: p. 574
 b Ascospores are produced → 5
- 5(4). a Asci produce a single, ellipsoidal ascospore and completely deliquesce *Galactomyces*: p. 209
 b Asci produce 4–100-plus ellipsoidal ascospores and deliquesce at the tip *Dipodascus*: p. 181
- 6(2). a Cell division is by bipolar budding on a broad base → 7
 b Cell division is by multilateral budding, or not exclusively by bipolar budding on a broad base → 10
- 7(6). a Ascospores are formed → 8
 b Ascospores are not formed → 9
- 8(7). a Ascospores are cap-shaped *Wickerhamia*: p. 409
 b Ascospores are smooth and spheroidal; asci are unconjugated, persistent, and form 4 spores, which often conjugate in pairs *Saccharomyces*: p. 372
 c Ascospores are roughened and spheroidal; asci show conjugation between a cell and its bud, are persistent, and form 1–2 spores, often with a bud serving as an ascus *Nadsonia*: p. 268
 d Ascospores are hat-shaped, or roughened or smooth and spheroidal, and with or without an equatorial ledge; asci are unconjugated, persistent or deliquescent, and form 1–4 spores when hat-shaped or 2 when spheroidal *Hanseniaspora*: p. 214
- 9(7). a Glucose is fermented *Kloeckera*: p. 580
 b Glucose is not fermented *Schizoblastosporion*: p. 602
- 10(6). a Budding cells are markedly triangular *Trigonopsis*: p. 605
 b Budding cells are not markedly triangular → 11
- 11(10). a Some budding cells have an ogival shape; cultures smell of acetic acid and are short-lived → 12
 b Budding cells lack an ogival shape; cultures produce little or no acetic acid → 13
- 12(11). a Ascospores are formed *Dekkera*: p. 174
 b Ascospores are not formed *Brettanomyces*: p. 450
- 13(11). a Ascospores are formed → 14
 b Ascospores are not formed → 28
- 14(13). a Asci are borne on the tips of refractile tube-like cells *Pachysolen*: p. 271
 b Asci form brush-like clusters on the tips of erect ascophores *Cephaloascus*: p. 143
 c Asci form percurrently inside older asci *Ascoidea*: p. 136
 d Asci form between hyphae following conjugation, are globose, persistent and have an apical cap cell *Stephanoascus*: p. 400
 e Asci form between hyphae following conjugation, are globose, persistent, but lack an apical cap *Zygoascus*: p. 422
 f Asci are elongated, open by apical deliquescence, and produce 32–100-plus ellipsoidal to reniform spores *Dipodascopsis*: p. 178
 g Asci not as above → 15
- 15(14). a Ascospores are needle-like, sometimes with a terminal extension; asci are deliquescent *Eremothecium*: p. 201
 b Ascospores are needle-like; asci are persistent *Metschnikowia*: p. 256
 c Ascospores are elongate, asymmetrical, roughened, and of minute size; asci deliquesce at the terminus and appear corrugated following release of the single spore *Wickerhamiella*: p. 411
 d Ascospores are clavate; asci are deliquescent *Clavispora*: p. 148
 e Ascospores not as above → 16
- 16(15). a Hyphal septa have plugged pores that appear as small dots under the light microscope *Ambrosiozyma*: p. 129
 b Hyphal septa, if present, do not have plugged pores → 17
- 17(16). a Asci are predominantly attached to hyphae, or if free, are spindle-shaped; gelatin is not strongly liquified *Saccharomyces*: p. 374
 b Asci may be free or attached to hyphae; strong liquefaction of gelatin *Yarrowia*: p. 420
 c Asci are usually free and not spindle-shaped; gelatin is not strongly liquified → 18
- 18(17). a Growth occurs between 30–40°C; amino acids, B-vitamins, and an increased level of atmospheric CO₂ are required for growth *Cyniclomyces*: p. 154
 b Specialized growth conditions are not required → 19
- 19(18). a Asci arise as sac-like attachments on a cell → 20
 b Asci are not as sac-like attachments → 21
- 20(19). a Cultures are usually mucoid; ascospores are amber; asci do not arise attached to the bridge of conjugating cells *Lipomyces*: p. 248
 b Cultures are usually mucoid; ascospores are amber; some asci arise attached to the bridge of conjugating cells *Zygozoma*: p. 433
 c Cultures are not mucoid; ascospores are hyaline *Babjevia*: p. 141
- 21(19). a Ascospores are spheroidal; asci are unconjugated and persistent → 22
 b Ascospores are long ellipsoidal; asci are unconjugated and persistent *Lodderomyces*: p. 254
 c Ascospores are smooth, spheroidal or ellipsoidal, and have an equatorial ledge; asci may be conjugated and either deliquescent or persistent → 24
 d Ascospores are hat-shaped or spheroidal with a small subequatorial ledge; asci are either deliquescent or persistent *Pichia*: p. 273
 e Ascospores and asci show combinations different from above → 25
- 22(21). a Early formation of pellicles on liquid media *Issatchenkia*: p. 221
 b No early formation of pellicles on liquid media → 23
- 23(22). a Ascospores are roughened; nitrate is assimilated *Citeromyces*: p. 146
 b Ascospores are roughened; nitrate is not assimilated *Arxiozyma*: p. 134
 c Ascospores are smooth; nitrate is not assimilated *Saccharomyces*: p. 358

- 24(21). a D-Xylose is assimilated *Williopsis*: p. 413
 b D-Xylose is not assimilated *Saturnispora*: p. 387
- 25(21). a Glucose fermentation is early and vigorous → 26
 b Glucose fermentation is slow, weak, or absent → 27
- 26(25). a Asci are persistent and may be conjugated or unconjugated; ascospores are roughened or smooth and spheroidal; cells with tapered protuberances are often present *Torulasporea*: p. 404
 b Asci are persistent, often conjugated, with conjugation predominantly between independent cells, both of which usually produce ascospores; ascospores are smooth and spheroidal to short ellipsoidal *Zygosaccharomyces*: p. 424
 c Asci are deliquescent; ascospores are smooth and reniform, bacilliform, ellipsoidal or spheroidal *Kluyveromyces*: p. 227
- 27(25). a Inositol is not assimilated as a sole source of carbon; ascospores are roughened or smooth, spheroidal or ellipsoidal, with or without an equatorial ledge, or smooth and lenticular; asci are usually conjugated and may be persistent or deliquescent *Debaryomyces*: p. 157
 b Inositol is assimilated as a sole source of carbon; ascospores are smooth and spheroidal, subglobose, ellipsoidal, or bacilliform; asci are deliquescent *Sporopachydermia*: p. 395
- 28(13). a Cultures are red, pink, lavender or light yellow in color → 29
 b Cultures are white or tannish-white in color → 30
- 29(28). a Cultures are salmon red; weak presence of extracellular starch-like compounds *Protomyces*: p. 353
 b Cultures are salmon red; extracellular starch-like compounds are not present *Saitoella*: p. 600
 c Cultures are pink, lavender or light yellow; extracellular starch-like compounds are present *Lalaria (Taphrina)*: p. 582
 d Cultures are light pink to light orange; cells with endospores are present *Oosporidium*: p. 598
- 30(28). a Cultures are mucoid; extracellular starch-like compounds are present *Myxozyma*: p. 592
 b Cultures are not mucoid; extracellular starch-like compounds are not present → 31
- 31(30). a Blastoconidia with a needle-shaped terminus and a rounded base are present *Aciculoconidium*: p. 439
 b Terminal pseudohyphal cells are dichotomously branched *Botryozyma*: p. 449
 c Blastoconidia form on short denticles; nitrate is assimilated *Arxula*: p. 441
 d Blastoconidia form on denticles; nitrate is not assimilated *Blastobotrys*: p. 443
 e Sympodial production of blastoconidia on short conidiophores that arise directly from yeast cells; nitrate is not assimilated *Sympodiomyces*: p. 603
 f Blastoconidia do not arise on markedly denticulate conidiophores and are not sympodially produced; nitrate may or may not be assimilated *Candida*: p. 454

Chapter 16

A key to the anamorph genera of yeastlike Archi- and Euascomycetes

G.S. de Hoog

Contents

1. Introduction	123
2. Key to yeastlike Archi- and Euascomycetes	123

1. Introduction

A number of filamentous ascomycetous fungi (Euascomycetes) grow yeastlike in culture and may be confused with yeasts, which in the present book are conceived as either being of saccharomycetous or of basidiomycetous affinity. Euascomycetous anamorphs are distinguished from Saccharomycetes by having true hyphae with simple septal pores with Woronin bodies rather than micropores or dolipores, although in some genera of black yeasts Woronin bodies may be absent. Teleomorphs, where known, are perithecial or cleistothecial and belong to different orders of Ascomycetes. Hence the genera mentioned below are often of quite divergent relationships.

Ascospores are rarely produced in culture. The fungi mostly reproduce as Hyphomycetes by conidia, with additional budding cells. The main criteria for distinction of yeastlike Hyphomycetes are found in their morphology with the accent on details of conidiogenesis (Fig. 34). This classification does not correspond exactly with natural relationships based on teleomorph connections and supported by partial 18S rDNA sequence data. Some genera, thus, have to be taken as artificial entities (for example *Phialophora* and *Microdochium*), while in others the morphological groups have already been subdivided along natural lines (for example *Sporothrix*).

The following biological relationships have been established thus far:

- (1) Archiascomycetes, order Taphrinales, genera *Taphrina* and *Protomyces* (Nishida and Sugiyama 1994, Nishida et al. 1995).
- (2) Euascomycetes, order Dothideales, fam. Dothideaceae.

2. Key to yeastlike Archi- and Euascomycetes

1. a Conidiogenesis meristematic, by gradual swelling of the entire thallus, and with subsequent disarticulation; colonies slimy or moriform, restricted, black → 2
- b Conidiogenesis blastic or phialidic, by blowing out conidia; colonies more expanding, black, pink, yellow or white → 4
- 2(1). a Conidiogenesis endogenous; conidia liberated by disruption of parent cell walls; L-rhamnose and inulin not assimilated (Sigler et al. 1981) *Phaeothea* Sigler, Tsuneda & Carmichael
- b Conidia in packets, liberated by disarticulation; L-rhamnose and inulin assimilated → 3

The “black yeast” genera *Aureobasidium*, *Hormonema*, and probably *Hortaea* and the meristematic “black yeasts” *Botryomyces*, *Phaeothea* and *Sarcinomyces* (de Hoog and Yurlova 1994, de Hoog et al. 1997b).

- (3) Euascomycetes, order Chaetothyriales, fam. Herpotrichiellaceae. The “black yeast” genera *Exophiala*, *Phialophora*, *Rhinochadiella* and *Phaeococcomyces* (de Hoog 1977). Note that *Phaeococcomyces* is morphologically reminiscent of the basidiomycetous yeasts *Moniliella* and *Trichosporonoides*, which are distinguished by fermentation of glucose. *Phialophora* is phylogenetically heterogeneous, but a small group around the generic type species, *P. verrucosa*, contain herpotrichiellaceous species.
- (4) Euascomycetes, order Ophiostomatales, fam. Ophiostomataceae. Genus *Sporothrix*. Note that basidiomycetous *Sporothrix*-like species are now classified in *Cerinosterus*, and saccharomycetous *Sporothrix*-like species in *Candida* (de Hoog 1992).
- (5) Euascomycetes, Sphaeriales, fam. Coniochaetaceae. Most *Lecythophora* species probably are cultural states of members of this family (Mahoney and LaFavre 1981).
- (6) Euascomycetes, Leotiales, fam. Leotiaceae. *Aureohiphomyza* is an anamorph genus of *Gelitanipulnivella* (Hosoya and Otani 1995). *Myriogonium* (Malloch and de Hoog, ch. 31, p. 198) and *Calyptrozyma* (Boekhout et al. 1995b) may also be related, the latter having some similarity to members of the Thelebolaceae.

Physiological patterns have been determined for a limited number of species. Diagnostic features are given in a simplified manner in the generic key below. Since characters may be variable within each genus, additional criteria are sometimes listed. For each genus, some references are given for further reading.

Fig. 34. Diagram of characteristic morphologies of anamorph genera of yeastlike Euascomycetes: (1) *Botryomyces*; (2) *Sarcinomyces*; (3) *Phaeothecca*; (4) *Phaeococcomyces*; (5) *Aureobasidium*; (6) *Hormonema*; (7) *Hortaea*; (8) *Exophiala*; (9) *Rhinocladiella*; (10) *Sporothrix*; (11) *Trichosporiella*; (12) *Phialophora*; (13) *Phialemonium*; (14) *Lecythophora*; (15) *Hyphozyma*.

- 3(2). a Conidial packets black, with septa at right angles; additional blastic conidia occasionally present; glucuronate assimilated (Sigler et al. 1981) *Sarcinomyces* Lindner
- b Conidial packets initially whitish, cauliflower-like, with oblique septa; blastic conidia absent; glucuronate not assimilated (de Hoog and Rubio 1982, de Hoog and Guarro 1995) *Botryomyces* de Hoog & Rubio
- 4(1). a Hyphae absent or nearly absent → 5
- b Hyphae predominant → 6
- 5(4). a Colonies pale pigmented, mostly pinkish or purplish (Kramer 1987) Taphrinales
- b Colonies black (de Hoog 1977 (as *Phaeococcus*), de Hoog et al. 1995) *Phaeococcomyces* de Hoog
- 6(4). a Conidia sessile or on denticles, formed next to each other on the same cell (at least initially), occasionally in short chains that elongate at the apex → 7
- b Conidia produced one after another through the same scar or opening and adhering in slimy balls (phialidic or annellidic) → 10
- 7(6). a Hyphae mostly over 3 μm wide, locally transformed into chlamydoconidia (Hermanides-Nijhof 1977, de Hoog and Yurlova 1994) *Aureobasidium* Viala & Boyer
- b Hyphae mostly less than 3 μm wide; chlamydoconidia absent → 8
- 8(7). a Conidial apparatus dark olivaceous brown (de Hoog 1977, Veerkamp and Gams 1983) *Rhinocladiella* Nannfeldt
- b Conidial apparatus hyaline or subhyaline → 9

- 9(8). a Conidia close together on terminal denticles, often also alongside hyphae; erythritol and nitrate assimilated (de Hoog 1974, 1992) *Sporothrix* Hektoen & Perkins ex Nicot & Mariat
 b Conidia scattered alongside hyphae only; erythritol and nitrate not assimilated (de Hoog et al. 1985) *Trichosporiella* Kamyschko ex W. Gams & Domsch
- 10(6). a Colonies olivaceous-black; hyphae regularly olivaceous → 11
 b Colonies pale pinkish, reddish or yellowish, often later turning brown; hyphae hyaline or locally becoming pigmented → 13
- 11(10). a Expanding hyphae mostly less than 2.5 µm wide; conidia produced from inconspicuous annellated zones or from collarettes → 12
 b Expanding hyphae often over 3 µm wide; annellated zones conspicuous, about 2 µm wide (Miyaji and Nishimura 1985, de Hoog and Gerrits van den Ende 1992) *Hortaea* Nishimura & Miyaji
- 12(11). a Conidia produced through pronounced collarette openings (Domsch et al. 1980, Wang and Zabel 1990, Yan et al. 1995) *Phialophora* Medlar
 b Conidia produced from inconspicuous annellated zones (de Hoog 1977, de Hoog et al. 1995, de Hoog and Guarro 1995) *Exophiala* Carmichael
- 13(10). a Conidia produced from flat, barely visible openings → 14
 b Conidia produced from hyaline collarettes (Gams and McGinnis 1983) *Lecytophora* Nannfeld
- 14(13). a Hyphae often over 3 µm wide, with local chlamydo-spores (Hermanides-Nijhof 1977) *Hormonema* Lagerberg & Melin
 b Hyphae mostly less than 3 µm wide; chlamydo-spores absent → 15
- 15(14). a Colonies pink → 16
 b Colonies whitish or cream-colored (Gams and McGinnis 1983) *Phialemonium* W. Gams & McGinnis
- 16(15). a Conidia formed on ampulliform cells; local clusters of brown chlamydo-spores present (Domsch et al. 1980) *Microdochium* H. Sydow
 b Conidia formed alongside hyphae or on irregular protrusions; chlamydo-spores absent → 17
- 17(16). a Colonies pink, occasionally becoming brown (de Hoog and Smith 1981, 1986) *Hyphozyma* de Hoog & M.Th. Smith
 b Colonies yellowish to olive-brown, then with yellow pigment exuded into the medium → 18
- 18(17). a Melibiose and ethylamine assimilated (Boekhout et al. 1995b) *Calyptrozyma* Boekhout & Spaaij
 b Melibiose and ethylamine not assimilated (Hosoya and Otani 1995) *Aureohyphozyma* Hosoya & Otani

17. *Ambrosiozyma van der Walt*

M.Th. Smith

Diagnosis of the genus

Abundant formation of true mycelium with blastoconidia; in addition, budding yeast cells and pseudomycelium are present. Hyphal septa have a central, plugged pore surrounded by a thickening of the wall (dolipore-like). In light microscopy, the plugged pore shows as a small dark dot in the middle of the septum. Asci are generally formed on the hyphae. Ascospores are hat-shaped.

Sugars are fermented, often slowly and weakly. Nitrate is assimilated by some species. Diazonium blue B reaction is negative.

Type species

Ambrosiozyma monospora (Saito) van der Walt

Species accepted

1. *Ambrosiozyma ambrosiae* (van der Walt & D.B. Scott) van der Walt (1972)
2. *Ambrosiozyma cicatricosa* (D.B. Scott & van der Walt) van der Walt (1972)
3. *Ambrosiozyma monospora* (Saito) van der Walt (1972)
4. *Ambrosiozyma philentoma* van der Walt, D.B. Scott & van der Klift (1972)
5. *Ambrosiozyma platypodis* (J.M. Baker & Kreger-van Rij) van der Walt (1972)

Key to species

Systematic discussion of the species

17.1. *Ambrosiozyma ambrosiae* (van der Walt & D.B. Scott) van der Walt (1972)

Synonyms:

Pichia ambrosiae van der Walt & D.B. Scott (1971b)

Hormoascus ambrosiae (van der Walt & D.B. Scott) van der Walt & von Arx (1985)

Growth in malt extract: After 3 days at 25°C, the cells are spheroidal to ovoidal or short ellipsoidal (2.0–6.0) × (4.0–9.0–12.0) µm, and occur singly, in pairs or in

small clusters. A sediment and occasionally a ring are formed. After one month at room temperature the culture consists of a thick sediment of yeast cells and mycelial hyphae.

Growth on malt agar: After one month at room temperature, the streak culture is butyrous, somewhat raised, rather dull, smooth or slightly rugose and gray-white to creamish-brown or occasionally pink in areas which sporulate heavily. The margin is slightly irregular without aerial mycelium.

Dalmou plate cultures on potato- and corn meal agar: Pseudohyphae as well as true, branched hyphae are produced in the agar under the coverslip. Clusters of small, spheroidal blastoconidia develop near or at the septa of the mycelial hyphae. Anastomoses are occasionally observed between the hyphae.

Formation of ascospores: Ascus formation is usually preceded by conjugation between independent cells. The zygote generally divides to form a short chain of cells, and one or sometimes several successive terminal cells serve as asci. The asci, which become deliquescent, usually produce four hat-shaped spores. Van der Walt and Scott (1971a) reported that single-spore isolates form sporogenous colonies, thus indicating the species to be homothallic.

Ascospores were observed on V8- and 5% Difco malt agars.

Co-Q: 7, CBS 6003 (Yamada et al. 1987b)

Mol% G + C: 34.7 (S.A. Meyer, cited in Barnett et al. 1990)

Origin of the strains studied: CBS 6003 (ATCC 24613; NRRL Y-7524), from tunnels of *Platypus externedentatus*, Zululand, South Africa, type strain of *Pichia ambrosiae*; CBS 6816, unknown, N.J.W. Kreger-van Rij; CBS 7108, from *Crossotarsus* sp. infestation of moribund *Ficus sycomorus*, South Africa, J.P. van der Walt; CBS 8256, from tunnels of *Crossotarsus externedentatus*, South Africa, J.P. van der Walt.

Type strain: CBS 6003 (ATCC 24613), isolated by van der Walt.

17.2. *Ambrosiozyma cicatricosa* (D.B. Scott & van der Walt) van der Walt (1972)

Synonym:

Pichia cicatricosa D.B. Scott & van der Walt (1971b)

Growth in malt extract: After 3 days at 25°C, cells are short-ovoidal to elongate, pear- and lemon-shaped, (3–8) × (6–14) μ m, single or in pairs. Buds are formed on a broad base; more than one bud may be formed at the same site leading to multiple scars on the parent cell. Abundant branched mycelium with a diameter of 2.5–5 μ m is present. A flocculant sediment is formed. After one month at 17°C a thick lumpy mass is present. The culture has a fragrant odor.

Growth on malt agar: After one month at 17°C, the streak is cream colored to yellow, tough, dull and raised in the middle. The edge is fringed with mycelium.

Dalmou plate cultures on potato- and corn meal agar:

Branched mycelium is formed with groups of spheroidal to elongate blastoconidia at the end of the hyphae or alongside them, often in loose groups. Some blastoconidia produce a series of buds at the top and show polar elongation with multiple scars, the dactyloid cells (Scott and van der Walt 1971b). Pseudomycelium may be present.

Formation of ascospores: Asci are spheroidal or short-ovoidal and situated singly or in groups, occasionally among blastoconidia, at the end of the hyphae or alongside hyphae at the septa. Asci contain one to four, often two hat-shaped spores which are generally not liberated. Spores measure (5–6) × (10–12) μ m, including the brim (Scott and van der Walt 1971b).

Ascospores were observed on corn meal, oatmeal, and V8 agars.

Starch formation	-		

Co-Q: Not determined.**Mol% G+C:** 40.2 (S.A. Meyer, cited in Barnett et al. 1990)

Origin of the strains studied: CBS 6157 (ATCC 24611), from tunnels of *Xyleborus torquatus* in *Cussonia umbelifera*, Natal, South Africa, J.P. van der Walt, type strain of *Pichia cicatricosa*; CBS 6158, from tunnels of *Xyleborus torquatus* and *Platypus externedenatus* in *Macaranga capensis*, South Africa, received from J.P. van der Walt.

Type strain: CBS 6157.**17.3. *Ambrosiozyma monospora* (Saito) van der Walt (1972)****Synonyms:***Endomycopsis monospora* Saito (1932)*Endomycopsis fibuligera* (Lindner) Dekker var. *monospora* (Saito) Lodder & Kreger-van Rij (1952)*Pichia monospora* (Saito) Pignal (1968)*Endomyces bispora* Verrall (1943) [nec *Endomyces bisporus* Beck (1922)]*Endomycopsis fasciculata* Batra (1963a)*Pichia fasciculata* (Batra) Boidin, Abadie & Lehodey (1965a)*Pichia crossotarsi* Batra (1971)

Growth in malt extract: After 3 days at 25°C, the culture consists of mycelial hyphae with side branches with a diameter of 1.5–5.5 µm, and spheroidal to short-ovoidal, budding yeast cells measuring (7–9) × (7–13) µm, single, in pairs or in chains. Pseudomycelium may also be present. The culture has a fragrant odor. A loose, flocky sediment is formed. After one month at 17°C a thick, lumpy sediment, filling up the liquid, and a broad ring are present.

Growth on malt agar: After one month at 17°C, the streak culture is yellow to yellow-brown, tough, raised, dull, and delicately wrinkled over the whole surface. The margin is fringed with mycelium.

Dalmau plate cultures on potato- and corn meal agar: True, branched mycelium is formed. Spheroidal to short-ovoidal blastoconidia occur in chains or in clusters at the end of the mycelial hyphae or alongside them. Small protuberances may occur on the hyphae. Pseudomycelium may be present.

Formation of ascospores: Asci are spheroidal or ovoidal, and are situated at the end of the mycelial hyphae or alongside them at the septa. Single spores give cultures which sporulate again (Batra 1963a). Spores are hat-shaped; one to two are formed per ascus. They measure, including the brim, (3–4) × (6–8) µm, and are released from the ascus. The presence of many spores give the culture a brownish appearance.

Ascospores were observed on 5% Difco malt-, corn-meal-, potato-, and YM agars.

Wickerham; CBS 6392 (ATCC 18855), type strain of *Pichia crossotarsi*, ambrosia fungus of *Crossotarsus wollastoni*.

Type strain: CBS 2554, the original strain described as *Endomycopsis monospora* by Saito and isolated from coconut palm.

17.4. *Ambrosiozyma philentoma* van der Walt, D.B. Scott & van der Klift (van der Walt 1972)**Synonym:***Hormoascus philentomus* (van der Walt, D.B. Scott & van der Klift) van der Walt & von Arx (1985)

Growth in malt extract: After 3 days at 25°C, cells are spheroidal, short-ovoidal and ovoidal, (3.5–7) × (5–10) µm, single, in pairs or small chains. Pseudomycelium and true mycelium, may be present. A loose sediment is present. After one month at 17°C a thick lumpy sediment filling up the liquid is formed. The culture has a fragrant odor.

Growth on malt agar: After one month at 17°C, the streak culture is cream colored to brownish, tough, raised, slightly wrinkled or smooth and dull. The margin is fringed with mycelium.

Dalmou plate cultures on potato- and corn meal agar: Abundant formation of branched mycelium with spheroidal to ovoidal and long-ovoidal blastoconidia at the ends of hyphae, along them, at the septa in between, or often in small branched chains. Pseudomycelium, may be present.

Formation of ascospores: Fusion between loose yeast cells occurs. Asci are spheroidal or ovoidal, situated terminally or laterally on the hyphae, often in small chains. They contain one to four, usually four, hat-shaped ascospores which are easily liberated. According to van der Walt (1972), the species is homothallic.

Ascospores were observed on V8-, 5% Difco malt-, and corn meal agars.

Co-Q: 7 (Goto and Takami 1986)

Mol% G + C: 35.1 (S.A. Meyer, cited in Barnett et al. 1990)

Origin of the strains studied: CBS 6276 (ATCC 24607, IFO 1847, NRRL Y-7523); CBS 6279, tunnel of *Xyleborus aemulus*, South Africa, J.P. van der Walt.

Type strain: CBS 6276, received from J.P. van der Walt.

17.5. *Ambrosiozyma platypodis* (J.M. Baker & Kreger-van Rij) van der Walt (1972)

Synonyms:

Endomycopsis platypodis J.M. Baker & Kreger-van Rij (1964)

Hansenula platypodis (J.M. Baker & Kreger-van Rij) Fiol (1967)

Hormoascus platypodis (J.M. Baker & Kreger-van Rij) von Arx (1972)

Growth in malt extract: After 3 days at 25°C, the cells are spherical, 5–9 μ m, single or in pairs. Mycelial hyphae and pseudomycelium are also present. A sediment and a ring are formed. The culture has a sour fruity odor.

Growth on malt agar: After one month at 17°C, the streak culture is yellow with an orange tinge, tough, raised in the middle, dull and strongly plaited; the edge is fringed with mycelium.

Dalmou plate cultures on potato- and corn meal agar: True branched mycelium with spheroidal, ovoidal to long-ovoidal, blastoconidia is abundantly formed. The blastoconidia occur singly, in clusters or in short chains near the septa or in between. Anastomoses between the hyphae may occur. Pseudomycelium may be present.

Formation of ascospores: Conjugation between yeast cells may occur. The zygote forms buds or hyphae; the former may turn directly into asci, the latter may bear spheroidal or ovoidal asci terminally or laterally, often in small clusters. Anastomoses between hyphae may also occur. Asci contain one to four, usually four, hat-shaped spores which are easily released from the ascus. The presence of many spores gives the culture a brownish color. Single ascospores give cultures which sporulate again.

Ascospores were observed on 5% Difco malt-, corn-meal-, potato and YM agars.

Mol% G + C: 28.5–33.4, 4 strains (T_m : Nakase and Komagata 1969); 36.6–36.8 (Nakase and Komagata 1971b); 38.3–39.5 (S.A. Meyer, cited in Barnett et al. 1990)

Origin of the strains studied: CBS 4111 (ATCC 24747; NRRL Y-6732), tunnel of *Platypus cylindrus*, UK, J.M. Baker; CBS 4380, ex CBS 4111, J. Lodder; CBS 7105, CBS 7106, from *Platypus* sp. in *Notophagus cunninghamii*, Tasmania, G.S. de Hoog.

Type strain: CBS 4111, isolated by J.M. Baker

Comments on the genus

Van der Walt (1972) introduced *Ambrosiozyma* to accommodate mycelial yeast species which are associated with bark beetles and are characterized by hyphal septa with dolipores. He transferred *Pichia ambrosiae* and *P. cicatricosa*, as well as some *Endomycopsis* species, such as *E. monospora* and *E. platypodis*, to this genus. Shortly thereafter, von Arx (1972) described *Hormoascus* to accommodate the nitrate assimilating *A. platypodis*.

Kreger-van Rij (1984b) retained *A. platypodis* in the genus *Ambrosiozyma* but excluded *A. ambrosiae* because Kreger-van Rij and Veenhuis (1973) were unable to find dolipores. Consequently, Kurtzman (1984d) retained this latter species in *Pichia*. Van der Walt and von Arx (1985) emended *Hormoascus* to include nitrate-positive and nitrate-negative species and transferred *P. ambrosiae*, *A. platypodis* and *A. philentoma* to *Hormoascus*. Kurtzman and Robnett (1994a, 1995) demonstrated from comparisons of rRNA/rDNA sequences that *Ambrosiozyma* and *Hormoascus* are congeneric.

18. *Arxiozyma* van der Walt & Yarrow

C.P. Kurtzman

Diagnosis of the genus

Asexual reproduction is by multilateral budding on a narrow base. Cells are spheroidal, ovoidal or occasionally elongate. True hyphae are not produced, but pseudohyphae may form. Pellicles are not formed on the surface of liquid media.

Asci are unconjugated, persistent, and produce one, or rarely two, spheroidal ascospores. Ascospores are verrucose to tuberculate.

Glucose is fermented. Coenzyme Q-6 is produced. Diazonium blue B reaction is negative.

Type species

Arxiozyma telluris (van der Walt) van der Walt & Yarrow

Species accepted

1. *Arxiozyma telluris* (van der Walt) van der Walt & Yarrow (1984)

Systematic discussion of the species

18.1. *Arxiozyma telluris* (van der Walt) van der Walt & Yarrow (1984b)

Anamorph: *Candida pintolopesii* (van Uden) S.A. Meyer & Yarrow

Synonyms:

Saccharomyces telluris (as *S. tellustris*) van der Walt (1957)

Torulopsis pintolopesii van Uden (1952)

Candida pintolopesii (van Uden) S.A. Meyer & Yarrow (Yarrow and Meyer 1978)

Candida bovina van Uden & do Carmo-Sousa (1957)

Torulopsis bovina (van Uden & do Carmo-Sousa) van Uden & Vidal-Leiria (1970)

Candida slooffii van Uden & do Carmo-Sousa (1957)

Torulopsis pintolopesii van Uden var. *slooffii* Mendonça-Hagler & Phaff (1975) nom. inval.

Candida pintolopesii (van Uden) S.A. Meyer & Yarrow var. *slooffiae* (van Uden & do Carmo-Sousa) Mendonça-Hagler & Phaff ex S.A. Meyer, Ahearn & Yarrow (1984)

Growth on 5% malt extract agar: After 3 days at 25°C, the cells are spheroidal, ellipsoidal, or infrequently elongate (2.9–6.0) × (4.5–7.5) μm, and single, in pairs, or in small clusters. Growth is butyrous, dull-glistening, and tannish-white.

Growth on the surface of assimilation media: Pellicles are not formed.

Dalmau plate culture on morphology agar: After 7 days at 25°C, growth under the coverglass shows no true hyphae. Pseudohyphae may be formed by some strains. Aerobic growth is white to tannish-white, faintly glistening, and butyrous. Single colonies are low convex with a depressed center. A pleasant, faintly acidic odor is present.

Formation of ascospores: Asci are transformed from unconjugated vegetative cells and produce one, or infrequently two, spheroidal ascospores. Asci are persistent (Fig. 35). Transmission electron microscopy shows ascospore surfaces to be roughened by protuberances that arise from the outer layer of the spore wall (van der Walt

and Yarrow 1984b). It is not known whether this species is homothallic or heterothallic.

Ascospores were observed on McClary's acetate, YM, and V8 agars after 4–7 days at 25°C. Acetate agar gave markedly better ascospore germination than the other media tested.

Type strain: CBS 2685, from soil, South Africa.

Comments on the genus

Arxiozyma telluris was initially isolated and described by van der Walt (1957) as *Saccharomyces tellustris*. The original spelling of the species name was treated as an orthographic error and changed to *telluris* (van der Walt 1970d). Kreger-van Rij (1966b) and Kurtzman et al. (1980b) reported the ascospore walls of *S. telluris* to have surface protuberances, and with the redescription of *Saccharomyces* by Yarrow (1984a), *S. telluris* became the only species in the genus to have roughened ascospore walls. Because of this unique ascospore topology, van der Walt and Yarrow (1984b) proposed that *S. telluris* was phylogenetically isolated and they described the new genus *Arxiozyma*.

Kreger-van Rij (1958) proposed that *S. telluris* represented the teleomorph of *Candida bovina*, noting the phenotypic similarity between the two species as

Fig. 35. *A. telluris*, CBS 2685. Unjugated asci, each with a spheroidal ascospore. After 1 week on McClary's acetate agar at 25°C. Bar = 5 µm.

well as ascospore germination in one strain of *C. bovina*. Mendonça-Hagler and Phaff (1975) compared the extent of nDNA complementarity between *S. telluris*, *C. bovina*, *C. slooffii* and *Torulopsis pintolopesii* and showed that all species shared 80% or greater nDNA relatedness. Although Mendonça-Hagler and Phaff (1975) considered all four taxa to be conspecific, they proposed designating *C. slooffii* as a variety of *T. pintolopesii* because strains of *C. slooffii* consistently differed from other strains of the species by having a minimum growth temperature of 28°C, by exhibiting an absolute requirement for inositol, and by formation of pseudomycelium.

19. *Ascoidea* Brefeld & Lindau

G.S. de Hoog

Diagnosis of the genus

Colonies are smooth, moist or dry, mostly with an expanding, submerged mycelium. Species are often dimorphic, with colonies being restricted and yeastlike or expanding and hyphal. Budding cells and pseudomycelium are present or absent. Wide, true hyphae are present and form blastoconidia which are sessile or on denticles and occur singly or in short, branched chains.

Asci are lateral or terminal on hyphae, ellipsoidal or acicular, with firm walls, and contain numerous ascospores which are liberated through a terminal opening; new asci are formed percurrently inside the remains of a previous ascus. Ascospores are ellipsoidal, with a unilateral, mucilaginous brim.

Fermentation is absent. Urease is absent. Diazonium blue B reaction is negative, rarely weak.

Type species

Ascoidea rubescens Brefeld

Species accepted

1. *Ascoidea africana* Batra & Francke-Grosmann (1964)
2. *Ascoidea corymbosa* W. Gams & Grinbergs (1970)
3. *Ascoidea hylecoeti* Batra & Francke-Grosmann (1961)
4. *Ascoidea rubescens* Brefeld (1891)

Key to species

Systematic discussion of the species

19.1. *Ascoidea africana* Batra & Francke-Grossmann (1964)

Growth on 4% malt extract agar: After 10 days at 20–22°C, colonies are cream colored, smooth, thin, moist at the center and with a flat, somewhat farinose marginal zone. Hyphae are 3–5 µm wide, irregularly branched, and bear groups of blastoconidia at irregular distances. Conidia are sessile, clavate, of variable size, and bear a dense cluster of ellipsoidal secondary conidia on small denticles at the tip; secondary conidia are about 3×5 µm.

Formation of ascospores: Asci are formed singly or in small whorls alongside hyphae, mostly inserted just below distal septa, and broadly ellipsoidal, (8–13)×(20–30) µm, with firm walls containing 16–70 ascospores which are liberated by apical deterioration of the ascus. Ascospores are hat-shaped, (2.5–4.0)×(3.5–5.5) µm, cohering in slimy balls after liberation. New asci are formed percurrently 2 to 3 times inside the remains of a previous ascus, and the wall remnants become retracted (Fig. 36). The species is homothallic.

Fermentation: absent.

Co-Q: Not determined.

Mol% G+C: Not determined.

Origin of the strain studied: CBS 377.68 (ATCC 24275), from larva, West Africa, Batra.

Type strain: CBS 377.68.

Fig. 36. *A. africana*, CBS 377.68. Asci, liberated ascospores and true hyphae with clusters of conidia. Malt extract agar, 22°C, 30 days.

Comments: The species grows poorly in liquid medium and physiological test results were therefore judged with difficulty. The type strain was isolated from a larva infesting *Chlorophora excelsa* wood from West Africa, imported into Germany. The species is probably an ambrosia fungus disseminated by insect vectors.

19.2. *Ascoidea corymbosa* W. Gams & Grinbergs (1970)

Growth on 4% malt extract agar: After 10 days at 20–22°C, colonies are cream colored, smooth, slimy, and with or without expanding submerged mycelium. Hyphae are 4–5 µm wide with lateral branches, 2.5–3.5 µm wide, bearing whorls of sessile blastoconidia in short, branched, acropetal chains just below the septa. Conidia are ellipsoidal, (2.5–3.5)×(4–8) µm. Budding is mostly absent.

Formation of ascospores: Asci are formed in small groups in distal portions of hyphae. They are mostly ellipsoidal, (10–14)×(20–40) µm, with firm walls and contain 16–40 ascospores which are liberated by apical deterioration of the ascus. Ascospores are hat-shaped, (3.0–3.5) µm in diameter, and cohere in dense slimy balls after liberation. New asci are formed percurrently 2 to 3 times inside the remains of a previous ascus; the wall

remnants are extended or retracted (Fig. 37). The species is homothallic.

Fermentation: absent.

Co-Q: Not determined.

Mol% G + C: Not determined.

Origin of the strains studied: CBS 457.69 (ATCC 24275) and three additional strains, all from decaying wood of *Araucaria araucana*, Chile, Grinbergs.

Type strain: CBS 457.69.

Comments: The species has only been isolated from rotten *Araucaria* wood in Chile. Cultures show a remarkable dimorphism. Some strains formed a large zone with submerged, expanding hyphae while others mainly consisted of more typical, restricted, slimy microcolonies. Hyphal strains show little growth in submersion and physiological test results were therefore not presented. The species was synonymized with *A. africana* by von Arx and Müller (1984) but differs by smaller ascospores and by physiological characters listed in Table 17.

19.3. *Ascoidea hylecoeti* Batra & Francke-Grosmann (1961)

Growth on 4% malt extract agar: After 10 days at 20–22°C, colonies are cream colored, restricted (4 mm diameter), and slimy or expanding (15 mm) and thinly floccose. Slimy colonies consist of budding cells and fragile pseudomycelium bearing conidia in groups on large, butt-shaped denticles. Dry colonies are comprised of sparingly septate hyphae which are up to 8 μ m wide and often have irregular protrusions.

Formation of ascospores (Batra and Francke-Grosmann 1961): Asci are borne terminally on erect hyphae later becoming lateral due to further growth of supporting hypha; asci are formed in percurrent succession and are obclavate, (15–24) \times (160–400) μ m, apex 3–4.5 μ m wide, base 12–18 μ m wide, and contain 150–400 ascospores. Asci open by terminal deterioration and liberate a cirrus of ascospores (Fig. 38). Ascospores are ellipsoidal, (1.5–2.0) \times (2.5–3.2) μ m and appear hat-shaped due to a unilateral mucilaginous fringe.

Fermentation: absent.

Fig. 37. *A. corymbosa*, CBS 177.70. Asci, in part deteriorating apically, with new asci arising through retracted remains of the previous ascus. Liberated ascospores and true hyphae with clusters of conidia. Malt extract agar, 22°C, 3 weeks.

Fig. 38. *A. hylecoeti*, CBS 355.80. Asci, in part being produced through remains of a previous ascus; ascospores (from Batra and Francke-Grosman 1961); true, non-sporulating hyphae, pseudomycelial budding state.

Co-Q: Not determined.

Mol% G + C: Not determined.

Origin of the strain studied: CBS 355.80, from oak wood infested with a bark beetle (*Hylecoetus dermestoides*), Sweden, Francke-Grosman.

Type strain: CBS 355.80.

Comments: The authentic strain no longer produced ascospores. It showed a remarkable dimorphism with subcultures easily segregating into restricted, purely yeastlike and expanding, hyphal colonies. Due to this dimorphism, physiological test results were often difficult to judge.

19.4. *Ascoidea rubescens* Brefeld (Brefeld & Lindau 1891)

Growth on 4% malt extract agar: After 10 days at 20–22°C, colonies are cream colored, glassy, thin, flat and expanding with a fimbriate margin. Budding cells are absent. Hyphae are 12–22 µm wide, thick-walled, branched at acute angles and produce ellipsoidal conidia singly or in sympodial order from terminal cells. Conidia are ellipsoidal with a truncate base, sessile, subhyaline, (15–20) × (23–38) µm.

Formation of ascospores: Asci are single, formed terminally on hyphae or lateral branchlets and are clavate, (25–30) × (100–150) µm, with thick walls. They contain 16–160 ascospores which are liberated by apical rupture of the ascus. Ascospores are ellipsoidal with a unilateral, gelatinous brim, (5–9) × (7–10) µm and cohere in slimy heads after liberation. New asci are formed percurrently 2 to 3 times inside the remains of a previous ascus; ascus remains are not retracted (Fig. 39). The species is homothallic.

Fermentation: absent.

Assimilation:

Co-Q: Not determined.

Mol% G+C: Not determined.

Origin of the strains studied: CBS 116.35, Fitzpatrick; CBS 111.48, from tree, Varitchak, Yugoslavia.

Type strain: A living ex-type culture is not available.

Comments: Extensive descriptions and illustrations of the species were given by Walker (1931) and Batra (1978). All cells of the thallus, including conidia, are multinucleate, with the exception of ascospores, which are uninucleate (Walker 1935). Ascogenesis was described and illustrated by Popta (1899). The species is easily recognized by its conidial dimensions and by conidia being non-catenate and lacking budding cells. *A. rubescens* grows very poorly in submersion, which hampered interpretation of physiological test results.

Comments on the genus

Ascoidea species live in close association with bark beetles, in slime fluxes of trees or behind bark. All species appear primarily disseminated by insect vectors (Batra 1963b). Hyphal septa are perforated by micropores (von Arx and van der Walt 1986).

No specimen of *A. asiatica* Batra & Francke-Grosmann (1964) was available for study; live cultures of this species may be lost (L.R. Batra, personal communication).

Fig. 39. *A. rubescens*, CBS 111.48. Asci, opening at the apex and liberating ascospores. True hyphae with symphycol conidia; liberated conidia with truncate bases. Malt extract agar, 22°C, 2 months.

Ascoidea saprolegnioides Holtermann (1898) is not known in culture. It would differ from the remaining *Ascoidea* species in having spherical ascospores.

20. *Babjevia* van der Walt & M.Th. Smith

M.Th. Smith

Diagnosis of the genus

Asexual reproduction is by multilateral budding, mainly on a broad base. The cells are spherical, ovoidal, or occasionally elongated. Short, septate hyphae may be formed. Septa have a single, open, central pore. Cultures grow slowly.

Asci are saccate, attached to another cell, and produce one to many spores. Ascospores are hyaline, spherical to ovoidal, smooth and with a single layered wall.

Sugars are not fermented. Imidazole is utilized as source of nitrogen, but not nitrate. Diazonium blue B reaction is negative.

Type species

Babjevia anomala (Bab'eva & Gorin) van der Walt & M.Th. Smith

Species accepted

1. *Babjevia anomala* (Bab'eva & Gorin) van der Walt & M.Th. Smith (1995)

Systematic discussion of the species

20.1. *Babjevia anomala* (Bab'eva & Gorin) van der Walt & M.Th. Smith (Smith et al. 1995b)

Synonym:

Lipomyces anomalus Bab'eva & Gorin (1975).

Growth in malt extract: Growth is very slow. After 10 days at 20°C, the cells are spheroidal or ovoidal, (4.3–7.0) × (5.4–9.0) μm. A rudimentary pseudomycelium is formed. After 1 month at 20°, a small amount of sediment is present.

Growth on malt agar: Growth is slow and becomes visible only after one week at 20°C. After 10 days at 18°C, vegetative reproduction is mainly by budding on a broad base and the cells occur mostly as pseudohyphae. The cells are spheroidal or ovoidal, (4.5–7.0) × (5.3–9.0) μm and occasionally elongated, (4.0–10.0) × (8.0–18.0) μm. Capsules are not formed. Young cells usually contain one large vacuole and several small dark granules. After one month at 20°C, the streak culture is cream-colored, mat, and corrugated. Large spheroidal or ovoidal cells with many buds are common.

Dalmau plate cultures on potato agar: A simple pseudomycelium consisting of rows of cells formed by bud-fission is abundantly formed (Fig. 40).

Formation of ascospores: In the original description the generative life-cycle is described as follows. The species is homothallic. Asci are usually formed by conjugation of two buds on the same cell or on different cells. The conjugating buds are always separated from the parent cells by septa. This process closely resembles gametogangiangamy. After conjugation, the larger bud may separate from the parent cell. Several sac-like asci may be formed on the same cell (Fig. 40). Sometimes ascospores are formed within pseudomycelial cells or in cells with a great number of buds. The number of spores per ascus varies from 4 to 30 or more. The three strains investigated produced 1–4 ascospores; these are spheroidal, rarely

ovoidal, and with one or two small droplets. The surface of the spores is smooth.

Ascosporeulation was observed after 1–2 months incubation on diluted (1/10 or 1/20) V8 or YM agars at low temperatures (12–17°C).

Fermentation: absent.

Mol% G + C: 43.8, CBS 6740 (BD: Phaff and Holzschu, in Phaff and Kurtzman 1984); 41.7–44.9, 3 strains (T_m : Smith, unpublished)

Origin of the strains studied: CBS 6740 (ATCC 32435; NRRL Y-7931; VKM Y-1969), type strain, podzolic soil, Armenia, I.P. Bab'eva; CBS 7606 (VKM Y-2716), V.I. Golubev; CBS 7607 (KBP-2593), USSR, I. Chernov.

Fig. 40. *B. anomala*. Budding cells, pseudohyphae and a cell with multisporous asci. (After Bab'eva and Gorin 1975; from Phaff and Kurtzman 1984).

Type strain: CBS 6740, isolated by Bab'eva and Gorin (1975).

Comments on the genus

During a study of yeasts associated with podzolic soils of the northern Taiga zone, Bab'eva and Gorin (1975) recovered strains which formed multisporous, saccate asci borne on other cells. Regarding these isolates as representatives of the genus *Lipomyces*, they assigned them to a new taxon, *L. anomalus*, based on differences with the type species *L. starkeyi*. Major characteristics of *L. anomalus* included formation of non-encapsulated cells, pseudohyphal cell aggregates, pulvinate colonies on solid substrates, lower optimal growth temperature and utilization of relatively few carbon sources. Kurtzman and Liu (1990) and Yamada and Nogawa (1990b) compared partial sequences of large and small subunit rRNAs from species of *Lipomyces* and concluded that *L. anomalus* represented a divergent member of *Lipomyces*. Based on these analyses and reexamination of the fine structure of septa and ascospore walls, Smith et al. (1995b) transferred *L. anomalus* to the new genus *Babjevia*.

21. *Cephaloascus* Hanawa

G.S. de Hoog and C.P. Kurtzman

Diagnosis of the genus

Colonies are smooth or farinose, and white to pale cream-colored. Budding cells may be present; pseudomycelium and true hyphae are prevalent. Conidia are formed sympodially on large denticles, in short chains; ultimate conidia are clavate.

Ascophores are erect, hyaline or locally brown, and bear a cluster of asci at their apex. Asci arise in short, branched chains, ellipsoidal, thin-walled, and open by apical deterioration; asci mostly contain 4 hat-shaped ascospores.

Sugars may be weakly fermented. Nitrate is not assimilated. Diazonium blue B reaction is negative.

Type species

Cephaloascus fragrans Hanawa

Species accepted

1. *Cephaloascus albidus* Kurtzman (1977)
2. *Cephaloascus fragrans* Hanawa (1920)

Key to species

See Table 18.

1. a Melibiose assimilated; ascophores without metulae, bearing branched chains of asci *C. albidus*: p. 143
- b Melibiose not assimilated; ascophores bearing whorls of metulae with asci *C. fragrans*: p. 144

Table 18
Key characters of species in the genus *Cephaloascus*

Species	Glucose fermentation	Assimilation			Mating system
		Melibiose	Raffinose	Salicin	
<i>Cephaloascus albidus</i>	w	+	+	+	Heterothallic
<i>C. fragrans</i>	–	–	–	–	Homothallic

Systematic discussion of the species

21.1. *Cephaloascus albidus* Kurtzman (1977)

Growth on 4% malt extract/0.5% yeast extract agar:

After 10 days at 20–22°C, colonies attain 10 mm diameter, are slimy, hyaline at the center, with a soft texture. The teleomorph is formed in the dry, farinose, snow-white expanding zone. Margins are straight. Hyphae are 2–3 µm wide, hyaline, profusely branched, and bear apical clusters of conidia which are sessile or on marked denticles; the conidial apparatus easily falls apart into separate cells. Conidia are ellipsoidal to clavate, (1.5–2.5) × (3–5) µm.

Growth on the surface of assimilation media:

A heavy, dry pellicle is formed.

Formation of ascospores: Ascophores are erect, stout, hyaline, smooth and firm-walled, (5–7) µm wide, slightly tapering towards the tip, and up to 200 µm high. Asci are formed in short chains in a terminal cluster on the ascophore, are thin-walled, and ellipsoidal, (2.5–3.0) × (5–7) µm; occasionally they are formed on undifferentiated hyphae. Asci mostly contain 4 ascospores which are hat-shaped, (1.5–2.0) × (2.5–3.0) µm; asci open by apical deterioration (Fig. 41). The species is heterothallic.

Co-Q: 9, CBS 389.77 (Yamada et al. 1987b).

Mol% G+C: 37.8, CBS 389.77 (BD: Kurtzman, unpublished).

Origin of the strain studied: CBS 389.77 (NRRL Y-7343), from cranberry pumace, Canada.

Complementary mating types: CBS 390.77 (NRRL Y-7343-2) and 391.77 (NRRL Y-7343-6), obtained as single-ascospore isolates from the diploid type strain.

Type strain: CBS 389.77, from cranberry pumace.

Comments: The species was described in detail by Kurtzman (1977). Wang and Zabel (1990) described several strains from treated pine poles, which were identified as *C. albidus* on the basis of hyaline conidiophores. However, the difference in pigmentation of ascophores in the two species is unreliable as a specific criterion (Batra 1963c). Judging from the absence of growth with

raffinose, these strains were probably *C. fragrans*, which is known as a common inhabitant of pine wood.

Cephaloascus albidus has septa with a central micropore. This is in contrast to *C. fragrans*, which has a simple pore without Woronin bodies but with numerous electron-dense circular bodies (Kurtzman 1977).

21.2. *Cephaloascus fragrans* Hanawa (1920)

Synonyms:

Ascocybe grovesii Wells (1954)

Aureomyces mirabilis Ruokola & Salonen (1970)

Growth on 4% malt extract/0.5% yeast extract agar:

After 10 days at 20–22°C, colonies attain 10 mm diameter, are slimy, pale cream-colored, dry and become pale brown due to production of the teleomorph. Cultures with the teleomorph often exude a brown pigment into the medium. The margin is straight. Hyphae are 1–2 μ m wide, hyaline, profusely branched, and apically bear clusters of conidia which are sessile or on marked denticles; the conidial apparatus easily falls apart into separate cells. Conidia are ellipsoidal, (1.5–2.5) \times (4–6) μ m when terminal, or much longer when derived from disarticulating hyphae.

Growth on the surface of assimilation media: A dry, climbing pellicle is formed.

Formation of ascospores: Ascophores are erect, stout, thick-walled, often become rough-walled and golden brown in the apical part, about 8 μ m wide at the base, tapering to (4–6) μ m just below the slightly swollen apex, and up to 500 μ m high. Asci are formed in short chains on metulae at the apex of ascophores, thin-walled, ellipsoidal, (3–4) \times (5–7) μ m, and open by deterioration at the tip (Fig. 42). Asci contain 2–4 ascospores which are hat-shaped, (1.8–2.5) \times (2–3) μ m. The species is homothallic.

Fermentation: absent.

Co-Q: 9, CBS 121.29 and 5 additional strains (Yamada et al. 1987b).

Mol% G+C: 39.9, CBS 121.29 (BD: Kurtzman, unpublished).

Origin of the strains studied: CBS 121.29 (ATCC 36174, NRRL Y-6742), from human ear, Hanawa; CBS 150.61 (ATCC 12091, DAOM 33766), type strain of *Ascochybe grovesii*, from pine (*Pinus* sp.) wood, Wells, Canada; CBS 183.71 (ATCC 22396), type strain of *Aureomyces mirabilis*, from pine (*Pinus* sp.) wood, Ruokola, Finland; from pine (*Pinus* sp.) wood (1); from oak (*Quercus* sp.) wood (1).

Type strain: CBS 121.29, from a human ear.

Comments: The species was originally isolated from a human ear, but its prevalent ecological niche seems to be pine or oak wood in association with bark insects. An extended description of the species was given by Schippers-Lammertse and Heyting (1962).

The teleomorph is abundantly produced on nutritionally poor media. Cultures with teleomorphs often exude a brown, water-soluble pigment into the medium. The pigment was produced by nearly all strains in growth tests with ethylamine, lysine and cadaverine, but remained absent with most carbon compounds tested.

Kurtzman (1977) found the species to have simple septal pores without Woronin bodies but with numerous, electron-dense circular bodies. The species is diploid

Fig. 42. *C. fragrans*. Ascophores with sterile metulae bearing chains of asci which deteriorate at the distal end, CBS 150.61, 5% malt extract agar, 25°C, 1 week; hyphae with conidia, CBS 121.29.

(Wilson 1961). The cell walls are rich in mannose, while cellulose and rhamnose are absent (Weijman 1976).

22. *Citeromyces* Santa María

C.P. Kurtzman

Diagnosis of the genus

Asexual reproduction is by multilateral budding on a narrow base. Cells are spheroidal to ellipsoidal. Neither pseudohyphae nor true hyphae are produced.

Asci are persistent and contain one or, infrequently, two roughened spheroidal ascospores. Asci arise from diploid cells or from conjugation between complementary mating types.

Sugars are fermented. Nitrate is assimilated. Coenzyme Q-8 is present. Diazonium blue B reaction is negative.

Type species

Citeromyces matritensis (Santa María) Santa María

Species accepted

1. *Citeromyces matritensis* (Santa María) Santa María (1957)

Systematic discussion of the species

22.1. *Citeromyces matritensis* (Santa María) Santa María (1957)

Anamorph: *Candida globosa* Yarrow & S.A. Meyer

Synonyms:

Hansenula matritensis Santa María (1956a)

Torula globosa Olson & Hammer (1935) nom. nud.

Torulopsis globosa (Olson & Hammer) Lodder & Kreger-van Rij (1952) nom. nud.

Candida globosa Yarrow & S.A. Meyer (1978)

Growth on 5% malt extract agar: After 3 days at 25°C, the cells are spheroidal to ellipsoidal (3.0–9.5) × (4.0–10.5) μm, occur as singles, pairs, or in threes, and may have one or two buds. Growth is butyrous and white to faintly tannish-white.

Growth on the surface of assimilation media: Pellicles are not formed.

Dalmou plate culture on morphology agar: After 7 days at 25°C, growth under the coverglass lacks pseudohyphae or true hyphae. Aerobic growth is butyrous, cream colored and slightly glistening with fine striations and a tannish, depressed center. Colony margins are entire or finely lobed.

Formation of ascospores: Many natural isolates are diploid and the vegetative cells convert directly into asci. Asci have thick persistent walls and contain one or, infrequently, two spheroidal ascospores with a roughened wall and a prominent lipid droplet (Fig. 43). Sporulation is usually abundant on YM agar, and well-sporulated cultures turn red to brown. Wickerham (1958) demonstrated *C. matritensis* to be heterothallic by heat treatment of a sporogenous culture of the type strain. In addition, he showed that the type strain of *Candida* (*Torulopsis*) *globosa* (NRRL Y-1506, CBS 162) conjugated with one of the mating types (NRRL Y-2407-9), but apparently represents a unisexual diploid form of this species because it also sporulated alone on media with high sugar concentrations. Complementary mating types show a strong sexual agglutination reaction if grown in liquid medium rather than on an agar medium (Wickerham 1958).

Ascospores were observed on YM-, malt extract-, and V8 agars after 10 days at 25°C.

Mol% G + C: 45.5, 45.2, CBS 2764 (*T_m*: Nakase and Komagata 1968a; BD: C.P. Kurtzman, unpublished).

Origin of the strains studied: NRRL Y-2407 (CBS 2764), fermenting fruit in syrup, J. Santa María, Spain (1); sugar, J. Santa María, Spain (1); condensed milk from the Netherlands (1), Spain (1); NRRL Y-1506 (CBS 162), type strain of *Candida* (*Torulopsis*) *globosa*, from condensed milk, U.S.A.; flux from sandalwood (*Myoporum sandwicense*), Hawaii, U.S.A. (5).

Fig. 43. *C. matritensis*, CBS 2764. Asci with ascospores, after 10 days, YM agar, 25°C. Bar = 5 μ m.

Complementary mating types: NRRL Y-2407-9 (CBS 7103) and NRRL Y-2407-10 (CBS 7104), isolated following heat treatment of the diploid type strain.

Type strain: CBS 2764 (NRRL Y-2407) received from J. Santa Maria as the type strain of *Hansenula matritensis*. This strain was isolated from fruit preserved in syrup.

Comments on the genus

Citeromyces is unusual among taxa that form rugose spheroidal ascospores because it is characterized by coenzyme Q-8. Whether *Citeromyces* represents a unique phylogenetic line is unknown and, consequently, knowledge of its position among the yeasts must await future molecular comparisons.

Original isolates of *C. matritensis* were from foods with high sugar content. More recently, the occurrence of this species has been documented in nature with repeated isolations from fluxes of the sandalwood tree (H.J. Phaff and W.T. Starmer, personal communication).

23. *Clavispora* Rodrigues de Miranda

M.A. Lachance and H.J. Phaff

Diagnosis of the genus

Asexual reproduction is by multilateral budding on a narrow base. Cells are ovoid, ellipsoidal or elongate. Pseudomycelium may be formed, but true mycelium is not formed.

Conjugation of haploid cells of opposite mating types precedes ascus formation. The ascospores are clavate, sometimes containing a small oil droplet; one or two (rarely three or four) ascospores are formed per ascus. The spore wall may have small warts visible by electron microscopy. The spores are easily liberated from the ascus.

Glucose is fermented. Nitrate is not assimilated. Coenzyme Q-8. Diazonium blue B reaction is negative.

Type species

Clavispora lusitaniae Rodrigues de Miranda

Species accepted

1. *Clavispora lusitaniae* Rodrigues de Miranda (1979)
2. *Clavispora opuntiae* Phaff, Miranda, Starmer, Tredick & Barker (1986)

Systematic discussion of the species

23.1. *Clavispora lusitaniae* Rodrigues de Miranda (1979)

Anamorph: *Candida lusitaniae* van Uden & do Carmo-Sousa

Synonyms:

Candida lusitaniae van Uden & do Carmo-Sousa (1959)

Candida parapsilosis (Ashford) Langeron & Talice var. *obtusa* Dietrichson (1954) nom. nud.

Candida obtusa (Dietrichson) van Uden & do Carmo-Sousa ex van Uden & H.R. Buckley (1970)

Saccharomyces carmosousae Montrocher (1967)

Growth on YM agar: After 3 days at 25°C, the cells are subglobose, ovoidal, to elongate, (2–6) × (3–10) µm, single, in pairs or in short chains. Growth is butyrous, white to cream colored, glistening or occasionally dull and rugose.

Growth in glucose–yeast extract broth: A sediment is normally formed after 2 weeks at 25°C. Occasionally growth may be flocculent.

Dalmau plate culture on corn meal agar: After

one week at 25°C, pseudomycelium is abundant and well developed. Colonies may be fringed with pseudohyphae.

Formation of ascospores: Asci are bilobate, containing usually one or two (rarely three or four) clavate ascospores (Fig. 44). Warts may (Rodrigues de Miranda 1984a) or may not (Rodrigues de Miranda 1979) be visible by electron microscopy. The ascospores are liberated from the asci soon after their formation. On rare occasions, spherical ascospores are formed.

Abundant sporulation occurs 2–4 days at 17–25°C after mixing cultures of compatible mating types on 1% malt extract agar. Nearly all isolates are fertile.

Co-Q: 8 (Yamada and Kondo 1973).

Mol% G + C: 45.1–45.7, 5 strains, including CBS 4413 and CBS 6936 (BD: Lachance et al. 1986).

Origin of the strains studied: CBS 1944, clinical specimen, Dietrichson, Norway, type strain of *Candida obtusa*; CBS 4413, type strain of *Candida lusitanae*, and CBS 4415, from pig digestive tract, van Uden, Portugal; CBS 6936, from peel juice of *Citrus*, Mateles, Israel; CBS 7270, received by CBS as *Candida kruisii*, clinical specimen, Woodgyer, New Zealand. SU(B)79-257.1, from trunk rot of boojum tree (*Idria columnaris* Kellogg), and SU(B)79-267.12 and SU(B)86-460.5, from stem rot of agria cactus, [*Stenocereus gummosus* (Engelmann) Gibson & Horak], Baja California N.; SU(B)80-29, from leaf rot of *Agave* L. sp., Arizona; SU(B)86-287, from rotting tissue of cactus, [*Cephalocereus russelianus*, (Otto) Rose], Venezuela; SU(B)86-780.2, from stem rot of cactus [*Cephalocereus hoppenstedtii* (Weber) K. Schum.] Mexico; SU(B)86-968.1, from cladode rot of prickly pear [*Opuntia ficus-indica* (L.) Miller] Florida, U.S.A., Starmer; UCD-FST 81-467C, from cladode rot of prickly pear, (*Opuntia phaeacantha* Engelmann), Arizona, U.S.A.;

UWO(PS)83-1068.1 and UWO(PS)83-1080.1, from decaying fruit of prickly pear (*Opuntia stricta* Haworth) and UWO(PS)83-1156.2, from fly (*Drosophila bromeliae* Sturtevant) collected on morning glory (*Ipomoea* L. sp.), Cayman Islands; UWO(PS)85-286.1, from fly (*Drosophila carbonaria* Patterson & Wheeler) collected on mesquite [*Prosopis juliflora* Swartz (DC)], Arizona, U.S.A. and UWO(PS)WN9-8 and UWO(PS)WN9-20, from effluents of chocolate factory, Ontario, Canada.

Complementary mating types: CBS 6936 (h^+) and CBS 4413 (h^-).

Type strain: CBS 6936, isolated by Mateles from citrus peel juice; strain CBS 4413, isolated by van Uden from a pig is the isotype.

Comments: It was initially thought (Rodrigues de Miranda 1984a; Lachance et al. 1986) that *C. lusitanae* consistently assimilates L-rhamnose, suggesting that this response could serve as a diagnostic species character. Some strains examined more recently, CBS 7270 and SU(B)86-287, failed to utilize L-rhamnose, but their identity was ascertained by mating experiments. An imperfect positive correlation was found between L-rhamnose utilization and that of citric acid in this case. In a study of 13 clinical isolates, Gargeya et al. (1990) found two strains that neither utilized L-rhamnose nor exhibited mating reactions. DNA reassociation, however, demonstrated a high degree of genetic relatedness between these variants and authentic *C. lusitanae* strains. Also, one of their mating strains failed to utilize maltose. Rodrigues de Miranda (1984a) reported that *C. lusitanae* exhibits vitamin independence. None of the strains we have examined grew on vitamin-free medium. The 11 strains studied by van Uden and Buckley (1970) and the 10 strains examined by Barnett et al. (1983) required biotin, pyridoxine, and thiamin for growth.

Mating compatibility among strains of *C. lusitanae* generally follows a pattern clearly consistent with a single-locus, biallelic system. The holotype (CBS 6936) has been arbitrarily designated h^+ , and the isotype (CBS 4413), h^- (Lachance et al. 1986). According to Gargeya et al. (1990), h^+ corresponds to the designation a used by other authors (and accordingly h^- corresponds to α), although the initial assignment

of mating types is not clear due to a typographical error in Rodrigues de Miranda's (1979) original description. Strains CBS 1944, CBS 7270, SU(B)79-257.1, SU(B)80-29, and UWO(PS)WN9-8 are of mating type h^+ , while CBS 4415, SU(B)79-267.12, SU(B)86-460.5, SU(B)86-287, SU(B)86-780.2, SU(B)86-968.1, UCD-FST 81-467C, UWO(PS)83-1068.1, UWO(PS)-83-1080.1, UWO(PS)83-1156.2, UWO(PS)85-286.1, and UWO(PS)WN9-20 are of mating type h^- .

The ecological niche of *C. lusitaniae* is ill-defined. The yeast is recovered quite frequently in clinical specimens, but is not regarded as a true human pathogen (Hurley et al. 1987). It was first recognized as an opportunistic infectious organism by Holzschu et al. (1979), and has since turned up in over a hundred specimens from patients suffering from immune deficiencies (Gargeya et al. 1990). A study of 35 clinical isolates (Merz et al. 1992) revealed that a significant amount of genetic variation occurs from clone to clone. These could be assigned, on the basis of their electrokaryotypes, to 15 groups corresponding to the 15 patients from which they had been isolated. Although *C. lusitaniae* occurs in cactus, it cannot be considered cactophilic, having been reported only 10 times in nearly two thousand samples (Starmer et al. 1990). Its ability to grow at elevated temperatures combined with its recovery in several samples from warm-blooded animals (van Uden and Buckley 1970) may provide clues on the nature of its natural habitat, but alternatively may reflect the greater intensity of research efforts in that area in the past.

23.2. *Clavispora opuntiae* Phaff, Miranda, Starmer, Tredick & Barker (1986)

Synonymy:

Lodderomyces opuntiae Starmer (1981) nom. nud.

Growth on YM agar: After 3 days at 25°C, the cells are subglobose, ovoidal to elongate (2–5) × (3–16) μm, single, in pairs or in short chains. Growth is butyrous, white to cream colored and glistening. A characteristic fringe of submerged pseudomycelium is formed. After storage on YM agar slants covered with mineral oil for several months, growth on YM agar may take the form of rugose, convoluted colonies.

Growth in glucose-yeast extract broth: A sediment is normally formed after 2 weeks at 25°C. After storage on YM agar slants covered with mineral oil for several months, a heavy pellicle may be formed on liquid media after a week.

Dalmou plate culture on corn meal agar: After one week at 25°C, pseudomycelium is abundant and well developed. Colonies are fringed with pseudohyphae.

Formation of ascospores: Asci are bilobate, containing usually one or two (rarely three or four) clavate ascospores similar to those formed by *C. lusitaniae* (Fig. 44). Warts are visible by electron microscopy only (Phaff et al. 1986). The ascospores are liberated from the asci soon after their formation.

In most strains, abundant sporulation occurs 2–4 days at 17–25°C after mixing compatible mating types on 1% malt extract agar.

Co-Q: 8 (Phaff et al. 1986).

Mol% G + C: 43.1–44.1, 11 strains, including UCD-FST 77-279 (CBS 7068) and UCD-FST 78-540A (CBS 7069) (BD: Phaff et al. 1986).

Origin of the strains studied: UCD-FST 77-279 (CBS 7068) and UCD-FST 78-540A (CBS 7069) are among hundreds of strains isolated from various species of prickly pear: in Australia, *Opuntia vulgaris* Miller (syn. *O. monacantha*), *O. stricta* Haworth, *O. streptacantha* Lemaire, *O. tomentosa* Salm-Dyck; in Venezuela, *O. boldinghii* Britton & Rose, *O. elatior* Miller; in Hawaii, *O. megacantha* Salm-Dyck (syn. *O. ficus-indica*); in Peru, *Opuntia* (Tournefort) Miller sp.; in Arizona, U.S.A., *O. ficus-indica*, *O. phaeacantha*; in Texas, *O. lindheimeri* Engelm; in the Bahamas, the Antilles, and the Caribbean, *O. moniliformis* (L.) Haworth, *O. stricta* [UWO(PS)83-877.1 (ATCC60725)]; in Mexico, *O. ficus-indica*, *O. oricola* Philbrick, *O. wilcoxii* Britton & Rose, *Nopalea* Salm-Dyck sp. (syn. *Opuntia* sp.); in Spain and South Africa, *O. ficus-indica*; in Brazil, *O. vulgaris* (received from Rosa). Some strains are from columnar cactus species, *Stenocereus alamosensis* (Coulter) Gibson & Horak, *S. griseus* (Hawthorn) Buxbaum, *S. hystrix* (Hawthorn) Buxbaum, *S. pruinosus* (Otto) Buxbaum, *S. stellatus* (Pfeiffer) Riccobono, *Cephalocereus royenii* (Linnaeus) Britton & Rose [UWO(PS)-718.1], *C. lanuginosus* (L.) Britton & Rose, *Myrtillocactus cochal* (Orcutt) Britton & Rose. A few strains are from cactus flies:

Drosophila mettleri Heed and *D. nigrospiracula* Patterson & Wheeler recovered on giant saguaro cactus [*Carnegiea gigantea* (Engelmann) Britton & Rose], Arizona, U.S.A.; *D. mulleri* Sturtevant [UWO(PS)83-803.2 (ATCC 60724)] and *D. mayaguana* Vilela collected on *Opuntia* L. spp., Caribbean. Several strains were recovered from the prickly pear moth, *Cactoblastis cactorum* Berg. Some strains (received from Rosa) were recovered from feeding sites of the moth *Sigelgaita* (Heirich) sp. in *Pilosocereus arrabidaei* (Lem.) Byles et Rowl. in Brazil. Strain UWO(PS)85-351.1 is from the exudate of an oak (*Quercus emoryi* Torr.) growing in the vicinity of cacti in Arizona.

Complementary mating types: CBS 7068 (h^+) and CBS 7069 (h^-).

Type strain: CBS 7068; strain CBS 7069 is the isotype. Both are prickly pear isolates from Australia.

Comments: *C. opuntiae* was described (Phaff et al. 1986) to accommodate isolates consistently recovered from prickly pear (*Opuntia* L. spp.), and less frequently from other cacti. Although *C. opuntiae* occurs in decaying cactus fruit as well as somatic tissue, its host specificity is remarkable, in view of its worldwide distribution. Found in 10% of all prickly pear samples ever collected (Lachance et al. 1988), *C. opuntiae* accounts for 5% of the yeasts isolated from prickly pears and 2% or less of isolates from other cactus species (Starmer et al. 1990). Many vectors (e.g., *Drosophila* spp.) are likely to contribute significantly to the yeast's distribution, but the prickly pear moth, *Cactoblastis cactorum* Berg, is thought to play a major role in confining *C. opuntiae* mostly to *Opuntia* spp., as the occurrence of the moth coincides to some extent with the abundance of the yeast (Starmer et al. 1988a). DNA fingerprinting (Lachance 1990a) indicated that cacti may bear, in their *C. opuntiae* biota, a genetically diverse resident component as well as a more homogeneous population associated with *C. cactorum*. Rosa et al. (1992), working in the region of Rio de Janeiro, Brazil, reported that *C. opuntiae* occurs there less abundantly in *Opuntia* species than in the columnar cactus *Pilosocereus arrabidaei* (Lem.) Byles & Rowl., where the yeast appears to exist in association with the moth *Sigelgaita* (Heirich) sp.

Mating compatibility in *C. opuntiae* is typically a single-locus, biallelic system. The holotype (CBS 7068) is designated h^+ , and the isotype (CBS 7069), h^- (Phaff et al. 1986). Considerable inequalities are observed in the distribution of mating types within local populations (Lachance 1990a). An $h^+ : h^-$ ratio greater than 30:1 is observed among Australian isolates (Phaff et al. 1986), with the nearly exact reverse in strains collected on the Bahamian Island of Great Inagua (M.A. Lachance, H.J. Phaff and W.T. Starmer, unpublished data). Brazilian isolates exhibited a 20:1 mating type ratio (Rosa et al. 1992). Even more extreme disparities are known to exist on islands of the Hawaiian archipelago (M.A. Lachance and W.T. Starmer, unpublished data).

Although some strains of *C. opuntiae* may exhibit delayed reactions for the assimilation of trehalose and a few other carbon compounds, variation is rather minimal in this species. The exception is strain UWO(PS)83-718.1 (Lachance et al. 1986), which differs from others by its very weak growth on 2-keto-D-gluconate and its higher sensitivity to inhibition by saponins of the agria cactus, *Stenocereus gummosus* (Englemann) Gibson & Horak. These differences are paralleled by the fact that this is the only strain of *C. opuntiae* ever recovered from *Cephalocereus royenii* (L.) Britton & Rose, even though nearly 100 plants of that cactus have been sampled (Starmer et al. 1990). Matings between strain UWO(PS)83-718.1 (h^-) and several h^+ strains invariably lead to very low meiotic recombination (P. Lo and M.A. Lachance, unpublished data). In addition, the large subunit rDNA coding region of that strain contains a unique restriction site not found in the rest of the species (Lachance 1990a). While it would be premature to describe a variety on the basis of a single strain, the anticipated recovery of additional strains from *Cephalocereus royenii* or from hosts sympatric to that cactus is expected to provide insight on trans-specific evolution in this yeast species.

C. opuntiae is capable of ethanol production from D-xylose under aerobic conditions (Nigam et al. 1985). Of 11 strains studied, UWO(PS)83-803.2 (ATCC60724) and UWO(PS)83-877.1 (ATCC60725) had the highest yields of 34 and 57% of the theoretical value under certain conditions.

Comments on the genus

Rodrigues de Miranda (1979) described the monotypic genus *Clavispora* after observing that strains previously assigned to *Candida lusitanae* mated with a new strain isolated from *Citrus* peel juice by Mateles, in Israel, giving rise to clavate ascospores. The type strain of *Candida obtusa* (CBS 1944) was also found to be compatible. A strain isolated from a mushroom and designated as *Candida obtusa* var. *arabinosa* did not show sexual reactions with any of the mating types, and was reassigned to *Pichia mississippiensis* (Kurtzman et al. 1980a).

Prior to the publication of the genus *Clavispora* by Rodrigues de Miranda (1979), *C. opuntiae* was thought to represent a species of *Lodderomyces* because of the shape of its ascospores (e.g., Starmer 1981b). The morphological similarity of the new species with *C. lusitanae* later became obvious and prompted the description by Phaff et al. (1986).

Although the two *Clavispora* species are barely distinguishable on the basis of physiology and morphology, they are sharply distinct at the genetic level. Without exception, mating is restricted to intraspecific crosses. DNA reassociation and rDNA restriction mapping clearly delineate the two taxa along the same boundaries (Lachance et al. 1986). Ecologically, a small amount of niche overlap is evident, *C. lusitanae* being recovered on occasion

from prickly pear and *C. opuntiae* from columnar cacti. Because of its less diverse habitat, its slightly narrower nutritional range, its shorter rDNA repeat unit (7.6 as opposed to 9.0 kb), and its lower mol% G + C, *C. opuntiae* is viewed as the more evolutionarily derived of the two species.

The position of the genus *Clavispora* relative to other yeast genera is beginning to be clarified. Several other yeasts share DNA base compositions in the mid-40% values. Among those, certain *Metschnikowia* and *Pichia* species have physiological profiles that bear a superficial resemblance with those of *Clavispora* species. Only a few *Pichia* species share the Co-Q 8 characteristic. The ribosomal RNA sequencing studies of Barns et al. (1991) and Hendricks et al. (1991) together indicate that *Clavispora* (represented by *C. lusitaniae*) is phylogenetically distinct from *Candida albicans* and related *Candida* species,

from *Candida guilliermondii*, from *Issatchenkia* species (represented by *Candida krusei*), from *Pichia* species (represented by *Pichia angusta* – syn. *Hansenula polymorpha*), from the moderately related species *Saccharomyces cerevisiae*, *Kluyveromyces lactis*, *Torulasporea delbrueckii* and *Candida glabrata*, or from *Yarrowia lipolytica*. Of all the yeasts compared in the distance matrix presented by Barns et al. (1991), *Candida guilliermondii* is the nearest neighbor to *Clavispora lusitaniae*.

Candida oleophila exhibits a remarkably high degree of phenetic similarity to *C. opuntiae*, has 42 mol% G + C (Nakase and Komagata 1971f), and could eventually be shown to have a sexual life cycle typical of *Clavispora*. Unlike *C. opuntiae* however, *Candida oleophila* grows vigorously on glucono- δ -lactone, utilizes L-lysine as sole nitrogen source, grows in the presence of 100 mg/l cycloheximide, and fails to grow at 37°C.

24. *Coccidiascus* Chatton emend. Lushbaugh, Rowton & McGhee

H.J. Phaff

Diagnosis of the genus

Vegetative cells spheroidal to ovoidal, 5–15 μm in length, with a large vacuole and nucleus. Vegetative reproduction by budding. Mycelium, pseudomycelium, or ballistospores are lacking. Vegetative cells, which are transformed into asci, elongate, forming banana-shaped to crescent-shaped asci arranged within parasitophorous vacuoles of *Drosophila* intestinal epithelium cells in the manner of coccidian schizonts. Thick-walled asci observed in host tissue range from 13–18 μm tip to tip. Mature asci contain two relatively thin-walled ascospores, closely intertwined in a helix. Asci from dead flies have been observed to contain up to eight ascospores. Ascospores extruded from asci are spindle-shaped, bilaterally flattened, without apical cytoplasmic appendages, each with an apical nucleus. Fermentation and assimilation reactions are unknown.

Type species

Coccidiascus legeri Chatton

Species accepted

1. *Coccidiascus legeri* Chatton (1913)

Systematic discussion of the species

24.1. *Coccidiascus legeri* Chatton (1913)

This organism has not been cultured and the description of this species therefore is the same as the generic description.

Type strain: Neotype material collected in *Drosophila melanogaster* intestine from Athens, Georgia, U.S.A., has been deposited in the New York Botanical Garden Cryptogamic Herbarium and in the Julian H. Miller Mycological Herbarium (GAM).

Comments on the genus

Chatton (1913) observed and named this species, which parasitized the intestinal cells of *Drosophila funebris* Fabr.

in France. He was unable to cultivate it and as far as is known no type material was deposited in a herbarium. This species was rediscovered by Lushbaugh et al. (1976) as a parasite within vacuoles of the intestinal epithelium of *Drosophila melanogaster* Meigen in the state of Georgia, U.S.A. They provided an expanded description of *Coccidiascus legeri* illustrated by electron micrographs and light microscope photographs of material in situ (Fig. 45). They also were unable to culture the organism and, in the absence of a known holotype or lectotype, they designated a neotype which was deposited in the New York Botanical Garden Cryptogamic Herbarium (New York, U.S.A.).

Fig. 45. *C. legeri*. Transmission electron micrograph of ascospores (A). One of the spores is shown nearly in its entirety, whereas only a portion of the second spore is seen. The ascus wall (CW) is noticeably thickened (from Lushbaugh et al. 1976). Bar = 1 μm .

25. *Cyniclomyces* van der Walt & D.B. Scott

H.J. Phaff and M.W. Miller

Diagnosis of the genus

Cells are long-ovoidal to cylindrical. In liquid media they occur in branched chains; on solid media they are mainly singles or pairs. Vegetative reproduction is by budding at the poles or on broad shoulders. In liquid media a sediment is formed.

Ascospores are ovoidal to cylindrical, one to four per ascus. No conjugation of cells prior to sporulation. Upon germination an exosporium is evident.

Fermentation of sugars is weak. Growth occurs only between 30 and 40°C. Amino acids, B-vitamins, and an increased level of CO₂ in the gas atmosphere are required for growth. The cells are short-lived at room temperature or above. Diazonium blue B reaction is negative.

Type species

Cyniclomyces guttulatus (Robin) van der Walt & D.B. Scott

Species accepted

1. *Cyniclomyces guttulatus* (Robin) van der Walt & D.B. Scott (1971)

Systematic discussion of the species

25.1. *Cyniclomyces guttulatus* (Robin) van der Walt & D.B. Scott (1971b)

Synonyms:

Cryptococcus guttulatus Robin (1853)

Saccharomyces guttulatus (Robin) Winter (1884)

Saccharomycopsis guttulatus (Robin) Schönning (1903)

Atelosaccharomyces guttulatus (Robin) de Beurmann & Gougerot (1909)

Growth in liquid medium: (1% w/v yeast autolyzate, 1% Proteose peptone, 2% glucose, pH 4.5). After one day at 37°C, cells are long-ovoidal to cylindrical (Fig. 46). Budding occurs polar and at the shoulders of the cells, resulting in branched pseudomycelial formations. Often, the original parent cell appears dead by the time the chain is formed, as judged by complete granulation of its cytoplasm. After 48 h the range of cell dimensions is (4.4–6.1) × (14–21) μm. The cells have a tendency to grow on the glass wall of a tube, about 1 cm below the surface of the liquid. In older cultures the cells form a loose, often

granular sediment. No ring or pellicle is formed even after an extended period of incubation.

Growth on solid medium: When a plate of yeast autolyzate–Proteose-peptone–glucose agar (pH 4.5) is inoculated with cells of *C. guttulatus*, smooth, semiglossy colonies appear after 24 h, provided the plates are incubated in an atmosphere high in CO₂ content (optimal concentration 15%). Cells are ovoidal to cylindrical, (4.7–7.9) × (8.8–19.5) μm, mainly single or in pairs.

Formation of ascospores: No conjugation immediately preceding ascospore formation; the vegetative cells are presumed to be diploid. Asci contain one to four (rarely more) ovoidal to cylindrical ascospores, (3.6–4.8) × (7.0–10) μm (Fig. 47), which are lying free in the ascus. This arrangement is quite different from the tightly fitting spores in asci of species of *Saccharomyces*. Asci rarely deliquesce at maturity. Ascospores germinate directly or after conjugation with another spore. Germination tubes

Fig. 46. *C. guttulatus*. Two-day old pseudomycelial formation in liquid medium. Bar = 20 μm.

Fig. 47. *C. guttulatus*. Two-spored asci after 7 days at 18°C on sporulation medium. Bar = 12 μm.

Fig. 48. *C. guttulatus*. Germination of a single ascospore. The exosporium is being shed at the base of the spore. Bar = 16 μ m.

are formed with simultaneous shedding of an outer spore coat (exosporium) (Fig. 48). Germination is followed by formation of buds. Ascospores are formed only at temperatures lower than the growth temperature, best at about 18°C, where vegetative growth is not possible. Agar slants of the following composition are a suitable sporulation medium: 0.3% yeast autolyzate, 0.3% malt extract, 0.15% Bacto-peptone, 1% glucose. The slants are inoculated with about 1 ml sedimented cell material grown in a liquid medium. The slants are incubated in a horizontal position for 5–7 days at 18°C.

Fermentation:

Glucose	w	Raffinose	w,s
Galactose	–	Trehalose	–
Sucrose	w	Melibiose	–
Maltose	–	Inulin	–
Lactose	–		

Assimilation:

Assimilation tests were carried out in Yeast nitrogen base (w/o amino acids and w/o ammonium sulfate) plus 0.1% yeast extract and 0.5% Proteose-peptone in screw-capped test tubes flushed with CO₂ before autoclaving. Control tubes without glucose showed no growth. The tubes were incubated at 37°C on a Rollordrum.

Glucose	+	<i>N</i> -Acetyl-D-glucosamine	–

Additional assimilation tests and other growth characteristics:

2-Keto-D-gluconate	–	Cycloheximide 10 μ g/ml	–
5-Keto-D-gluconate	–	Growth at 37°C	+
5% NaCl/5% glucose	–		

Temperature range for growth is 30–37°C in the presence of CO₂.

Vitamins required for growth are nicotinic acid, pantothenic acid, thiamin, and inositol (Shifrine and Phaff 1959).

Co-Q: 6, Strain UCD-FST 73-90 (Yamada and Phaff, unpublished results).

Mol% G + C: 34.5, Strain UCD-FST 73-90 (BD: Mendonça-Hagler and Phaff 1975).

Origin of the strain studied: UCD-FST 92-2, a newly isolated strain from a domestic rabbit.

Type strain: Phaff (1970b) designated a newly isolated strain from a domestic rabbit as the type (CBS 5913), since no designated type strain existed at that time. Phaff and Miller (1984a) also designated CBS 5913 as the type strain. However, the 1987 CBS catalogue listed CBS 8137, isolated by D. Yarrow from a rabbit, as the only strain available because the original type was no longer viable.

Comments on the genus

The long history of the genus *Cyniclomyces* has been reviewed by Phaff (1970b) and by van der Walt and Scott (1971b). Buecher and Phaff (1970) studied the requirements of various gasses for growth in the atmosphere. *C. guttulatus* grew exponentially at a maximal growth rate under a continuous gas phase of 15% CO₂, 2% O₂ in nitrogen. The growth rates were almost the same when the oxygen concentration was varied between 0.25 and 20%, but in the absence of oxygen, growth was poor. Buecher and Phaff (1972) also isolated and described an atypical dimorphic, filamentous strain of *C. guttulatus* from a wild jack rabbit. The colonies of this strain were irregular, rough, and dull and the vegetative growth consisted of septate, branched hyphae, radiating from the central origin of growth. New filaments originated by fragmentation of older aggregates. The atypical strain was not CO₂ dependent at 37°C but did require oxygen. At 30°C, the lower limit for growth, a morphogenetic change took place from the filamentous form to the yeast form, which was stimulated by anaerobic conditions. The budding form of the filamentous strain was relatively stable in culture; at either 30 or 37°C it was CO₂ dependent. Spontaneous reversions from the budding to the filamentous form took place sporadically. Unfortunately this strain has not been preserved.

One of the problems of working with *C. guttulatus* is the high death rate of the cells. The low pH required for the isolation of this yeast causes early granulation and death of the cells. If sufficient CO₂ is not present and the inoculum contains low cell numbers, the cells may die before they can grow out and generate their own CO₂ in liquid media. This species is therefore difficult to maintain in culture. A lyophilized preparation of a young sporulating culture is recommended for extended storage. Sporulating slants

may be stored in a refrigerator for 6–12 months. Vegetative growth on slants of 1% yeast autolyzate, 1% Proteose peptone–2% glucose, pH 5.0 can be stored for about one month in a refrigerator. Reinoculation of preserved material into liquid growth medium at 37°C in a container with elevated CO₂ atmosphere results in good growth after 4–7 days. More recently, Zierdt et al. (1988) recommended a very complex new medium, “Fastidious Microorganism Medium” with or without agar. They claimed that elevated CO₂ levels were not required for growth on agar medium. We prepared the new FMM medium and found that after addition of 1% glucose, growth at 37°C in air was poor and slow. In the presence of 10% CO₂ growth was moderate to good, but somewhat less vigorous than on our Yeast autolyzate–Proteose peptone–glucose medium. No growth occurred on either medium in the absence of glucose. Because the FMM medium is costly to prepare, we recommend our medium described in this chapter. Zierdt et al. (1988) also produced some excellent ultrastructural TEM photographs of vegetative cells and asci of *C. guttulatus*.

Because *C. guttulatus* is short-lived and thus easily lost in collections, a brief description is given of a reliable isolation procedure.

Isolation principle: The yeast is most easily isolated from stomach contents of a rabbit, but because fecal material is more readily available, the procedure described below is based on fecal pellets. The yeast requires a balanced mixture of amino acids and vitamins (as found in yeast autolyzate and Proteose peptone), grows between 30 and 40°C, and, for growth on solid media, it requires an elevated concentration of CO₂ in the atmosphere. Additionally, it is very tolerant to low pH values of the medium. Use is made of these properties to isolate pure cultures.

Method of isolation: Samples of fecal pellets of rabbits, preferably samples of soft feces (the latter normally have

a higher yeast content) are inspected microscopically for the presence of the large *C. guttulatus* cells by suspending small samples in a drop of water on a microscope slide. Material in which the yeast is present in significant numbers gives the best results. The isolation medium contains 1% powdered yeast autolyzate, 1% Proteose peptone (Difco), 2% glucose and the pH is adjusted to 2.8–3.0 with 1 N HCl. Fifty-ml portions of this medium in 125-ml Erlenmeyer flasks are sterilized in flowing steam for 10 min.

1. Add one or two rabbit pellets to a flask and incubate for 2–3 days at 37°C. A whitish, granular sediment of yeast forms at the bottom, which should consist of clusters and chains of the characteristic, large cells of *C. guttulatus*.

2. If the sediment appears satisfactory, transfer 1 ml of the sediment with a sterile pipet to a second flask of the same medium and incubate at 37°C.

3. After growth has developed, transfer two drops of the sediment to an agar plate (1% yeast autolyzate, 1% Proteose peptone, 2% glucose, pH 5.0) and spread with a loop. The plate is incubated in a small desiccator with a little water in the bottom to raise the humidity. Flush the desiccator with CO₂ from a cylinder or place a short piece of lighted candle in the desiccator and put the lid in place. After a few minutes, when the CO₂ level has increased, the candle extinguishes and the desiccator is placed at 37°C for 3 days.

4. An isolated colony is then inspected for purity. If bacteria are not eliminated during the previous steps, they would develop on the rich medium at pH 5.0. If the colony is pure, it is transferred to a slant and to a liquid medium of the same composition as used in step 3 and incubated as described above.

Note: Growth in liquid medium is always in the form of branched chains of cells, whereas on solid medium the cells occur more typically in short chains, pairs, or singly.

26. *Debaryomyces* Lodder & Kreger-van Rij Nom. Cons.

T. Nakase, M. Suzuki, H.J. Phaff and C.P. Kurtzman

Diagnosis of the genus

Vegetative reproduction is by multilateral budding. Pseudomycelium is absent, primitive, or occasionally well developed.

Heterogamous conjugation between a cell and its bud generally precedes ascus formation. Isogamous conjugation also occurs. Ascospores are spheroidal, globose, ovoidal or lenticular and have smooth or warty walls (verrucose to colliculate) that may also have an equatorial ledge or spiral ridges. Ascospores are not liberated from the ascus except for three species, whose asci lyse. One to two spores are usually formed per ascus; in some species up to four spores are present in the ascus.

Fermentation is absent, weak or occasionally vigorous. Nitrate is not assimilated. The major ubiquinone is Q-9. Diazonium blue B reaction is negative.

Type species

Debaryomyces hansenii (Zopf) Lodder & Kreger-van Rij

b Melibiose not assimilated *D. vanriijiae* var. *yarrowii*: p. 170

Growth on the surface of assimilation media: Thin to moderately heavy pellicles are formed.

Dalmu plate culture on morphology agar: After 7 days at 25°C, growth under the coverglass shows abundant but sparingly branched pseudohyphae. True hyphae are not produced. Aerobic growth is tannish-white, dull to faintly glistening, butyrous and with an entire or occasionally notched margin.

Formation of ascospores: Asci may show conjugation between a cell and its bud or may be unconjugated. One to four smooth spheroidal spores form in each ascus, and asci may be persistent or deliquescent. Single-spore isolates from four-spored asci are sporogenous, thus indicating the species to be homothallic.

Ascospores were observed on YM agar after 5–10 days at 25°C.

Fermentation: absent.

Type strain: CBS 2285 (NRRL YB-4275), from *Quercus kelloggii*.

Comments: *Pichia vini* was first isolated by Zimmermann (1938) from spoiled wine and described as *Debaryomyces vini*. Later, Phaff (1956) transferred this species when he emended the genus *Pichia*. Several additional strains were isolated and appeared identical

to the original strain except for the presence of deliquescent asci (Kreger-van Rij 1970c). Santa María (1963a) obtained two similar cultures from ‘alpechin’ but described them as *P. vini* var. *melibiosi* because they assimilated melibiose and raffinose.

Pichia carsonii described by Phaff and Knapp (1956), appeared identical with *P. vini* except for its hat-shaped ascospores. Kreger-van Rij (1970c) showed by transmission electron microscopy that the rather small spores of *P. carsonii* were actually spheroidal and practically smooth. Consequently, she considered this species a synonym of *P. vini*. Van der Walt and Johannsen (1975a) pointed out that Zimmermann (1938) failed to provide a Latin diagnosis for *Debaryomyces vini* and that *P. carsonii* was the legitimate name. However, they transferred the species to *Torulaspota* as *T. carsonii* when they revised that genus.

Kurtzman and Smiley (1979) demonstrated by scanning electron microscopy that the ascospores from all extant strains of *Pichia carsonii* and its synonyms were spheroidal and essentially smooth. Furthermore, they showed by DNA reassociation that the type strains of *Pichia vini*, *P. vini* var. *melibiosi* and *P. carsonii* were highly related and represented the same species. They rejected the transfer of *Pichia carsonii* to *Torulaspota*, pointing out that the originally described species of that genus have roughened ascospore walls and coenzyme Q-6 in the electron transport system, whereas *P. carsonii* has smooth-walled ascospores and forms coenzyme Q-9.

Yamada et al. (1992b) compared partial 18S and 26S rRNA sequences from *P. carsonii* and *P. etchellsii* and noted their similarity to species of *Debaryomyces*. From this analysis, Yamada et al. (1992d) transferred *P. carsonii* and *P. etchellsii* to *Debaryomyces*.

26.2. *Debaryomyces castellii* Capriotti (1958e)

Synonyms:

Zymodebaryomyces castellii (Capriotti) Novák & Zsolt (1961)

Pichia castellii (Capriotti) Campbell (1973)

Torulaspota castellii (Capriotti) van der Walt & E. Johannsen (1975a)

Debaryozyma castellii (Capriotti) van der Walt & E. Johannsen (1978)

Growth in YM broth: After 3 days at 25°C, the cells are spheroidal to short-ovoidal, (3.8–7.5) × (5–8.5) μm, and single, in pairs or in groups. A sediment and a thin, dull, creeping pellicle are formed.

Growth on YM agar: After one month at 17°C, the streak culture is yellowish-white, dull or glistening, smooth, with an occasionally sinuous margin.

Dalmu plate culture on corn meal agar: No pseudomycelium is formed. Short, cylindrical cells may be present.

Formation of ascospores: Conjugation between a cell and its bud precedes ascus formation. The spores are spheroidal with a warty wall. The warts are not always distinctly visible with the light microscope. One to three, but generally one spore per ascus (Fig. 49).

Fig. 49. *D. castellii*, CBS 2923. Asci with ascospores, after one month at 20°C on V8 agar. Bar = 5 µm.

Ascospores were observed on V8, Gorodkova, and acetate agars after 1–2 weeks at 20°C.

Co-Q: 9 (minor components 8 and 10), CBS 2923 (Billon-Grand 1987).

Mol% G+C: 37.1, CBS 2923 (BD: Price et al. 1978).

Origin of the strain studied: Soil in Sweden (CBS 2923).

Type strain: CBS 2923, isolated by Capriotti.

26.3. *Debaryomyces coudertii* Saëz (1960)

Synonyms:

Pichia coudertii (Saëz) Campbell (1973)
Torulaspora coudertii (Saëz) van der Walt & E. Johannsen (1975a)
Debaryozyma coudertii (Saëz) van der Walt & E. Johannsen (1978)

Growth in YM broth: After 3 days at 25°C, the cells are spheroidal to short-ovoidal, (3.5–5.1) × (4–5.8) µm, and single or in pairs. A thin sediment is formed.

Growth on YM agar: After one month at 17°C, the streak culture is yellowish-white, dull to shiny, soft, slightly raised in the middle and smooth.

Dalmau plate culture on corn meal agar: No pseudomycelium is formed.

Formation of ascospores: Conjugation between a cell and its bud precedes ascus formation. The spores are spheroidal with a warty wall; one spore is formed per ascus. The presence of many spores gives the culture a brown appearance.

Ascospores were observed on V8 agar after 1–2 weeks at room temperature.

Fermentation: absent.

Assimilation:

Glucose	+	<i>N</i> -Acetyl-D-glucosamine	+
Galactose	+	Methanol	–
L-Sorbose	–	Ethanol	s
Sucrose	–	Glycerol	+

Additional assimilation tests and other growth characteristics:

2-Keto-D-gluconate	+	10% NaCl/5% glucose	+
5-Keto-D-gluconate	–	Starch formation	–
Saccharate	–	Growth at 37°C	–

Co-Q: 9 (minor component 10), CBS 5167 (Billon-Grand 1987).

Mol% G+C: 37.4, CBS 5167 (BD: Price et al. 1978).

Origin of the strain studied: Feces of *Aptenodytes patagonica*, the emperor penguin (CBS 5167).

Type strain: CBS 5167, isolated by Saëz (1960).

Comments: In the description by Kreger-van Rij (1970a, 1984d), *D. coudertii* was reported not to assimilate L-rhamnose, but in the present study L-rhamnose was assimilated. Assimilation of this sugar was also reported by Barnett et al. (1983, 1990).

26.4. *Debaryomyces etchellsii* (Kreger-van Rij)

Maeda, Y. Yamada, Banno & van der Walt (Yamada et al. 1992d)

Synonyms:

Pichia etchellsii Kreger-van Rij (1964a)
Torulaspora etchellsii (Kreger-van Rij) van der Walt & E. Johannsen (1975a)

Kloeckera faecalis Batista & Silveira (1959a)

Pichia faecalis (Batista & Silveira) Aciole de Queiroz (1970)

Growth on 5% malt extract agar: After 3 days at

25°C, the cells are ovoidal to ellipsoidal (1.8–5.4) × (2.0–8.3) μm, and occur singly or in pairs. Growth is white, dull-glistening and butyrous.

Growth on the surface of assimilation media: Occasional rings are noted, but pellicles do not form.

Dalmau plate culture on morphology agar: After 7 days at 25°C, growth under the coverglass shows moderately well-branched pseudohyphae with few blastospores. True hyphae are not present. Aerobic growth on morphology agar is white, dull-glistening and butyrous with a finely striated margin.

Formation of ascospores: Asci show conjugation between a cell and its bud, or infrequently, conjugation between independent cells. One to four smooth, spheroidal ascospores are formed per ascus, and the asci eventually become deliquescent. Single-spore isolates gave sporogenous colonies, indicating the species to be homothallic.

Ascospores were observed on YM agar after 8–10 days at 25°C.

Fermentation:

Glucose	+w	Lactose	–
Galactose	–	Raffinose	–

Co-Q: 9, CBS 2011 (Yamada et al. 1973a).

Mol% G + C: 38.5, 40.6, CBS 2011 (T_m : Nakase and Komagata 1970b; BD: Price et al. 1978).

Origin of the strains studied: Fermenting cucumber brines, U.S.A. (2); human feces (1).

Type strain: CBS 2011 (NRRL Y-7121), one of the strains from cucumber brines.

Comments: *Debaryomyces etchellsii* is phenotypically similar to *D. carsonii*, differing from the former only by

its ability to ferment and by its failure to assimilate starch. However, Kurtzman (unpublished) found only 2% DNA base sequence complementarity between type strains of the two and considered them separate species.

As with *D. carsonii*, *D. etchellsii* has Q-9 ubiquinone in the electron transport system (Yamada et al. 1973a), and its ascospores are spheroidal and smooth when viewed under the scanning electron microscope (Kurtzman and Smiley 1974). For these reasons, its placement in the genus *Torulasporea* by van der Walt and Johannsen (1975a) was rejected. On the basis of rRNA comparisons, Yamada et al. (1992d) transferred *Pichia carsonii* and *P. etchellsii* to *Debaryomyces*.

26.5. *Debaryomyces hansenii* (Zopf) Lodder & Kreger-van Rij (1952)

This species has two varieties:

***Debaryomyces hansenii* (Zopf) Lodder & Kreger-van Rij var. *hansenii* (1985)**

Anamorph: *Candida famata* (Harrison) S.A. Meyer & Yarrow var. *famata*

Synonyms:

- Saccharomyces hansenii* Zopf (1889)
- Pichia hansenii* (Zopf) Campbell (1973)
- Torulasporea hansenii* (Zopf) van der Walt & E. Johannsen (1975a)

Eutorulopsis subglobosa Zach (Wolfram and Zach 1934b)
Debaryomyces matruchoti Grigoraki & Péju var. *subglobosus* Zach (Lodder and Kreger-van Rij 1952)
Debaryomyces subglobosus (Zach) Lodder & Kreger-van Rij (1952)
Debaryomyces fukuyamaensis Naganishi (1941b)
 ?*Debaryomyces orientalis* Naganishi (1941a)
Pichia adzetii F.H. Jacob (1969b)

Growth in YM broth: After 3 days at 25°C, the cells are spheroidal to short-ovoidal, (2–7.2) × (2.2–8.6) μm, and single, in pairs or in short chains. A sediment, a ring and, in some strains, a smooth or wrinkled, dry pellicle or islets are formed.

Growth on YM agar: After one month at 17°C, the streak culture is grayish-white to yellowish, soft, shiny or dull, smooth or partly or entirely striped or wrinkled.

Dalmau plate culture on corn meal agar: Pseudomycelium is usually lacking, but occasionally a primitive, or even a well-developed pseudomycelium is formed.

Formation of ascospores: Conjugation between a cell and its bud precedes ascus formation; conjugation between separate cells may also occur. The spores are spheroidal with a warty wall. The wartiness is not always distinct under the light microscope. With the scanning electron microscope, warts appear as small blunt protuberances or as small ridges (Kurtzman et al. 1975). In two strains, a unique wale-type of surface ornamentation of ascospores was observed by Banno and Mikata (1985). Usually one, seldom two spores are formed per ascus (Fig. 50). The presence of many spores gives the culture a brown color.

Ascospores were observed on V8, Gorodkova, acetate and YM agars after 1–2 weeks at or below 20°C.

Fig. 50. *D. hansenii* var. *hansenii*, JCM 2093. Ascii with one ascospore each, after one month on V8 agar at 20°C. Bar = 5 μm.

Co-Q: 9 (minor component 8) (Nakase and Suzuki 1985a).

Mol% G+C: 38.2–38.6, type strain and 5 additional strains (BD: Price et al. 1978); 36.3–37.8 mol%, type strain and 33 additional strains (T_m : Nakase and Suzuki 1985a), for the variety *hansenii*; 37.3 mol%, CBS 792 (Price et al. 1978), 36.4–36.8 mol%, type strain and 5 additional strains (T_m : Nakase and Suzuki 1985a), for the variety *fabryi*.

Supplemental description of *D. hansenii* var. *fabryi*:

The variety *fabryi* can be physiologically distinguished from the variety *hansenii* only by maximum growth temperature. The maximum growth temperature of the variety *fabryi* is 36–39°C, whereas that of the variety *hansenii* is 31–35°C. Growth at 37°C by the variety *fabryi* may be variable.

Origin of the strains belonging to the variety *hansenii*: Cheese, CBS 766 and three strains; sausages, CBS 773 and CBS 791; sake moto, CBS 2333 = JCM 2111; edomiso, CBS 2331 = JCM 2162; rennet, CBS 772; tobacco, CBS 811 and 2 other strains; psoriasis, CBS 161; infected nails, CBS 790; infected hand, CBS 5704; patient with angina, CBS 770; wound, CBS 788; salmon (shake in Japanese), JCM 2213; unknown, NRRL Y-7393 and 8 other strains.

Type strain: CBS 767, a strain with the name *Saccharomyces hansenii* received in the Delft CBS collection from the Carlsberg Laboratory.

Origin of the strains belonging to the variety *fabryi*: Interdigital mycotic lesion, CBS 789 = JCM 2104; tanning liquor, CBS 6066, type strain of *Pichia adzetii*; infected nail, CBS 792, type strain of *D. subglobosus*; rice vinegar mash, JCM 2207 = IFO 0037; skin lesion, CBS 1796; spoiled sake, JCM 1527 = IFO 0059.

Type strain: CBS 789.

Comments: Price et al. (1978) found that *D. subglobosus* (CBS 792) and *D. nepalensis* (CBS 5921) showed 39.7% and 15.4% relative DNA relatedness to the type strain of *D. hansenii* (CBS 767), respectively. Nakase and Suzuki (1985a,b) further investigated strains of *D. hansenii*, its anamorphs and *D. nepalensis* chemotaxonomically, and divided them into two species and two varieties based on DNA-DNA hybridization, i.e., *D. hansenii* var. *hansenii* (anamorph *Candida famata* var. *famata*), *D. hansenii* var. *fabryi* (anamorph *Candida famata* var. *flareri*) and *D. nepalensis* (anamorph *Candida naganishii*). Also, they showed *D. subglobosus* to be a synonym of *D. hansenii* var. *fabryi*. *Debaryomyces hansenii* var. *hansenii* can be distinguished from the variety *fabryi* and *D. nepalensis* by its lower maximum growth temperature and the lack of glucose-6-phosphate dehydrogenase (EC 1.1.1.49) activity. Almost all strains of *D. hansenii* var. *hansenii* can be clearly separated from the variety *fabryi* and *D. nepalensis* by the difference in maximum growth temperature. In the case of some strains, the separation of these taxa by enzyme patterns is more useful. The separation of *D. hansenii* var. *fabryi* from *D. nepalensis* based on maximum growth temperature is difficult because their ranges overlap. At present, these taxa can be distinguished from each other only by the different banding pattern of malate dehydrogenase (EC 1.1.1.37).

26.6. *Debaryomyces maramus* di Menna (1954a)

Synonyms:

Pichia marama (di Menna) Phaff (1956)

Zymodebaryomyces marama (di Menna) Novák & Zsolt (1961)

Growth in YM broth: After 3 days at 25°C, the cells are spheroidal to short-ovoidal, (2–4) × (3.4–9) µm, and single, in pairs or in chains. A sediment, a ring and, occasionally, a thin dull pellicle are formed.

Growth on YM agar: After one month at 17°C, the

Fig. 51. *D. maramus*, CBS 1958. Asci with ascospores, after one month on YM agar at 20°C. Bar = 5 µm.

streak culture is yellowish-white, soft, shiny to dull, and smooth.

Dalmat plate culture on corn meal agar: No pseudomycelium is formed. Short cylindrical cells may be present.

Formation of ascospores: Conjugation between a cell and its bud precedes ascus formation. The spores are ovoidal. In the scanning electron microscope, they have spiral ridges (Kurtzman et al. 1975). Under the light microscope they may appear to be smooth. One to four, usually two, spores are formed per ascus (Fig. 51). The presence of many spores gives the culture a brown color.

Ascospores were observed on V8 and YM agars after 1–2 weeks at or below 20°C.

Mol% G+C: 39.1, CBS 1958 (BD: Price et al. 1978).

Origin of the strains studied: Air in New Zealand, CBS 1958 = JCM 1528; cider, CBS 4264 = JCM 6179 = NRRL Y-7427; possible case of human disease, CBS 1794 = JCM 6178; soil in Iran, CBS 6905 = JCM 6277.

Type strain: CBS 1958, isolated by di Menna in New Zealand.

Comments: *D. maramus* is the only *Debaryomyces* species with spiral ridges on the spore wall.

26.7. *Debaryomyces melissophilus* (van der Walt & van der Klift) Kurtzman & Kreger-van Rij (1976)

Synonyms:

Pichia melissophila van der Walt & van der Klift (1972)

Torulopsis melissophila van der Walt & van der Klift (1972)

Torulaspora melissophila (van der Walt & van der Klift) van der Walt & E. Johannsen (1975a)

Debaryozyma melissophila (van der Walt & van der Klift) van der Walt & E. Johannsen (1980)

Growth in YM broth: After 3 days at 25°C, the cells are short-ovoidal or ovoidal, (1.4–4.2) × (2.4–5.6) µm, and single, in pairs or in short chains. A sediment is formed.

Growth on YM agar: After one month at 17°C, the streak culture is cream-colored, soft, smooth and dull to shiny.

Dalmu plate culture on corn meal agar: No pseudomycelium is formed.

Formation of ascospores: Conjugation between a cell and its bud or between separate cells precedes ascus formation. The spores are spheroidal with a warty wall which is detectable by scanning electron microscopy and in ultrathin sections (Kurtzman and Kreger-van Rij 1976), but not under the light microscope. One to four spores are formed in the zygote, either in one of the fused cells or distributed between both. The cells may form protuberances by which conjugation takes place. Single spores give cultures which sporulate again (van der Walt and van der Klift 1972, Kurtzman and Kreger-van Rij 1976).

Ascospores were observed on V8 and YM agars after 1–2 weeks at or below 20°C.

Fermentation: absent.

Co-Q: 9 (van der Walt and Johannsen 1980).

Mol% G+C: 39.8, CBS 6344 (BD: Price et al. 1978).

Origin of the strains studied: Digestive tract of the African honey bee (*Apis mellifera* var. *adansonii*), CBS 6344 = JCM 1707 = NRRL Y-7585; soil in South Africa, CBS 6694 = NRRL Y-7772 = JCM 6195; unknown, NRRL Y-7804 = JCM 1708.

Type strain: CBS 6344, isolated from an African bee.

26.8. *Debaryomyces nepalensis* S. Goto & Sugiyama (1968)

Anamorph: *Candida naganishii* Nakase & M. Suzuki

Synonyms:

Debaryomyces cavensis Giovannozzi (1941)

Debaryomyces japonicus Naganishi (1941a)

?*Saccharomyces disaccharomellis* Kawano, Kojima, Ohosawa & Morinaga (1976)

Candida naganishii Nakase & M. Suzuki (1985b)

Growth in YM broth: After 3 days at 25°C, the cells are spheroidal, sub-spheroidal, or short ovoidal, (2–6) × (2.5–6.5) µm, and single, in pairs, or in short chains. A sediment, a ring, and occasionally a thin, smooth or wrinkled pellicle or islets are formed.

Growth on YM agar: After one month at 17°C, the streak culture is grayish to yellowish, soft, shiny or dull, smooth or wrinkled.

Dalmu plate culture on corn meal agar: After 7 days at 25°C, pseudomycelium is absent or rudimentary.

Formation of ascospores: Conjugation between a cell and its bud precedes ascus formation. Spores are spheroidal and have a warty wall which was observed by Banno and Mikata (1985) using scanning electron microscopy. Usually, one spore is formed per ascus.

Ascospores were observed on YM agar after 1–2 weeks at or below 20°C.

Co-Q: 9 (minor component 8) JCM 2095 and JCM 2164 (Nakase and Suzuki 1985a); CBS 5230 (Billon-Grand 1987).

Mol% G + C: 37.6–38.0, type strain and 3 additional strains (T_m : Nakase and Suzuki 1985a); 39.1 mol%, CBS 5921 (BD: Price et al. 1978).

Origin of the strains studied: Soil in Nepal, CBS 5921 = JCM 2095 = NRRL Y-7534; fermenting Maryland tobacco, CBS 1325 = JCM 2164, type strain of *D. cavensis*; sediment in spoiled sake, CBS 2334, type strain of *D. japonicus*; unknown, JCM 2209 = IFO 0085.

Type strain: CBS 5921.

Comments: *D. nepalensis* shows close physiological similarity to *D. hansenii*, but it is a genetically distinct species from *D. hansenii* (Price et al. 1978, Nakase and Suzuki 1985a). See Comments under *D. hansenii*.

26.9. *Debaryomyces occidentalis* (Klöcker) Kurtzman & Robnett (1991)

This species has two varieties:

Debaryomyces occidentalis (Klöcker) Kurtzman & Robnett var. *occidentalis* (1991)

Synonyms:

Schwanniomyces occidentalis Klöcker (1909a)

Schwanniomyces castelli Capriotti (1957)

Schwanniomyces alluvius Phaff, M.W. Miller & Cooke (1960)

Debaryomyces occidentalis var. *persoonii* (van der Walt) Kurtzman & Robnett (1991)

Synonyms:

Schwanniomyces persoonii van der Walt (1962)

Schwanniomyces ukrainicus Kvasnikov, Nagornaya & Shchelokova (1979a)

Schwanniomyces occidentalis Klöcker var. *persoonii* (van der Walt) Phaff & M.W. Miller (1984b)

Growth in YM broth: After 3 days at 25°C, the cells are ovoidal, globose, or sometimes egg-shaped, (3.5–8.0) × (4.5–9.0) μ m, occasionally up to 10 μ m long, and single, in pairs or in short chains or clusters. No pellicle is formed, but a sediment is present.

Growth on YM agar: After one month at 17°C, the streak culture is cream-colored, smooth, and semi-glossy; the texture is pasty to soft. The cross section is broadly convex and the border entire.

Slide culture on corn meal agar: Pseudomycelium is absent aerobically and anaerobically.

Formation of ascospores: Cells are haploid. Before sporulation the nucleus divides, which is followed by fusion. The diploid nucleus ordinarily undergoes reduction division in a special open bud-like structure, the meiosis bud, and this is followed by the formation of one or, more rarely, two ascospores in the parent cell. Alternatively, the nucleus in the parent cell may divide, after which one of the daughter nuclei moves into a small bud which is temporarily separated from the parent cell by a septum. The septum then lyses, the two nuclei fuse, and meiosis follows. Rarely, diploidization is accomplished by the fusion of two individual cells. The spores are globose, have a warty surface, an equatorial ledge and a pronounced lipid globule. They somewhat resemble the appearance of a walnut. There is usually one spore per ascus, occasionally two (Fig. 52).

Sporulation is best after approximately 5–7 days on yeast autolyzate agar with 2% glucose. Ascospores are also observed on YM agar after 1–2 weeks at 25°C.

Fig. 52. *D. occidentalis* var. *occidentalis*, CBS 4516. Ascii with one or two ascospores, after one week on yeast autolyzate agar with 2% glucose at 25°C. Bars = 4 μ m.

Co-Q: 9, CBS 819 (Yamada et al. 1977).

Mol% G+C: 35.2, CBS 4516, type strain of *Schwanniomyces alluvius*; 35.2, CBS 2863, type strain of *Schwanniomyces castellii*; 35.3, CBS 1153, Carlsberg strain of *Schwanniomyces occidentalis* (BD: Price et al. 1978); 35.4, variety *persoonii* (BD: Price et al. 1978).

Supplementary description of *D. occidentalis* var.

***persoonii*:** The variety *persoonii* does not assimilate cellobiose, galactose or D-xylose and these differences allow it to be separated from the variety *occidentalis* using standard growth tests. In addition, the variety *persoonii* does not grow on salicin, or on 7.5% NaCl/5% glucose. Morphologically the two varieties are similar, as are their life cycles.

Origin of the strains belonging to the variety

***occidentalis*:** Soil samples in Ohio, Michigan, Spain, Island of St. Thomas (10).

Type strain: CBS 819 (ATCC 2322).

Origin of the strains belonging to the variety

***persoonii*:** Soil samples in the Transvaal, South Africa (2), Russia (1).

Type strain: CBS 2169 (NRRL Y-7400).

Comments: Kurtzman and Robnett (1991) proposed the transfer of *Schwanniomyces occidentalis* to the genus *Debaryomyces* on the basis of sequence similarity in partial ribosomal RNA sequences between *S. occidentalis* and several *Debaryomyces* spp. They determined the extent of divergence in three regions from 18S and 25S subunit ribosomal RNAs, comprising a total of 900 nucleotides.

D. occidentalis can be distinguished from other ascomycetous yeast species by the unique shape of the ascospores. Kurtzman et al. (1972) have illustrated the spore topography by scanning electron microscopy. Ferreira and Phaff (1959) described the life cycle of *Schwanniomyces* based on nuclear staining of cells in the process of meiosis. They presented evidence that, following karyogamy, meiosis took place in an open bud-like structure, the meiosis bud, and that the haploid nuclei moved back into the parent cell, where one, or more rarely two, developed into ascospores. Kreger-van Rij (1977a) restudied the life cycle and concluded that conjugation took place between a small bud cell and the parent cell by lysis of the connecting septum and that karyogamy and meiosis probably occur in the parent cell. This view was shared by Forrest et al. (1987). It is also possible that both types of life cycles mentioned above occur in this yeast. Kreger-van Rij (1977a) also determined, by electron microscopy of ultrathin sections, details of spore wall development and internal structure.

Price et al. (1978) carried out DNA/DNA reassociation experiments among the various strains of *Schwanniomyces*. Polynucleotide sequence relationships between reference DNA from *S. occidentalis* and DNA from *S. castellii* and *S. alluvius* were at the 97% level or greater and the last two species were therefore placed into synonymy with *S. occidentalis*. The type strain of *S. persoonii* showed 83% and a second strain 80% sequence complementarity with the DNA from *S. occidentalis*. This lower DNA relatedness coupled with several differences in carbon compound assimilation induced these authors to retain *S. persoonii* as a variety of *S. occidentalis*.

Yamada et al. (1991c) reported partial sequences of 18S and 26S ribosomal RNAs of strains of *S. occidentalis* var. *occidentalis* and *S. occidentalis* var. *persoonii*. They suggested that the genus *Schwanniomyces* might be retained as its own genus separate from the genus *Debaryomyces* based on the two base differences observed in 168 bases of 18S RNA between the type species of the genera. However, since the two base differences are considered to be too small for generic separation, we adopted the proposal by Kurtzman and Robnett (1991).

26.10. *Debaryomyces polymorphus* (Klöcker) Price & Phaff (1979)**Synonyms:**

Pichia polymorpha Klöcker (1912a)

Saccharomyces polymorphus (Klöcker) Novák & Zsolt (1961)

Torulaspora polymorpha (Klöcker) van der Walt & E. Johannsen (1975a)

Debaryozyma polymorpha (Klöcker) van der Walt & E. Johannsen (1978)

Debaryomyces cantarellii Capriotti (1961a)

Pichia cantarellii (Capriotti) Campbell (1973)

Debaryomyces phaffii Capriotti (1961b)

Torulaspora phaffii (Capriotti) van der Walt & E. Johannsen (1975a)

Growth in YM broth: After 3 days at 25°C, the

cells are ovoidal, long-ovoidal and cylindroidal, (1.5–7.5) × (3.5–13.5) μm and longer; they are single or in pairs. A sediment and a thin pellicle are formed.

Growth on YM agar: After one month at 17°C, the streak culture is cream-colored to yellowish, soft, flat, smooth or partly wrinkled, dull to shiny.

Dalmau plate culture on corn meal agar: No pseudomycelium is formed. Tree-like chains of cells may be present.

Formation of ascospores: Conjugation between a cell and its bud precedes ascus formation. Conjugation between two cells of nearly equal size may also occur. The spores are spheroidal with a warty wall. The warts are not always distinct with the light microscope. With scanning electron microscopy they are clearly observed (Kurtzman and Smiley 1974, Kurtzman et al. 1975). Asci may form up to two spores, but there is generally one spore per ascus.

Ascospores were observed on V8, Gorodkova and corn meal agars after 1–2 weeks at or below 20°C.

Fermentation:

Co-Q: 9 (minor components 7, 8 and 10) (Yamada et al. 1973a, 1976b, Billon-Grand 1987).

Mol% G+C: 35.7–35.9, 5 strains (BD: Price et al. 1978).

Origin of the strains studied: Soil in Denmark, CBS 186 = JCM 3647, CBS 1359; soil in the Netherlands (1); soil in Finland, CBS 4346, type strain of *Debaryomyces phaffii*; CBS 4349, type strain of *Debaryomyces cantarel-ii*; CBS 4350; toadstool (1); anthill in Russia (2).

Type strain: CBS 186, from Klöcker's collection.

Comments: Forrest et al. (1987) studied the nuclear behavior in growing, dividing, and ascospore-forming cells of a strain of *D. polymorphus* by light microscopy of fixed Giemsa stained preparations. They concluded that meiosis took place in the parent cell and not in the bud, and that the term “meiosis bud” therefore did not apply to this yeast.

26.11. *Debaryomyces pseudopolymorphus* (C. Ramírez & Boidin) Price & Phaff (1979)

Synonyms:

Pichia pseudopolymorpha C. Ramírez & Boidin (1953a)

Saccharomyces pseudopolymorphus (C. Ramírez & Boidin) Novák & Zsolt (1961)

Torulasporea pseudopolymorpha (C. Ramírez & Boidin) van der Walt & E. Johannsen (1975a)

Debaryozyma pseudopolymorpha (C. Ramírez & Boidin) van der Walt & E. Johannsen (1978)

Growth in YM broth: After 3 days at 25°C, the cells are long-ovoidal to cylindroidal, (3–6.5) × (4.5–16) μm, and single or in pairs. A sediment and a dull creeping pellicle are formed.

Growth on YM agar: After one month at 17°C, the streak culture is white or cream-colored to yellowish, soft, dull and wrinkled. The edge is fringed with pseudomycelium.

Dalmau plate culture on corn meal agar: A primitive pseudomycelium is formed that consists of tree-like chains of elongated cells.

Fig. 53. *D. pseudopolymorphus*, CBS 2008. Asci with ascospores, after one month on V8 agar at 20°C. Bar = 5 μm.

Formation of ascospores: Conjugation between a cell and its bud precedes ascus formation. The spores are spheroidal. They have a warty wall which is distinct in the scanning electron microscope (Kurtzman and Smiley 1974), but not always visible under the light microscope. One to four spores are formed per ascus (Fig. 53). According to Kreger-van Rij (1984d), one to two spores form on Gorodkova agar and two to four on acetate agar, but we observed one to four on Gorodkova agar.

Ascospores were observed on acetate, Gorodkova and V8 agars after 1–2 weeks at or below 20°C.

Mol% G+C: 35.7, 2 strains (BD: Price et al. 1978).

Origin of the strains studied: Tanning liquor, CBS 2008, CBS 2009 = JCM 6184.

Type strain: CBS 2009.

26.12. *Debaryomyces robertsiae* (van der Walt) Kurtzman & Robnett (1994b)

Synonyms:

Pichia robertsiae (as *P. robertsii*) van der Walt (1959a)

Wingea robertsii (van der Walt) van der Walt (1967) nom. inval.

Wingea robertsii (van der Walt) van der Walt (1971)

Growth on 5% malt extract agar: After 3 days at 25°C, the cells are spheroidal to ellipsoidal (2.1–7.0) × (2.6–7.0) μ m, and occur singly, in pairs or occasionally in small clusters. Growth is butyrous and light tannish-white in color.

Growth on the surface of assimilation media: Dry climbing pellicles are formed.

Dalmau plate culture on morphology agar: After 7 days at 25°C, only budding yeast cells are detected under the coverglass. Aerobic growth is white, butyrous, and with a smooth semi-glistening surface having a depressed center. Colony margins are smooth to finely scalloped. A faint acidic odor is present.

Formation of ascospores: Asci are occasionally unconjugated, but most show conjugation between independent cells or between a cell and its bud. Some asci form protuberances which may serve the function of bud conjugants. Asci are persistent and contain one to four ascospores; the ascospores are smooth, lenticular and show a light brown coloration (Figs. 54, 55). Heavily sporulating cultures become dark red in color. Single-spore isolates obtained by micromanipulation of random

Fig. 54. *D. robertsiae*, CBS 5637. Asci with 1–2 ascospores, after 1 week on YM agar at 25°C. Bar = 5 μ m.

Fig. 55. *D. robertsiae*, CBS 5637. Scanning electron micrograph of enzymatically freed ascospores. Bar = 0.5 μ m.

spores freed enzymatically from asci of NRRL Y-7680 (CBS 5637) gave only sporogenous colonies suggesting that *D. robertsiae* is homothallic (Kurtzman, unpublished data).

Ascospores were observed on YM agar after 1–2 weeks at 25°C. Sporulation is often sparse but some single-spore isolates sporulate heavily as do occasional colony sectors.

Co-Q: 9, CBS 2934 (Yamada et al. 1973a).

Mol% G+C: 42.7, CBS 2934 (BD: Price et al. 1978).

Origin of the strains studied: NRRL Y-6670 (CBS 2934), from a larval feed of the South African carpenter bee (*Xylocopa caffra*), Transvaal; NRRL Y-7680 (CBS 5637), from pollen carried by a South African carpenter bee, Transvaal.

Type strain: CBS 2934 (NRRL Y-6670), from van der Walt, South Africa.

Comments: *D. robertsiae* is unique among yeasts because of the lenticular shape of its ascospores, otherwise, it is phenotypically similar to other members of the genus *Debaryomyces*. Kurtzman and Robnett (1994b) showed from analysis of partial 18S and 26S rRNA sequences that *D. robertsiae* is a member of the genus *Debaryomyces*.

26.13. *Debaryomyces udenii* van der Walt, M.Th. Smith & Y. Yamada (1989b)

Growth in YM broth: After 3 days at 25°C, the cells are spheroidal to short-ovoidal (2.0–5.6) × (2.5–5.6) μ m, and single, in pairs, in short chains or in small clusters. A sediment and a thin pellicle are formed.

Growth on YM agar: After one month at 17°C, the streak culture is cream-colored, soft, smooth and dull.

Dalmu plate culture on corn meal agar: No pseudomycelium is formed.

Formation of ascospores: Conjugation between a cell and its bud precedes ascus formation. Asci also arise from the conjugation of independent cells. Asci slowly lyse, liberating the ascospores which tend to agglutinate. The ascospores are globose to ellipsoidal, and appear glabrous by light microscopy. By TEM, the surface appears to be colliculate to pusticulate (van der Walt et al. 1989b). One

Fig. 56. *D. udenii*, CBS 7056. Lysing asci with ascospores, after two weeks on YM agar at 25°C. Bar = 5 μ m.

to four spores per ascus are formed (Fig. 56). Actively sporulating cultures on YM agar are pale brown.

Ascospores were observed on YM agar after 1–2 weeks at 25°C.

Co-Q: 9, CBS 7056 (van der Walt et al. 1989b).

Mol% G+C: 35.8, CBS 7056 (T_m : van der Walt et al. 1989b).

Origin of the strains studied: Soil samples collected in the Pinery Provincial Park, Ontario, Canada (CBS 7056 and CBS 7057).

Type strain: CBS 7056.

Comments: The results from the present study are in agreement with the original description, except for the positive assimilation of soluble starch. *D. udenii* forms colliculate ascospores which can be liberated from the ascus. By comparison of 18S and 26S ribosomal RNA partial sequence analyses, Yamada et al. (1991a) showed that *D. udenii* is closely related to other *Debaryomyces* species. *D. udenii* physiologically resembles *D. castellii*,

D. pseudopolymorphus, and *D. yamadae*, but it is distinguished from these three species by its lytic asci and by differences in the assimilation of lactose, melibiose and erythritol.

26.14. *Debaryomyces vanriijae* (van der Walt & Tscheuschner) Abadie, Pignal & J.L. Jacob (1963)

This species has two varieties:

***Debaryomyces vanriijae* (van der Walt & Tscheuschner) Abadie, Pignal & J.L. Jacob var. *vanriijae* (1984)**

Synonyms:

Pichia vanriijae (as *P. vanriji*) van der Walt & Tscheuschner (1956a)

Azymomyces vanriji (van der Walt & Tscheuschner) Novák & Zsolt (1961)

Torulasporea vanriji (van der Walt & Tscheuschner) van der Walt & E. Johannsen (1975a)

Debaryozyma vanriji (van der Walt & Tscheuschner) van der Walt & E. Johannsen (1978)

Debaryomyces konokotinae Kudryavtsev (1960)

Debaryomyces formicarius Golubev & Bab'eva (1972)

Torulasporea formicaria (Golubev & Bab'eva) van der Walt & E. Johannsen (1975a)

***Debaryomyces vanriijae* var. *yarrowii* (Santa María & García Aser) Kreger-van Rij (1984d)**

Synonyms:

Debaryomyces yarrowii Santa María & García Aser (1971)

Torulasporea yarrowii (Santa María & García Aser) van der Walt & E. Johannsen (1975a)

Growth in YM broth: After 3 days at 25°C, the cells are spheroidal to short-ovoidal (3–8.5) × (3–20) µm, and single or in groups. A sediment and a white, wrinkled, creeping pellicle are formed.

Growth on YM agar: After one month at 17°C, the streak culture is yellow to yellowish-brown, dull or semi-glistening, and smooth with a sinuous margin.

Dalmau plate culture on corn meal agar: A primitive pseudomycelium is formed that consists of short elongated cells.

Fig. 57. *D. vanriijae* var. *vanriijae*, CBS 3024. Asci with ascospores, after one month on V8 agar at 20°C. Bar = 5 µm.

Formation of ascospores: Conjugation between a cell and its bud precedes ascus formation. The spores are spheroidal, and one to four are formed per ascus (Fig. 57). They have a warty wall which is not always visible under the light microscope, but is clearly observed by scanning electron microscopy (Kurtzman et al. 1975) and in ultrathin sections (Santa María and García Aser 1971).

Ascospores were observed on V8, acetate, YM and malt agars after 1–2 weeks at or below 20°C.

Co-Q: 9 (minor component 8) (Yamada et al. 1976b, Billon-Grand 1987).

Mol% G + C: 33.2–33.3, 4 strains (Price et al. 1978); 31.7, CBS 3024 (T_m : Suzuki and Nakase, unpublished data).

Supplementary description of *D. vanriijae* var. *yarrowii*: By the addition of one strain assigned to the variety *yarrowii*, the description given by Kreger-van Rij (1984d) is changed as follows:

Assimilation of carbon compound:

Trehalose	w/–	Salicin	v
Melibiose	–	Citric acid	v
Soluble starch	v	Growth at 37°C	–
Erythritol	v		

Mol% G + C: 33.0, CBS 6246 (BD: Price et al. 1978); 32.1, CBS 6246; 30.6, CBS 6755 (T_m : Suzuki and Nakase, unpublished data).

Origin of the strains belonging to the variety *vanriijae*: Soil in South Africa, CBS 3024; exudate of slippery-elm tree, CBS 5458; anthill, CBS 6454, type strain of *Debaryomyces formicarius*, CBS 6455; unknown, CBS 5709, CBS 6756.

Type strain: CBS 3024, isolated by van der Walt from soil in South Africa.

Origin of the strains belonging to the variety *yarrowii*: Excrements of insects on *Paulownia imperialis* in Madrid, CBS 6246; unknown, CBS 6755.

Type strain: CBS 6246.

Comments: Price et al. (1978) found the type strains of *D. yarrowii* and *D. vanrijae* to show 68.4% DNA base sequence complementarity. They maintained them as separate species, whereas Kreger-van Rij (1984d) reclassified *D. yarrowii* as a variety of *D. vanrijae*, based on the view by Kurtzman et al. (1980b) that this percentage relatedness may indicate that the two strains belong to the same species. In this study, our DNA–DNA hybridization by membrane filter method showed 74% DNA relatedness between the type strains of *D. yarrowii* and *D. vanrijae*. A single strain, CBS 6755, which has intermediate physiological properties between the two species, showed 87% DNA relatedness to the type strain *D. yarrowii* and 78% DNA relatedness to the type strain of *D. vanrijae* (Suzuki and Nakase, unpublished data). Based on the view of Kurtzman (1987b) that DNA relatedness of 65–70% or greater suggests strains to be conspecific in most comparisons, we accepted Kreger-van Rij's classification. Also, we assigned strain CBS 6755 to the variety *yarrowii*, and hence the physiological differences between the two varieties were reduced. The variety *yarrowii* may still be distinguished from the variety *vanrijae* by its inability to assimilate melibiose and lack of growth at 37°C.

26.15. *Debaryomyces yamadae* (van der Walt & E. Johannsen) van der Walt, M.Th. Smith & Y. Yamada (1989b)

Synonyms:

Debaryozyma yamadae van der Walt & E. Johannsen (1980)

Debaryomyces yamadae (van der Walt & E. Johannsen) J.A. Barnett, Payne & Yarrow (1990)

Growth in YM broth: After 3 days at 25°C, the cells are spheroidal, ovoidal or ellipsoidal (1.5–5.0) × (2.0–6.0) μm; they may be single, in pairs, short chains or in small clusters. A sediment and a slight ring are formed.

Growth on YM agar: After one month at 17°C, the streak culture is cream-colored or brownish and shiny. The margin is entire to undulating.

Dalmou plate culture on corn meal agar: No pseudomycelium is formed.

Formation of ascospores: Conjugation between a cell and its bud precedes ascus formation. The spores are spheroidal and warty with one to four spores per ascus. The wartiness is not always visible under the light microscope, but is detectable in a ultrathin section (van der Walt and Johannsen 1980).

Ascospores were observed on YM agar and malt extract agar after 1–2 weeks at or below 20°C.

Co-Q: 9 (van der Walt and Johannsen 1980).

Mol% G + C: 34.5, CBS 7035; 35.7, CBS 7036 (T_m : Suzuki and Nakase, unpublished data).

Origin of the strains studied: Soil, CBS 7035; arboricolous lichen, CBS 7036.

Type strain: CBS 7035.

Comments: Results from the present study are in agreement with the original description of this species, which was described as *Debaryozyma yamadae* by van der Walt and Johannsen. As a result of the acceptance of *Debaryomyces* Lodder & Kreger-van Rij nom. cons. during the International Botanical Congress (1987), the genus *Debaryozyma* van der Walt & Johannsen became a synonym of the genus *Debaryomyces*. For this reason, *Debaryomyces yamadae* is the valid name of this species. *Debaryomyces yamadae* (van der Walt & E. Johannsen) van der Walt, M.Th. Smith & Y. Yamada (1989b) has priority over *Debaryomyces yamadae* (van der Walt & E. Johannsen) J.A. Barnett, Payne & Yarrow (1990).

Comments on the genus

Lodder and Kreger-van Rij (1978) made an official proposal for conservation of the name *Debaryomyces* Lodder & Kreger-van Rij against *Debaryomyces* Klöcker. The type species of the latter, *Debaryomyces globosus* Klöcker, had been classified in the genus *Saccharomyces* (van der Walt 1970d), and it is now classified in the genus *Torulasporea*. After publication of this proposal, van der Walt and Johannsen (1978) proposed a new

name, *Debaryozyma*, for *Debaryomyces* species. However, in accordance with Recommendation 15A of the International Code of Botanical Nomenclature, the name *Debaryomyces* was applicable pending a decision on the proposal by the General Committee (Lodder and Kreger-van Rij 1979). Finally, in the 1988 International Code of Botanical Nomenclature (Greuter et al. 1988), the proposal by Lodder and Kreger-van Rij was accepted. Because *Schwanniomyces occidentalis* has nomenclatural priority over extant species of *Debaryomyces*, Kurtzman is submitting a proposal to conserve *Debaryomyces* against *Schwanniomyces*.

The genus *Debaryomyces* Lodder & Kreger-van Rij (1952) (Kreger-van Rij 1970a, 1984d) is distinguished from other ascomycetous yeast genera by the special structure of the spore wall (wartiness), multilateral budding, inability to assimilate nitrate, coenzyme Q-9, and fermentation that is absent, weak or vigorous. All *Debaryomyces* species are haploid and conjugation between a cell and its bud generally precedes ascus formation. Accompanied with the transfer of *Schwanniomyces occidentalis* to *Debaryomyces*, Kurtzman and Robnett (1991) emended the diagnosis of the genus *Debaryomyces* as follows: Ascospores have walls with warts that may also include the presence of ridges or an equatorial ring. Fermentation is absent, weak, or occasionally vigorous. In this edition, the generic description is emended further by the inclusion of *Debaryomyces udenii* which has lysing asci.

Kreger-van Rij and Veenhuis (1975a) described the internal ultrastructure of the spore wall of *D. hansenii* which is, as far as is known, also typical of the other *Debaryomyces* species. Spheroidal warty spores in other nitrate-negative genera, such as *Torulaspota*, *Saccharomyces* and *Zygosaccharomyces*, have, with the exception of *Zygosaccharomyces rouxii* (Kreger-van Rij 1979), a different wall structure. *Issatchenkia* species also have warty spores, but the asci are generally unconjugated. *Saccharomyces*, *Zygosaccharomyces*, *Torulaspota* and *Issatchenkia* differ from *Debaryomyces* in the number of isoprene units of the major coenzyme Q: *Saccharomyces*, *Zygosaccharomyces*, and *Torulaspota*, 6; *Issatchenkia*, 7; and *Debaryomyces*, 9 (Yamada et al. 1973a, 1976b, Nakase and Suzuki 1985a, Billon-Grand 1987).

A proposal by van der Walt and Johannsen (1975a) to combine *Debaryomyces* and *Torulaspota* species in the genus *Torulaspota* was rejected by Kreger-van Rij and Veenhuis (1976b). A distinct difference in the structure of the spore wall between *Debaryomyces* and *Torulaspota* species correlates with other differences between them. Price et al. (1978) gave additional arguments for keeping *Debaryomyces* separate from the *Torulaspota* species. Kocková-Kratochvílová et al. (1978) applied numerical taxonomy to *Debaryomyces* species and species of the *Torulaspota* group. The latter were clearly distinguishable from the *Debaryomyces* species.

Price et al. (1978) made an important study of DNA sequence relatedness among *Debaryomyces* and

several similar *Pichia* species which clarified taxonomic relations and resulted in merging of some species, e.g., *D. cantarellii* and *D. phaffii* with *Pichia polymorpha* to become *D. polymorphus*.

It is noted that, with respect to its ascospore surface structure, *D. udenii* is intermediate between smooth round spore-forming *Pichia* species possessing ubiquinone Q-9 (*P. tannicola*, *P. carsonii* and *P. etchellsii*) and other *Debaryomyces* species which form warty ascospores. Billon-Grand (1988, 1989 and personal communication) suggested the transfer of *P. abadieae*, *P. carsonii*, *P. etchellsii* and *P. humboldtii* to the genus *Debaryomyces* because they show the same major ubiquinone Q-9, similar intracellular oxidases and vitamin requirements, and produce round ascospores. Recently, Yamada et al. (1992b) reported the partial sequences of 18S and 26S ribosomal RNAs of the above four *Pichia* species, and suggested that *P. carsonii* and *P. etchellsii* have phylogenetically close relationships to *Debaryomyces* species and that *P. abadieae* (= *P. tannicola*) and *P. humboldtii* are phylogenetically distant from each other and from *P. carsonii*, *P. etchellsii* and *Debaryomyces* species. De Hoog et al. (1986) regarded *P. humboldtii* as a synonym of *Dipodascus ingens*. Consequently, it seems reasonable to transfer *P. carsonii* and *P. etchellsii* to the genus *Debaryomyces* along with emendation of the generic description to permit inclusion of species forming smooth spheroidal ascospores. By this emendation, however, wartiness of ascospores becomes less significant as a criterion for generic delimitation of the genus *Debaryomyces*.

Species not accepted in the genus

***Debaryomyces tamarii* Ohara & Nonomura (1954d):**

This species no longer forms ascospores and has several exceptional features among members of the genus *Debaryomyces*. Ribosomal RNA sequence comparisons by Kurtzman and Robnett (1991) showed *D. tamarii* to be well separated from other species of *Debaryomyces*. Its G+C content of nuclear DNA is much higher than that of the other *Debaryomyces* species (Nakase and Komagata 1971a, Price et al. 1978). We also found in this study that the assimilation of nitrate of the type strain was positive within one week after inoculation, and that its whole cell hydrolyzate contained glucose, mannose and galactose whereas those of other *Debaryomyces* species contained glucose and mannose (Suzuki and Nakase, unpublished data). For these reasons, this species is no longer maintained in the genus *Debaryomyces*. F.-L. Lee et al. (1992) and Suzuki et al. (1992) independently demonstrated that this species was conspecific with *Candida versatilis* based on DNA-DNA hybridization.

***Debaryomyces artagaveytiae* Batista, Silveira & Coelho (1960):**

Ribosomal RNA sequence comparisons by Kurtzman and Robnett (1991) showed that strain CBS 5285 (= NRRL YB-4906) represented a species so

divergent that its assignment to *Debaryomyces* could no longer be maintained. In this study, we found strain CBS 5285 to be urease positive and DBB positive, and that it contained glucose, mannose, galactose and fucose in acid hydrolyzates. D. Yarrow (personal communication) also

found CBS 5285 to hydrolyze urea and to be DBB positive, and suggested a relationship with *Sterigmatomyces*. Furthermore, strain CBS 5285 is not the type; the type strain of this species (IMUR 2201) is not available at present.

27. *Dekkera* van der Walt

M.Th. Smith

Diagnosis of the genus

Budding cells are spheroidal, subglobose to ellipsoidal, frequently ogival, or cylindroidal to elongate. Pseudomycelium and branched, one-celled, non-septate mycelium are sometimes formed.

Asci arise without conjugation, are evanescent, and form 1–4 ascospores. Ascospores are hat-shaped or somewhat spheroidal with tangential brims, and tend to agglutinate when released.

Cultures are slow growing and generally short-lived. Acetic acid is produced aerobically from glucose. Fermentation is usually stimulated by molecular oxygen. An extraneous vitamin source is required. Diazonium blue B reaction is negative.

Type species

Dekkera bruxellensis van der Walt

Species accepted

1. *Dekkera anomala* M.Th. Smith & van Grinsven (1984)
2. *Dekkera bruxellensis* van der Walt (1964)

Key to species

See Table 21.

1. a D-Glucitol assimilated → 2
 b D-Glucitol not assimilated → 3
- 2(1). a Succinate assimilated *Brettanomyces naardenensis*: p. 451
 b Succinate not assimilated *Brettanomyces nanus*: p. 452
- 3(1). Species with the following combinations of characters:
 - a Slender, often branched, non-septate filaments are produced on Dalmau plates; lactose fermented by most strains; succinate latently assimilated by most strains; galactose assimilated *Dekkera anomala*: p. 174
 - b Non-septate filaments are not produced; lactose not fermented; succinate not assimilated; galactose assimilation variable *Dekkera bruxellensis*: p. 175
 - c Non-septate filaments are not produced; lactose not fermented; succinate assimilated; galactose not assimilated *Brettanomyces custersianus*: p. 451

Systematic discussion of the species

27.1. *Dekkera anomala* M.Th. Smith & van Grinsven (1984)

Anamorph: *Brettanomyces anomalus* Custers

Synonyms:

- Momilia vini* Osterwalder (1912)
- Oospora vini* (Osterwalder) Janke (1924)
- Brettanomyces anomalus* Custers (1940)
- Brettanomyces claussenii* Custers (1940)
- Dekkera claussenii* F.-L. Lee & S.-C. Jong (1985)
- Torulopsis cylindrica* Walters (1943)
- Brettanomyces claussenii* Custers var. *sablieri* Legakis (1961) nom. inval.
- Brettanomyces cidri* Legakis (1961)

- Brettanomyces dublinensis* Gilliland (1962)
- Candida beijingsensis* Yue & Pna (1984)

Growth in malt extract: After 5 days at 25°C, the cells are spheroidal, ellipsoidal, ogival or cylindroidal to elongate (2.0–5.5) × (3.0–22.0) μm. Cells occur singly, in pairs, short chains or clusters. Pseudomycelium is usually formed; it is filamentous, and frequently branching, but non-septate cells are also produced. A floccose to mucoid sediment is formed. Pellicle formation is absent.

Growth on malt agar + 2% calcium carbonate: After 6 weeks at room temperature, the streak culture is

restricted, slightly raised in the center, white to cream-colored or creamish-brown, somewhat shiny to dull, and smooth or rugose. Margins are entire, lobate or fringed with mycelium. Acetic acid is produced.

Dalmau plate cultures on potato-, rice- and morphology agars: After 5 days at 25°C, pseudomycelium is produced, and consists of filamentous cells that form ellipsoidal to cylindrical blastoconidia that occur singly or in short chains. Slender, non-septate filaments are present and they are often branched (Fig. 58).

Fig. 58. *D. anomala*. Filaments on corn meal agar after 10 days at 25°C. Bar = 25 µm (from van der Walt 1970e).

Formation of ascospores: Vegetative cells are directly transformed into evanescent asci without preceding conjugation. One to four galeate ascospores are formed per ascus and agglutinate when liberated.

Ascospore formation, which may be sparse, is observed on 3% Difco malt agar after 3 weeks at 25°C.

- Dekkera abstinens* F.-L. Lee & S.-C. Jong (1986b)
- Dekkera lambica* F.-L. Lee & S.-C. Jong (1986a)

Growth in malt extract: After 5 days at 25°C, the cells are ovoidal, ellipsoidal, frequently ogival or cylindrical to elongate (2.0–7.0) × (3.5–28.0) µm. Cells occur singly, in pairs, short chains or small clusters (Fig. 59). Pseudomycelium is usually abundantly produced. A coherent

Fig. 59. *D. bruxellensis*. Budding cells in malt extract after 5 days at 25°C. Bar = 10 µm (from van der Walt 1970b).

floccose to somewhat mucoid sediment is formed; a slight ring is usually present and sometimes a creeping pellicle.

Growth on malt agar + 2% calcium carbonate:

After 6 weeks at room temperature, the streak culture is usually restricted, raised, cream-colored to brownish-cream, shiny, smooth, crisulate or rugose. The margin is entire, undulating, and occasionally fringed with pseudomycelium. Acetic acid is produced.

Dalmou plate cultures on potato-, rice- and morphology agars: After 5 days at 25°C, pseudomycelium is usually abundantly produced under aerobic and anaerobic conditions. It consists of filamentous cells with or without blastospores, which may be arranged in chains or small somewhat branched verticils.

Formation of ascospores: Vegetative cells are directly transformed into asci, which produce one to four ascospores that are hat-shaped or spheroidal with tangential brims (Fig. 60). Ascospores are liberated soon after maturation and tend to agglutinate. Sporulation is usually sparse. As mating types could not be recovered from heat-treated ascosporulating material, the strains studied are presumed to be homothallic.

Sporulation was observed in cultures at room temperature after 7–15 days on YM agar supplemented with vitamins.

Fig. 60. *D. bruxellensis*. Asci with ascospores on YM agar + vitamins after 14 days at 25°C. Bar = 10 µm (from van der Walt 1970b).

Co-Q: 9 (Yamada et al. 1980, Billon-Grand 1987).

Mol% G + C: 37.1–41.7, 21 strains, including CBS 72, CBS 73, CBS 74, CBS 75, CBS 78, CBS 1943, CBS 2976, CBS 5512, CBS 6955 (T_m : Smith et al. 1990b).

Origin of the strains studied: CBS 74, Belgium stout, Custers; CBS 72, lambic beer, Kufferath, type strain of *B. bruxellensis*; CBS 73, grape must, Krumbholz, type strain of *M. intermedia*; CBS 75, lambic beer, Custers, type strain of *B. lambicus*; CBS 78, beer, Skandinavisk Bryggeri Laboratory, Copenhagen, type strain of *B. bruxellensis* var. *nonmembranaefaciens*; CBS 1943, sour wine, André, authentic strain of *B. bruxellensis* var. *vini*; CBS 2796, sparkling wine, Peynaud, type strain of *B. schanderlii*; CBS 4914, tea-beer, van der Walt, type strain of *D. intermedia*; CBS 5206, grape must, van der Walt; CBS 5512, equipment Bantu-beer brewery, van der Walt, type strain of *B. custersii*; CBS 6055, dry ginger ale, Ahearn, type strain of *B. abstinens*; CBS 8027, Coca Cola, Put; and 18 additional strains isolated from stout (2), wine (12), equipment beer brewery (1), porter (1), secondary fermentation (1), sherry (1).

Type strain: CBS 74 (ATCC 36234) isolated by Custers.

Comments: van der Walt (1964) separated *D. bruxellensis* and *D. intermedia* on the basis of morphological and physiological differences. However, Smith et al. (1990b) demonstrated by DNA complementarity and electrophoretic comparisons of enzymes, the conspecificity of *D. intermedia* with *D. bruxellensis*, the teleomorph-anamorph relationship of *D. bruxellensis* with *B. bruxellensis*, and the synonymy of *B. abstinens*, *B. custersii*, *B. intermedius* and *B. lambicus* with *D. bruxellensis*.

Comments on the genus

Until 1984, *Dekkera* was comprised of two species, *D. bruxellensis* and *D. intermedia* (van der Walt 1984a). Smith and van Grinsven (1984) described *D. anomala*, which they considered to be the teleomorph of *B. anomalus* on the basis of morphological and physiological criteria. These authors also observed the ascospores of this taxon by transmission electron microscopy. Subsequently, five more *Dekkera* species were described to represent the teleomorphs of five known *Brettanomyces* species (Lee and Jong 1985, 1986a,b, Jong and Lee 1986). From comparisons of isozyme similarities and DNA homologies, Smith et al. (1990b) accepted only two *Dekkera* species, viz. *D. anomala* and *D. bruxellensis* with *D. intermedia* as its synonym. Smith et al. (1990b) considered the reported ascospores (Lee and Jong 1985, 1986a,b, Jong and Lee 1986) as artifacts and did not accept *D. custersianus* and *D. naardenensis*. In addition, *D. abstinens* and *D. lambica* were placed in synonymy with *D. bruxellensis*, and *D. clausenii* was considered a synonym of *D. anomala*. This species concept was supported by the results of restriction analysis of genes coding for rRNA by Molina et al. (1993).

Various mtDNA-based analyses have been performed. McArthur and Clark-Walker (1983) examined nine *Dekkera/Brettanomyces* species and reduced the number to six on the basis of similarities in restriction enzyme

digestion patterns, i.e., *D. bruxellensis* (*B. lambicus*), *D. intermedia*, *B. custersii* (*B. abstinens*), *B. anomalus* (*B. clausenii*), *B. custersianus* and *B. naardenensis*. In subsequent studies in which *Eeniella nana* was included, both the gene order (Hoeben and Clark-Walker 1986) and the nucleotide sequence of the mitochondrial-encoded cytochrome oxidase subunit gene (COX2) were determined (Clark-Walker et al. 1987, Hoeben et al. 1993). From these data, the preceding authors recognized five species, *D. bruxellensis* (*D. intermedia*), *B. custersii*, *B. anomalus*, *B. custersianus* and *B. naardenensis*. They also concluded that either *E. nana* should be included in *Brettanomyces* or *B. naardenensis* should be excluded from this genus.

From comparisons of partial sequences of 26S rDNA, Boekhout et al. (1994) accepted *D. bruxellensis*, *D. anomala*, *B. naardenensis* and *B. custersianus*, as well as *E. nana*, in *Brettanomyces*. The taxonomic position of *B. custersii*, considered conspecific with *B. bruxellensis* by Smith et al. (1990b), remained unsettled. Yamada et al. (1994d) studied the phylogeny of the four *Dekkera* species based on partial sequences of 18S and 26S rRNAs. These authors concluded that *D. custersiana* was phylogenetically distant from *D. bruxellensis* (*B. bruxellensis*), *D. anomala* (*B. anomalus*) and *D. naardenensis*. However, they postponed introduction of a new genus for this species until ascospore formation is confirmed.

28. *Dipodascopsis* Batra & P. Millner

M.Th. Smith and G.S. de Hoog

Diagnosis of the genus

Colonies are whitish, moist, somewhat slimy; true hyphae are present; arthroconidia are absent; multilateral budding cells are sometimes present. Asci are acicular or cylindrical, and formed laterally on hyphae after fusion of gametangia. Asci have persistent walls, and open by rupture at the apex. Ascospores are 32–128 per ascus, hyaline, ellipsoidal to reniform, and with a smooth wall and without a slime sheath.

Fermentation is absent. Extracellular starch is produced. Diazonium blue B reaction is negative. Coenzyme Q-9 system is present. Cell walls are multilamellar. Septa have narrow pores.

Type species

Dipodascopsis uninucleata Batra & P. Millner

Species accepted

1. *Dipodascopsis tothii* (Zsolt) Batra & P. Millner (1978)
2. *Dipodascopsis uninucleata* (Biggs) Batra & P. Millner (1978)

Systematic discussion of the species

28.1. *Dipodascopsis tothii* (Zsolt) Batra & P. Millner (Batra 1978)

Synonym:

Dipodascus tothii Zsolt (1963)

Growth on 4% malt extract/0.5% yeast extract agar:

After 10 days at 20–22°C, colonies are 4 mm in diameter, cream-colored, moist, and slimy. Budding cells are absent. Hyphae are firm with inflated cells and strongly amyloid. Arthroconidia are absent.

Formation of ascospores: Gametangia are formed laterally on hyphae as curved branches; asci arise after fusion of a terminal cell with its penultimate cell. Asci are acicular, 50–100 µm long, and contain 30–120 ascospores. Asci open by rupturing at the apex. Ascospores are subhyaline to hyaline, broadly ellipsoidal, occasionally bean-shaped, 1.0×(1.5–2.0) µm, and without a slime sheath (Fig. 61). The species is homothallic.

Fermentation: absent.

Assimilation:

Glucose	+	<i>N</i> -Acetyl-D-glucosamine	n
Galactose	+	Methanol	–
L-Sorbose	+	Ethanol	+
Sucrose	+	Glycerol	+
Maltose	+	Erythritol	–

Xylitol	+	50% Glucose	+
L-Arabinitol	+	60% Glucose	-
Arbutin	+	0.1% Cycloheximide	+
Cadaverine	+	Glucono- δ -lactone	-
L-Lysine	+	Acetic acid production	-
Ethylamine	w	Growth at 37°C	-

Co-Q: Not determined.

Mol% G + C: Not determined.

Origin of the strain studied: CBS 759.85 (NRRL Y-12690), from a cutting of beech (*Fagus sylvatica*), Hungary, Zsolt.

Type strain: CBS 759.85, from wood.

Comments: In contrast to *D. uninucleata*, gametangia of *D. tothii* extend from the hyphae which results in the formation of bipodal asci similar to those known in *Dipodascus*. The amyloid cell walls, absence of arthroconidia and extremely small ascospores lacking slime sheaths justify the classification of *D. tothii* in *Dipodascopsis*. Cells are uninucleate (Zsolt 1963). Ascospores become spheroidal after maturation, but further inflation and occasional budding, as seen in *D. uninucleata*, remain absent.

Ultrastructure of ascosporeogenesis was studied extensively by Curry (1985). He stressed the presence of vesicles surrounding each spore-initial which is in contrast to the ascus vesicles known in the Euascomycetes. Van der Walt et al. (1990a) demonstrated the presence of the siderophores ferrichrome-C and a hitherto unidentified ferrichrome in *D. tothii*.

28.2. *Dipodascopsis uninucleata* (Biggs) Batra & P. Millner (Batra 1978)

This species has two varieties:

Dipodascopsis uninucleata (Biggs) Batra & P. Millner var. *uninucleata* (1974)

Synonym:

Dipodascus uninucleatus Biggs (1937)

Dipodascopsis uninucleata var. *wickerhamii* Kreger-van Rij (1974)

Growth on 4% malt extract/0.5% yeast extract agar: After 10 days at 20–22°C, colonies are 4 mm in diameter, cream-colored, moist and slimy. Budding cells are sparse, spheroidal and thick-walled. Newly formed cells break through the parent cell wall and develop in more or less sympodial order. Hyphae are firm, with inflated cells, and produce abundant extracellular amyloid material. Arthroconidia are absent.

Formation of ascospores: Gametangia are undifferentiated adjacent cells or hyphal tips which fuse. Asci are produced laterally on the hyphae. Asci are acicular, 100–130 μ m long and contain 30–120 ascospores. Asci open by rupturing at the apex. Ascospores are hyaline or subhyaline, ellipsoidal to bean-shaped, (0.8–1.2) \times (2.0–2.8) μ m, and without a slime sheath (Fig. 62). The species is homothallic.

Fermentation: absent.

Assimilation:

Co-Q: Not determined.

Mol% G + C: Not determined.

Supplementary description of *D. uninucleata* var. *wickerhamii*: The variety *wickerhamii* does not assimilate sucrose, raffinose and inulin but assimilates L-rhamnose.

Origin of the strains studied belonging to the variety *uninucleata*: CBS 190.37, from dead pupa of a fruit fly (*Drosophila melanogaster*), Canada, Biggs; CBS 740.74 (NRRL Y-1268), from fruit fly, Mrak.

Type strain: CBS 190.37, from pupa.

Origin of the strain studied belonging to the variety *wickerhamii*: CBS 741.74 (NRRL Y-2181), from fruit fly (*Drosophila melanogaster*), Phaff.

Type strain: CBS 741.74, from fruit fly.

Comments: The most recent description was that given by Kreger-van Rij (1974). She attributed the binomial to Batra & Millner in an article cited as "in press" but actually it was published four years later. Consequently, the validation of *Dipodascopsis* should probably be attributed to Kreger-van Rij (1974). Kreger-van Rij (1974) noted that assimilation of soluble starch was variable, while D-mannitol and D-glucitol growth reactions were recorded as negative.

Budding cells are sparse. They arise from ascospores and are often found within the ascus. Liberated spores become thick-walled, occasionally form a few yeastlike cells but more often germinate with hyphae. Ascospores and hyphal cells are uninucleate (Biggs 1937). Hyphae bear hairy capsules and have multilamellar cell walls; septa are perforated by narrow, central canals with rounded edges (Kreger-van Rij and Veenhuis 1974). Van der Walt et al. (1990a) demonstrated the presence of ferrichrome as the main type of hydroxamate siderophores.

Fig. 62. *D. uninucleata* var. *uninucleata*, CBS 190.37. Ascus containing ascospores; liberated ascospores swell, become thick-walled prior to germination and occasionally form yeastlike cells. MEA, 2 weeks.

Comments on the genus

The taxonomic position of the genus *Dipodascopsis* is close to *Lipomyces* as discussed by Cottrell and Kock (1989), who used the presence of linolenic acid as a marker. Mitochondrial DNAs of *D. uninucleata* and other members of the Lipomycetaceae were compared by Lodolo et al. (1990); restriction patterns were found different in each genus.

29. *Dipodascus* de Lagerheim

G.S. de Hoog, M.Th. Smith and E. Guého

Diagnosis of the genus

Colonies are white or cream-colored, farinose or hairy, and usually dry; hyphae are hyaline, mostly disarticulating into rectangular arthroconidia (anamorph genus *Geotrichum*). Asci are acicular, cylindrical, ellipsoidal or subglobose, formed after fusion of gametangia located laterally on hyphae. Septa have micropores.

Asci have persistent walls and open by rupture at the apex. Ascospores are 4–128 per ascus, hyaline, ellipsoidal, with smooth walls and surrounded by regular slime sheaths.

Fermentation is mostly absent. Extracellular starch is not produced. Diazonium blue B reaction is negative.

Type species

Dipodascus albidus de Lagerheim

Species accepted

1. *Dipodascus aggregatus* Francke-Grosmann (1952)
2. *Dipodascus albidus* de Lagerheim (1892)
3. *Dipodascus ambrosiae* de Hoog, M.Th. Smith & Guého (1986)

12. *Dipodascus spicifer* de Hoog, M.Th. Smith & Guého (1986)
13. *Dipodascus tetrasperma* (Macy & M.W. Miller) von Arx (1977)

Key to species

See Table 23.

Morphological key (also see under *Geotrichum*):

1. a Asci acicular or long-cylindrical, with a narrow apex → 2
b Asci usually globose or ellipsoidal; when cylindrical, with a broadly rounded apex → 3
- 2(1). a Asci and ascospores cylindrical *D. macrosporus*: p. 189
b Asci subulate; ascospores ellipsoidal *D. albidus*: p. 183
- 3(1). a Asci 1–4-spored → 7
b Asci containing more than 4 spores → 4
- 4(3). a Asci cylindrical, up to 120 µm long, in rather dense groups, containing up to 30 ascospores; insect symbiont *D. aggregatus*: p. 182
b No combination of the above characters → 5
- 5(4). a Ascospores (2.8–3.2) × (3–4) µm; asci asymmetrically bipodal, somewhat tapering towards the tip *D. geniculatus*: p. 187
b Ascospores larger; asci cylindrical to ellipsoidal → 6
- 6(5). a Asci mostly in groups, broadly ellipsoidal, mostly present in culture; on rotting parts of tropical or subtropical succulents *D. australiensis*: p. 185
b Asci solitary, rather irregular in shape, not formed in culture; on carpophores of *Armillaria* in temperate zone *D. armillariae*: p. 184
- 7(3). a Asci borne on erect or suberect hyphae, anisogamous; ascospores (5.0–6.5) × (8.5–11.0) µm *D. magnusii*: p. 189
b Asci borne on undifferentiated hyphae, isogamous; ascospores smaller → 8
- 8(7). a Asci usually longer than wide → 9
b Asci appressed, usually shorter than wide; hyphae straight and stiff, 7–9 µm wide, with acuminate apices *D. tetrasperma*: p. 192
- 9(8). a Sympodial rachides abundant → 12
b Sympodial rachides absent or scarce → 10
- 10(9). a Initial growth with pseudomycelium → 11
b Initial growth with true hyphae *D. ambrosiae*: p. 184
- 11(10). a Thallus entirely pseudomycelial *D. ingens*: p. 188
b Thallus initially pseudomycelial, changing into true hyphae *D. ovetensis*: p. 190
- 12(9). a Branching regular, often verticillate; rachides straight; on warm-blooded animals *D. capitatus*: p. 186
b Branching rather irregular; rachides flexuose; on rotting parts of tropical or subtropical succulents *D. spicifer*: p. 191

Systematic discussion of the species

29.1. *Dipodascus aggregatus* Francke-Grosmann (1952)

Synonym:

Dipodascus albidus de Lagerheim var. *minor* Korf (1957)

Growth on 4% malt extract/0.5% yeast extract agar (MEYA): After 10 days at 20–22°C, colonies are 25 mm in diameter, glassy whitish, with a hispid center and smooth margin. Expanding hyphae are parallel, flexuose, 6–8 µm wide, with some basitonous branching; lateral branches are 3–5 µm wide, disarticulating into rectangular arthroconidia which are (2.6–5.0) × (6–10) µm, and that soon intermingle with larger conidia from main branches.

Formation of ascospores: Hyphae locally become densely septate and form clusters of isogamic gametangia. Asci are aggregated in small groups, cylindrical with rounded apex, (7–10) × (40–120) µm, mostly with 10–30 ascospores which are liberated by apical rupture of the ascus. Ascospores are subhyaline, broadly ellipsoidal, (3.0–4.5) × (3.8–6.0) µm, with a slime sheath 1.2–1.6 µm thick (Fig. 63). The species is homothallic.

Fermentation: absent.

Mol% G+C: 45.4–45.8, CBS 152.57, CBS 284.86 (BD: Guého et al. 1985).

Origin of the strains studied: CBS 175.53, from pupal galleries of bark-beetle *Ips acuminatus* in pine (*Pinus*

Fig. 63. *D. aggregatus*, CBS 175.53. Asci with ascospores; anamorph composed of hyphae disarticulating into arthroconidia. MEYA, 22°C.

sylvestris), Francke-Grosmann, Sweden; from frass of *Ips* in pine (*Pinus* sp.) roots (1); from slime flux of pine (*Pinus* sp.) attacked by *Ips* (1) or *Dendroctonus* (1); from unknown source (2).

Lectotype strain: CBS 175.53.

Comments: The species is obligately associated with bark beetles behind the bark of *Pinus* (Batra 1967). *D. aggregatus* is recognized by its broadly cylindrical asci with dome-shaped apices. Asci are easily produced on most routine media. The species was recently redescribed by Tsuneda (1987, 1989).

29.2. *Dipodascus albidus* de Lagerheim (1892)

Growth on 4% malt extract/0.5% yeast extract agar:

After 10 days at 20–22°C, colonies are 30 mm in diameter, white, farinose, and finally hispid. The reverse is whitish. Expanding hyphae are parallel, 6–8 µm wide, poorly branched, with little differentiation of main branches, and soon disarticulate into rectangular arthroconidia.

Formation of ascospores: Gametangia are mostly identical, and mostly formed on opposite sides of a septum. Asci are slightly swollen at the base, then tapering, acicular, 180–380 µm long, with narrow apical opening to release the spores. Ascospores are up to 128 per ascus, hyaline or subhyaline, broadly ellipsoidal, (1.2–1.8) × (1.8–3.2) µm, and with a slime sheath 0.5–1.0 µm thick (Fig. 64). The species is homothallic.

Fermentation: absent.

Assimilation:

Additional assimilation tests and other growth characteristics:

2-Keto-D-gluconate	–	Growth at 37°C	–
Arbutin	–		

Co-Q: Not determined.

Mol% G + C: 41.9, CBS 766.85 (T_m : de Hoog et al. 1986).

Origin of the strain studied: CBS 766.85 (IFO 1984), from exudate of a broadleaf tree, Nakase, Japan.

Neotype herbarium specimen: CUP 20140, Juel.

Comments: This very characteristic species is restricted to exudates of deciduous trees. There is some morphological resemblance to species of *Dipodascopsis*, but these have curved ascospores and produce extracellular starch.

29.3. *Dipodascus ambrosiae* de Hoog, M.Th. Smith & Guého (1986)

Growth on 4% malt extract/0.5% yeast extract agar: Colonies after 10 days are 13 mm in diameter, whitish, buttery, somewhat moist, smooth, with finely lobed margins. Hyphae arise bilaterally from ends of inflated cells, straight, without differentiation of main and lateral branches, mostly 2.5–3.5 μm wide, disarticulating into rectangular cells up to 20 μm long; liberated conidia often percurrently proliferate at their ends.

Formation of ascospores: Gametangia are formed on different hyphae or at opposite sides of hyphal septa. Asci are broadly ellipsoidal, (6–7) \times (10–13) μm , and contain 2–4 ascospores. Ascospores are hyaline or subhyaline,

ellipsoidal, (3–4) \times (4.5–5.5) μm , and with a slimy sheath 1–2 μm thick (Fig. 65). The species is homothallic.

Fermentation: absent.

Assimilation:

2-Keto-D-gluconate	–	Growth at 37°C	–
Arbutin	–		

Co-Q: Not determined.

Mol% G + C: 45.2, CBS 749.85 (T_m : de Hoog et al. 1986).

Origin of the strain studied: CBS 749.85 (BPI 3528), from insect tunnel, Batra, California.

Type strain: CBS 749.85.

Comments: The species is only known from the type locality. It might be one of the bark insect-associated species, but is clearly distinguished from *D. aggregatus* by small asci and a different hyphal structure. In these respects it is much more similar to *D. ovetensis*, but has considerably smaller asci and ascospores.

29.4. *Dipodascus armillariae* W. Gams (1983)

Anamorph: *Geotrichum decipiens* (L.R. Tulasne & C. Tulasne) W. Gams

Synonyms:

Hypomyces decipiens L.R. Tulasne & C. Tulasne (1865)

Geotrichum decipiens (L.R. Tulasne & C. Tulasne) W. Gams (1983)

Geotrichum armillariae von Arx (1977a)

Growth on 4% malt extract/0.5% yeast extract agar:

After 10 days at 20–22°C, colonies are 20–30 mm in diameter, white, dry, and centrally powdery to velvety. Expanding hyphae are loose, with irregular basitonous branching at acute angles; hyphae are 3.5–5.5 μm wide, with little differentiation between main and lateral branches, and soon disarticulate into rectangular arthroconidia (3.5–4.2) \times (7–18) μm . Pale brown, thick-walled, subglobose chlamydospores measuring (12–16) \times (13–17) μm are often present.

Formation of ascospores: Gametangia are formed only on the natural substrate, and located on opposite sides of

Fig. 65. *D. ambrosiae*, CBS 749.85. Early development of hyphae and mature hyphae with terminal and intercalary arthroconidia. Some asci have liberated their ascospores. MEYA, 22°C.

Fig. 66. *D. armillariae*. Asci on natural substrate, CBS-H 3348; hyphae disarticulate into arthroconidia, CBS 540.76, MEYA, 22°C; chlamydospores, CBS 817.71, MEYA, 22°C.

hyphal septa. Asci are broadly ellipsoidal to cylindrical, (7–10) × (17–28) µm, and contain 4–12 ascospores. Ascospores are ellipsoidal, (2.5–4.0) × (4–6) µm, with a slime sheath (Fig. 66).

Fermentation: absent.

Assimilation:

Glucose	+	<i>N</i> -Acetyl-D-glucosamine	n
Galactose	+	Methanol	n
L-Sorbose	–	Ethanol	v
Sucrose	–	Glycerol	+
Maltose	–	Erythritol	–

L-Rhamnose	–	Nitrate	–
D-Glucosamine	–	Vitamin-free	+

Additional assimilation tests and other growth characteristics:

2-Keto-D-gluconate	–	Growth at 37°C	–
Arbutin	–		

Co-Q: Not determined.

Mol% G+C: 42.2–42.3, CBS 834.71, CBS 540.76 (BD: Guého et al. 1985).

Origin of the strains studied: CBS 817.71 (ATCC 36758), on gills of mushroom (*Armillaria* sp.), van der Aa, Netherlands; 9 additional strains from gills of the *Armillaria mellea* aggregate.

Type strain: CBS 817.71.

Comments: The species is thus far only known from carpophores of *Armillaria* species in the Northern hemisphere. Asci are only produced on the natural substrate during a short period in October. Single-spore isolations invariably gave the *Geotrichum* anamorph with characteristic chlamydospores (de Hoog et al. 1986).

The species has often been confused with *Endomyces decipiens* Reess, but that species has hat-shaped ascospores. Nomenclatural separation of the two unrelated taxa was discussed by Gams (1983).

29.5. *Dipodascus australiensis* von Arx & Barker (von Arx 1977a)

Growth on 4% malt extract/0.5% yeast extract agar:

Colonies, after 10 days at 20–22°C, are 30–60 mm in diameter, white, evenly felty to fluffy, and with a straight margin. Expanding hyphae locally with dichotomous branching, main branches 4–7 µm wide, basitonously branched at acute angles, lateral branches 3–4 µm wide, and soon disarticulate into rectangular arthroconidia (3.5–5.5) × (6–12) µm.

Formation of ascospores: Equal gametangia are formed on opposite sides of septa; asci are subglobose to broadly clavate, (6–11) × (15–45) µm, with mostly 4–12 ascospores. Ascospores are subhyaline, ellipsoidal, often unilaterally flattened, (2.5–4.0) × (4–6) µm, and with a slime sheath 1.2–1.6 µm thick (Fig. 67). The species is homothallic.

Fermentation: absent.

Assimilation:

Glucose	+	<i>N</i> -Acetyl-D-glucosamine	n
Galactose	+	Methanol	n
L-Sorbose	+	Ethanol	+
Sucrose	–	Glycerol	+
Maltose	–	Erythritol	–

Fig. 67. *D. australiensis*. Branching pattern of expanding hyphae with hyphae disarticulating into arthroconidia, CBS 666.79; asci liberating ascospores, CBS 666.79, MEYA, 22°C.

Additional assimilation tests and other growth characteristics:

2-Keto-D-gluconate - Growth at 37°C +
Arbutin -

Co-Q: Not determined.

Mol% G + C: 39.9–40.2, CBS 625.74, CBS 666.79 (T_m : de Hoog et al. 1986).

Origin of the strains studied: CBS 625.74, from rotting cladodes of cactus *Opuntia inermis*, Barker, Australia; from necrosis in *Opuntia* (2); from *Euphorbia* (1).

Type strain: CBS 625.74.

Comments: The species is restricted to rotten fruits and leaves of succulents in desert areas. Asci are easily produced on routine laboratory media. They are sometimes formed in small clusters at hyphal septa, and then there is much similarity to poorly developed cultures of *D. aggregatus*. However, *D. australiensis* has local, dichotomously branched, expanding hyphae and much basitonous branching, leading to geniculate side branches after hyphae have disarticulated. In addition, *D. australiensis* is unable to assimilate citrate, but does

grow at 37°C. The two species clearly differ in their ecological preferences.

29.6. *Dipodascus capitatus* de Hoog, M.Th. Smith & Guého (1986)

Anamorph: *Geotrichum capitatum* (Diddens & Lodder) von Arx

Synonyms:

Trichosporon capitatum Diddens & Lodder (1942)

Geotrichum capitatum (Diddens & Lodder) von Arx (1977a)

Ascotrichosporon capitatum (Diddens & Lodder) Kocková-Kratochvílová, Sláviková, Zemek & Kuniak (1977b)

Blastoschizomyces capitatus (Diddens & Lodder) Salkin, Gordon, Samsonoff & Rieder (1985)

Sporotrichum spicatum Delitsch (1943)

Geotrichum linkii Vörös-Felkai (1961)

Blastoschizomyces pseudotrichosporon Salkin, Gordon, Samsonoff & Rieder (1985)

Growth on 4% malt extract/0.5% yeast extract agar: After 10 days at 20–22°C, colonies are 15–20 mm in diameter, glassy, later funiculose with a smooth expanding zone. Expanding hyphae are branched at acute angles, often somewhat penicillate, main branches up to 7.0 µm wide, lateral branches 2.5–3.5 µm wide and terminate in cylindrical conidiogenous cells with long, cicatrized rachides 2.5 µm wide. Conidia are clavate, with a truncate base, (2.5–3.5) × (7–10) µm. Arthroconidia are also common.

Formation of ascospores: Gametangia are formed at opposite sides of septa. Asci are subspherical to broadly ellipsoidal, (7–9) × (7–11) µm. Ascospores are hyaline, ellipsoidal, (2.5–3.2) × (5.5–6.5) µm, and with a persistent slime sheath 1–2 µm thick (Fig. 68). The species is heterothallic.

Ascospores are observed on vitamin-enriched V8 medium. Sporulation is sparse.

Fermentation: absent.

Assimilation:

Glucose	+	<i>N</i> -Acetyl-D-glucosamine	n
Galactose	+	Methanol	n
L-Sorbose	v	Ethanol	+
Sucrose	-	Glycerol	+

Fig. 68. *D. capitatus*. Conidial apparatus with sympodial rachides, sympodial conidia, arthroconidia and endoconidia, various cultures. MEYA, 22°C.

Additional assimilation tests and other growth characteristics:

2-Keto-D-gluconate – Growth at 37°C +

Arbutin –

Co-Q: 9 (Yamada et al. 1982).

Mol% G+C: 32.3–36.3 (T_m : Guého et al. 1987a).

Origin of the strains studied: CBS 571.82 (CBS 2364, ATCC 10663), from wood pulp factory with an air-tight warming system, Rennerfeldt, lectotype strain of *Trichosporon capitatum*; CBS 578.82, from sputum, authentic strain of *Geotrichum linkii*, do Carmo-Sousa; CBS 207.83 (ATCC 46132), from sputum, type strain of *Blastoschizomyces pseudotrichosporon*, Salkin, U.S.A.; from wood pulp (2); sputum (5); bovine mastitic milk (1); yeast cake (1); oral infections (2); digestive tract of swine (1); blood (2).

Complementary mating types: CBS 197.35 and 580.82.

Type strain: CBS 197.35 × 580.82.

Comments: Asci with ascospores are found in very low abundance on nutritionally rich media. They need several weeks to fully mature. A characteristic feature of *D. capitatus* is the sympodially produced conidia which are cylindrical to clavate, with truncate base and rounded apex. Arthroconidia are rare in this species.

The species is associated with human lung disorders. Recently it is increasingly being found in blood

of immunocompromised hosts, particularly in cases of leukemia.

29.7. *Dipodascus geniculatus* de Hoog, M.Th. Smith & Guého (1986)

Growth on 4% malt extract/0.5% yeast extract agar:

After 10 days at 20–22°C, colonies are 35 mm in diameter, white, flat, with fimbriate margin. Hyphae are stiff, branched at acute angles, 3–5 µm wide. Arthroconidia are absent.

Formation of ascospores: Gametangia are unequal and formed on opposite sides of septa; hyphae are often bent at the septa. Asci are broadly cylindrical to ellipsoidal, with a rounded apex and a strongly asymmetric base, (6–10) × (25–65) µm, and usually contain about 20 ascospores. Ascospores are subhyaline, broadly ellipsoidal, (2.8–3.2) × (3–4) µm, with a slime sheath 0.5 µm thick (Fig. 69). The species is homothallic.

Fermentation:

Glucose	w/–	Maltose	–
Galactose	–	Lactose	–
Sucrose	–	Raffinose	–

Assimilation:

Glucose	+	<i>N</i> -Acetyl-D-glucosamine	n

L-Arabinose	–	Citrate	+
D-Arabinose	–	Inositol	–
D-Ribose	–	Hexadecane	n
L-Rhamnose	–	Nitrate	–
D-Glucosamine	–	Vitamin-free	–

Additional assimilation tests and other growth characteristics:

2-Keto-D-gluconate – Growth at 37°C –

Arbutin –

Co-Q: Not determined.

Mol% G+C: 43.2, CBS 184.80 (T_m : de Hoog et al. 1986).

Origin of the strain studied: CBS 184.80, from *Psidium guajava* pulp, Bhide, India.

Type strain: CBS 184.80.

Fig. 69. *D. geniculatus*, CBS 184.80. Gametangia, asci and liberated ascospores. MEYA, 22°C.

Comments: The species, thus far only known from the type strain, can be recognized by absence of arthroconidia and by strongly asymmetric asci formed at the edges of kinks in supporting hyphae. Asci are produced in relative abundance on oatmeal agar, but only poorly on most other media. The species differs from *D. australiensis* by absence of arthroconidia, absence of growth at 37°C and by growth with maltose.

29.8. *Dipodascus ingens* Rodrigues de Miranda ex de Hoog, M.Th. Smith & Guého (1997a)

Anamorph: *Geotrichum ingens* (van der Walt & van Kerken) de Hoog, M.Th. Smith & Guého

Synonyms:

Candida ingens van der Walt & van Kerken (1961c)

Geotrichum ingens (van der Walt & van Kerken) de Hoog, M.Th. Smith & Guého (1997a)

Pichia humboldtii Rodrigues de Miranda & Török (1976)

Growth on 4% malt extract/0.5% yeast extract agar:

After 10 days at 20–22°C, colonies are 12 mm in diameter, glassy white, butyrous, smooth. The reverse is whitish. Hyphae are pseudomycelial, consisting of rounded-off cells of variable shape which are gradually narrower towards the distal end. Arthroconidia are cylindrical to ellipsoidal, and of variable size.

Formation of ascospores: Gametangia are mostly formed on different hyphae. Asci are broadly ellipsoidal, (10–17) × (12–20) µm, and contain 2–4 ascospores. Ascospores are hyaline or subhyaline, ellipsoidal, (3.0–4.5) × (5.5–7.0) µm, and with a slime sheath 1–3 µm thick (Fig. 70). The species is heterothallic.

Fermentation:

Glucose	w/–	Maltose	–
Galactose	–	Lactose	–
Sucrose	–	Raffinose	–

Assimilation:

Glucose	+	<i>N</i> -Acetyl-D-glucosamine	n
Galactose	+	Methanol	n
L-Sorbose	v	Ethanol	+
Sucrose	–	Glycerol	+
Maltose	–	Erythritol	–

D-Ribose	–	Hexadecane	n
L-Rhamnose	–	Nitrate	–
D-Glucosamine	–	Vitamin-free	+

Fig. 70. *D. ingens*. Pseudomycelial anamorph, CBS 7197, MEYA; asci with ascospores, CBS 7197 × 4827 and CBS 7197 × 4825, enriched V8, 22°C.

Additional assimilation tests and other growth characteristics:

2-Keto-D-gluconate	–	Growth at 37°C	v
Arbutin	–		

Co-Q: Not determined.

Mol% G+C: 39.5, CBS 4603 (T_m : de Hoog et al. 1986).

Origin of the strains studied: CBS 4603 (ATCC 60122, IFO 10057) type strain of *Candida ingens*; CBS 4827 and 2 additional strains, all from a wine cellar, van der Walt, South Africa; CBS 7197, Hofer; from industrial sulphite waste (1); from phenolic waste water (1); from asphalt waste (1).

Complementary mating types: CBS 7197 and CBS 4827.

Type strain: CBS 7197×4827.

Comments: Judging from the list of sources of this fungus, there appears some preference for phenolic compounds. The species has been described as a supposedly homothallic species, *Pichia humboldtii* Rodrigues de Miranda & Török (1976), but with the discovery of heterothallism in this species, the earlier results were interpreted as endoconidia. The species is close to *D. ovetensis*; for differential diagnosis see under that species.

29.9. *Dipodascus macrosporus* Madelin & Feest (1982)

Growth on 4% malt extract/0.5% yeast extract agar:

After 10 days at 20–22°C, colonies are 5 mm in diameter, whitish, buttery, composed of minute, confluent satellite colonies, and become somewhat cerebriform. Expanding hyphae are 3.5–6.5 µm wide, branched at acute angles, and without differentiation of main branches.

Formation of ascospores: Terminal hyphal cells become cylindrical asci after fertilization at the base by adjacent hyphae. Asci are cylindrical, about 80 µm long, contain 10–30 uniseriate ascospores, and open by rupture at the apex. Ascospores are hyaline or subhyaline, cylindrical to ellipsoidal, (2.5–3.2) × (6–8) µm, and with a slime sheath 1.2–2.0 µm thick (Fig. 71). The species is homothallic.

Fermentation: absent.

Assimilation:

Glucose	+	<i>N</i> -Acetyl-D-glucosamine	–
Galactose	+	Methanol	–
L-Sorbose	+	Ethanol	+
Sucrose	–	Glycerol	+
Maltose	–	Erythritol	–

L-Rhamnose	–	Nitrate	–
D-Glucosamine	–	Vitamin-free	+

Additional assimilation tests and other growth characteristics:

2-Keto-D-gluconate – Growth at 37°C –
Arbutin –

Co-Q: Not determined.

Mol% G+C: 41.5, CBS 259.82 (T_m : de Hoog et al. 1986).

Origin of the strains studied: CBS 259.82 (IMI 263027) and an additional strain, both from the myxomycete *Badhamia utricularis*, Madelin and Feest, U.K.

Type strain: CBS 259.82.

Comments: This rare, homothallic species found on myxomycete thalli is easily recognizable by the absence of arthroconidia on agar media and the presence of terminal, cylindrical asci with subcylindrical ascospores. Arthroconidia may be formed in shaken liquid culture. Another mycoparasitic *Dipodascus* species is *D. armillariae*. This species occurs on Agaricales and forms its ellipsoidal asci only on natural substrates. Its anamorph is characterized by the presence of large, brown chlamydospores.

Fig. 71. *D. macrosporus*, CBS 259.82, MEYA, 22°C. Tubular asci with ascospores and pseudomycelial hyphae.

29.10. *Dipodascus magnusii* (Ludwig) von Arx (1977a)

Anamorph: *Geotrichum ludwigii* (Hansen) Fang, Cheng & Chu

Synonyms:

Endomyces magnusii Ludwig (1886)

Magnusiomyces ludwigii Zender (1925a)

Geotrichum ludwigii (Hansen) Fang, Cheng & Chu (1966)

Magnusiomyces magnusii (Ludwig) Zender (1925b)

Endyllum magnusii (Ludwig) Clements (Clements & Shear 1931)

Oospora magnusii Stautz (1931)

Oidium ludwigii Hansen (Holtz 1901)

Oospora ludwigii (Hansen) P. Saccardo & D. Saccardo (1906)

Geotrichum ludwigii (Hansen) Saëz (1968a)

Growth on 4% malt extract/0.5% yeast extract agar:

After 10 days at 20–22°C, colonies are 25 mm in diameter, glassy white, buttery; the margin is smooth and strongly lobed. Expanding hyphae are stiff; main branches are 7–12 µm wide, branched at acute angles in a penicillate manner, lateral branches are 4–7 µm wide, and soon disarticulate into rectangular arthroconidia (4–7) × (10–18) µm which often show some annellations at one or both ends.

Formation of ascospores: Gametangia are formed on the ends of side branches, an anisogamous, terminal cell being connected by a tube originating from a few cells further down. Asci are broadly ellipsoidal, (9–16) × (17–30) µm, containing 4 ascospores. Ascospores are subhyaline, ellipsoidal, (5.0–6.5) × (8.5–11.0) µm, and have a slime sheath 1.2–2.5 µm thick (Fig. 72). The species is homothallic.

Ascospores are observed on vitamin-enriched V8 medium.

Co-Q: 9 (Yamada et al. 1973b).

Mol% G+C: 34, CBS 107.12 (T_m : Guého 1979), 37.8 (BD: Guého et al. 1985); 40.9, CBS 234.85 (T_m : de Hoog et al. 1986).

Origin of the strains studied: CBS 108.12, Lindner; CBS 151.30, type strain of *Oospora magnusii*, from exudate of oak (*Quercus* sp.), Stautz; CBS 234.85, from exudate of oak, Wright, Pennsylvania.

Possible type strain: CBS 108.12.

Comments: Asci are produced on enriched V8 juice

agar, but often only in low abundance. CBS 107.12 and 108.12, which do not form asci in pure culture, are Ludwig's authentic strains, but unfortunately no exact collection data are available.

The species is probably restricted to the slime flux of oak. *D. magnusii* is remarkable for its anisogamous ascus production. Anascogenous cultures morphologically resemble *Geotrichum fragrans*, but do not produce the strong odor characteristic of the latter species.

The mol% G+C of 43.7 in CBS 234.85 was obtained after calculation of the derivative peak. With total DNA, 40.9 mol% was found (de Hoog et al. 1986). The marked spread of G+C values in *D. magnusii*, as well as in several other *Dipodascus* species is at least partly caused by considerable amounts of mtDNA or rDNA with a lower mol% G+C.

Fig. 72. *D. magnusii*. Branching pattern of expanding hyphae, arthroconidia with annellated zones, CBS 107.12, MEYA; anisogamous asci liberating ascospores, CBS 234.85, enriched V8, 22°C.

29.11. *Dipodascus ovetensis* (Peláez & C. Ramírez) von Arx (1977a)

Anamorph: *Geotrichum sericeum* (Stautz) de Hoog, M.Th. Smith & Guého

Synonyms:

Endomyces ovetensis Peláez & C. Ramírez (1956b)

Endomycopsis ovetensis (Peláez & C. Ramírez) Kreger-van Rij (1964a)

Zendera ovetensis (Peláez & C. Ramírez) Redhead & Malloch (1977)

Oospora sericea Stautz (1931)

Trichosporon sericeum (Stautz) Diddens & Lodder (1942)

Ascotrichosporon sericeum (Stautz) Kocková-Kratochvílová, Sláviková, Zemek & Kuniak (1977b)

Geotrichum sericeum (Stautz) de Hoog, M.Th. Smith & Guého (1986)

Growth on 4% malt extract/0.5% yeast extract agar: After 10 days at 20–22°C, colonies are 15–25 mm in diameter, whitish, moist, buttery. Expanding hyphae are 4.5–6.0 µm wide, arising from a short series of inflated cells, little branched with narrower lateral branches 3.5–5.0 µm wide, and disarticulating into cylindrical arthroconidia about 10–30 µm length.

Formation of ascospores: Gametangia are mostly located on different hyphae. Asci are broadly ellipsoidal, contain 2–4 ascospores and rupture irregularly at maturity. Ascospores are hyaline or subhyaline, ellipsoidal, (3.0–4.5) × (5.5–7.0) µm, and with a slime sheath 1–3 µm thick (Fig. 73). The species is homothallic.

Ascospores are observed on vitamin-enriched V8 medium.

Co-Q: 9 (Yamada et al. 1973b).

Mol% G + C: 51.2–51.5, CBS 192.55, CBS 634.85 (T_m : de Hoog et al. 1986).

Origin of the strains studied: CBS 192.55 (CBS 2508), from tannin concentrate, Ramírez; CBS 634.85 (CBS 2544), authentic strain of *Oospora sericea*, from slime flux of oak (*Quercus* sp.), Stautz, Germany; from slime flux of oak (3); from unknown source (1).

Type strain: CBS 192.55.

Comments: The species seems to be restricted to the slime fluxes of deciduous trees, *Quercus* in particular. The strain from tannin concentrate initially may have had a similar ecological niche.

Fig. 73. *D. ovetensis*. Gametangia, mature asci and liberated ascospores, CBS 635.85, enriched V8; hyphae disarticulate into arthroconidia and conidia with annellated zones, CBS 192.55, MEYA, 22°C.

The species is close to *D. ingens*, but has true hyphae. In addition, larger conidia often show percurrent proliferation (de Hoog et al. 1986). The two species are physiologically identical but have remarkably different G + C percentages of their DNAs.

29.12. *Dipodascus spicifer* de Hoog, M.Th. Smith & Guého (1986)

Growth on 4% malt extract/0.5% yeast extract agar:

After 10 days at 20–22°C, colonies are 20 mm in diameter, whitish, with a regular, straight margin; the texture is soft and butyrous. Expanding hyphae are loose and branched at acute angles; hyphae are 2.5–5.0 µm wide, with little differentiation of main and lateral branches; locally they terminate in cylindrical conidiogenous cells with long, cicatrized sympodial rachides. Sympodial conidia are clavate, about 3 × 7 µm. Hyphae show early disarticulation into rectangular arthroconidia.

Formation of ascospores: Gametangia are formed at opposite sides of hyphal septa. Asci are subglobose to broadly cylindrical, (10–12) × (11–20) µm, and mostly contain 4 ascospores. Ascospores are subhyaline, ellipsoidal to subcylindrical, 4.5 × (6–7) µm, and with a slime sheath 1.2–1.6 µm thick (Fig. 74). The species is homothallic.

Fermentation: absent.

Fig. 74. *D. spicifer*. Asci with liberated ascospores, CBS 244.85; hyphae with sympodial rachides, clavate sympodial conidia and cylindrical arthroconidia, CBS 244.85, MEYA, 22°C.

Assimilation:

Glucose	+	<i>N</i> -Acetyl-D-glucosamine	n
Galactose	+	Methanol	n
L-Sorbose	+	Ethanol	+
Sucrose	-	Glycerol	+
Maltose	-	Erythritol	-

Soluble starch	-	D,L-Lactate	+
D-Xylose	+	Succinate	+
L-Arabinose	-	Citrate	+
D-Arabinose	-	Inositol	-
D-Ribose	-	Hexadecane	n
L-Rhamnose	-	Nitrate	-
D-Glucosamine	-	Vitamin-free	-

Additional assimilation tests and other growth characteristics:

2-Keto-D-gluconate	-	Growth at 37°C	+
Arbutin	+		

Co-Q: Not determined.

Mol% G+C: 30.6, CBS 244.85 (T_m : Guého et al. 1987a).

Origin of the strain studied: CBS 244.85 from cactus rot, Arizona, Lachance.

Type strain: CBS 244.85.

Comments: The species is close to *D. capitatus*, but differs by its ability to grow with cellobiose, salicin and arbutin. Both species form sympodial rachides.

Ascospores are rather abundant in the homothallic strain CBS 244.85, but scarce in the heterothallic species, *D. capitatus*.

The recent finding of strains from human blood, physiologically identical to *D. spicifer* but without ascospores, complicates the distinction of taxa within the *D. capitatus* group. Guého et al. (1987a) noted that the distinction of three taxa was justified on the basis of DNA/DNA reassociation experiments. The blood cultures may belong to either *D. capitatus* or *Geotrichum clavatum*. The latter species grows with salicin, arbutin and cellobiose, but the diagnosis should be expanded to accommodate strains with sympodial rachides. The strain described by Mahul et al. (1989) from a systemic infection in a patient with leukemia also fits *G. clavatum*. The type of *D. spicifer*, an insect-associated strain on *Opuntia* rots, occupies an ecological niche quite different from that of *D. capitatus*.

29.13. *Dipodascus tetrasperma* (Macy & M.W. Miller) von Arx (1977a)

Synonyms:

Endomyces tetrasperma Macy & M.W. Miller (1971)

Zendera tetrasperma (Macy & M.W. Miller) Redhead & Malloch (1977)

Growth on 4% malt extract/0.5% yeast extract agar:

After 10 days at 20–22°C, colonies are 22 mm in diameter, whitish, smooth and with finely feathered margins. Expanding hyphae are stiff, 7–9 µm wide, branched at acute angles, and, as they become older, disarticulate into short cylindrical arthroconidia (7–9) × (12–20) µm.

Formation of ascospores: Gametangia are formed with groups on opposite sides of septa. Asci are subglobose, 8–12 µm in diameter, and contain 2–4 ascospores. Ascospores are hyaline, broadly ellipsoidal, (4–5) × (6–7) µm and with a slime sheath 1.5 µm thick (Fig. 75). The species is homothallic.

Fermentation:

Glucose	+	Maltose	-
Galactose	-	Lactose	-
Sucrose	-	Raffinose	-

Fig. 75. *D. tetrasperma*, CBS 765.70, MEYA, 22°C. Expanding hyphae with gametangia, asci liberating ascospores and disarticulated hyphae with remains of asci.

Additional assimilation tests and other growth characteristics:

2-Keto-D-gluconate - Growth at 37°C +

Co-Q: Not determined.

Mol% G+C: 38.8, CBS 765.70 (BD: Guého et al. 1985); 38, CBS 765.70 (T_m : Guého 1979).

Origin of the strain studied: CBS 765.70 (ATCC 22540), from wet conveyor at prune dehydration plant, Miller, California.

Type strain: CBS 765.70.

Comments: The species is close to *D. magnusii* but distinguished from it by the asci which form laterally alongside main branches, whereas those of *D. magnusii* are formed terminally on lateral branches.

Comments on the genus

Kurtzman and Robnett (1995) compared described species of *Dipodascus* from the extent of nucleotide divergence in the 5' end of large subunit rDNAs. Phylogenetic analysis of these data divided *Dipodascus* into two subclades, one of which included species of *Galactomyces* (see Fig. 170, p. 385).

30. *Endomyces* Reess

G.S. de Hoog

Diagnosis of the genus

Colonies on natural substrates are white, floccose, pseudomycelial or with true hyphae. Conidia, if present, are sympodially produced in short chains. Species are homothallic. Asci are subglobose to clavate, thin-walled and open by a rupture at the apex. Ascospores are 2–12 per ascus, hyaline, ellipsoidal or unilaterally flattened and helmet-shaped in outline due to a unilateral slimy brim. Species are parasitic on mushrooms.

Type species

Endomyces decipiens Reess

Species accepted

1. *Endomyces cortinarii* Redhead & Malloch (1977)
2. *Endomyces decipiens* Reess (1870)
3. *Endomyces polyporicola* (T. Schumacher & Ryvarden) de Hoog, M.Th. Smith & Guého (1986)
4. *Endomyces scopularum* Helfer (1991)

1. a Asci upright, produced on creeping hyphae; parasitizing Aphyllophorales *E. polyporicola*: p. 195
b Asci formed in whorls laterally on hyphae; parasitizing Agaricales → 2
- 2(1). a Asci containing 2 ascospores → 3
b Asci mostly containing 4 ascospores; on *Armillaria* *E. decipiens*: p. 194
- 3(2). a Species parasitizing *Cortinarius* *E. cortinarii*: p. 194
b Species parasitizing *Tricholoma* *E. scopularum*: p. 195

Systematic discussion of the species

30.1. *Endomyces cortinarii* Redhead & Malloch (1977)

Colonies on natural substrates: Colonies are white and floccose. Hyphae are hyaline, about 1 µm wide, profusely branched, and slightly constricted at the septa. Conidia are sympodially produced in short chains, and are hyaline and clavate, (1.0–2.0) × (5–15) µm. Asci have crozier-like appendages at the base, are solitary or in small groups alongside hyphae, thin-walled, subglobose, (5.5–6.5) × (7.5–12.0) µm, and contain two ascospores. Ascospores are ellipsoidal, unilaterally flattened, (3.5–4.0) × (4.0–5.5) µm, and with a prominent slimy brim at the flattened side (Fig. 76).

Origin of the strain studied: TRTC 47587, dried specimen on old carpophore of *Cortinarius huronensis*, Ontario, Canada.

Type specimen: TRTC 47587, on an agaric.

Comments: The species is only known from a single collection; it has not been cultured. The connection with the sympodial anamorph has not unambiguously been proven. The asci, having crozier-like appendages and containing two ascospores, are characteristic for the species.

30.2. *Endomyces decipiens* Reess (1870)

Colonies on natural substrates: Colonies are white and

floccose. Hyphae are hyaline, 2–3 µm wide, cylindrical or with inflated cells and constricted at the septa. Hyphae terminally disarticulate into separate cells. Asci are in small clusters just below septa and are subglobose to

Fig. 76. *E. cortinarii*, TRTC 47587. Asci and ascospores on the natural substrate. Bar = 10 µm.

Fig. 77. *E. decipiens*, neotype TRTC. Asci and ascospores on the natural substrate. Bar = 10 μm .

clavate, (10–14) \times (14–19) μm , thin-walled and contain 4 ascospores. Ascospores are broadly ellipsoidal, unilaterally flattened, (5.0–6.5) \times (7.0–8.5) μm , and with a thin slime sheath which forms a brim at the flattened spore side (Fig. 77).

Origin of the specimen studied: Rehm Ascom. 1050 (TRTC), on *Armillaria mellea*, Krieger, Germany.

Neotype specimen: Rehm 1050, on an agaric.

Comments: The complicated nomenclatural history of this species was discussed by Redhead and Malloch (1977) who indicated a neotype specimen maintained at the TRTC herbarium in Toronto, Canada.

Endomyces decipiens has not been grown in culture. Similar to *Dipodascus armillariae* W. Gams, with which it has often been confused (Gams 1983), the species can be found as a parasite on carpophores of *Armillaria* (Agaricales) in autumn. A strain, mentioned by Hausner et al. (1992) as *E. decipiens* was reidentified by Kurtzman & Robnett (1995) as *Dipodascus armillariae*.

30.3. *Endomyces polyporicola* (T. Schumacher & Ryvarden) de Hoog, M.Th. Smith & Guého (1986)

Synonym:

Dipodascus polyporicola T. Schumacher & Ryvarden (1981)

Colonies on natural substrates: Colonies are whitish and hamper development of the host carpophore. Asci are single or in clusters, clavate to cylindrical, (6–8) \times (15–28) μm , and contain 4–6 ascospores which are liberated by apical deterioration of the ascus. Ascospores are hyaline, ellipsoidal, unilaterally flattened, (3–5) \times (4.5–6.0) μm , and with a thin slime sheath which forms a brim at the flattened spore side (Fig. 78).

Fig. 78. *E. polyporicola*, CBS-H 1225. Asci and ascospores on the natural substrate. Bar = 10 μm .

Origin of the strain studied: CBS-H 1225, on polypore (*Piptoporus soloniensis*), Schumacher, Thailand.

Isotype specimen CBS-H 1225, on a polypore.

Comments: The species was reported as a parasite on developing carpophores of *Piptoporus soloniensis* (Aphyllphorales). Due to the abundant overgrowth by the parasite, basidia were totally lacking from the host hymenium and only asci were found (Schumacher and Ryvarden 1981).

De Hoog et al. (1986) found conidia produced sympodially in low abundance, which possibly represented the anamorph of *E. polyporicola*. This sympodial rather than arthric anamorph, and the unilaterally hat-shaped ascospores favor the classification of this species in *Endomyces* rather than in *Dipodascus*. The species has as yet not been cultured.

30.4. *Endomyces scopularum* Helfer (1991)

Colonies on natural substrates: Colonies are white and floccose. Hyphae are hyaline, 1–2.5 μm wide, profusely branched, and slightly constricted at the septa. Conidia are sympodially produced in short chains, and are hyaline, clavate and about 1.5 \times 5 μm . Asci have crozier-like appendages at the base, are solitary or in small groups alongside hyphae, thin-walled, subglobose, (5.5–8) \times (7–9) μm , and contain two ascospores. Ascospores are ellipsoidal, unilaterally flattened, (4–5.5) \times (6.5–9) μm , and separated by a unilateral brim (Fig. 79).

Type specimen: PBR M 13/84, on an agaric.

Comments: No material was available for study. Judging from the description given by Helfer (1991), the species is very close to *E. cortinarii*, also having a fragile, *Candida*-like anamorph with clavate conidia. The ascospores in *E. scopularum* were described

Fig. 79. *E. scopularum*, anamorph, asci and ascospores on the natural substrate. From Helfer (1991).

as lining each other with their brims, while this is less strictly the case in *E. cortinarii*. Three strains labeled *Endomyces scopularum* deposited in the CBS culture collection show an expanding, *Sporothrix*-like anamorph with conidial denticles. For one of these, CBS 131.86, partial rDNA sequences were determined by Kurtzman and Robnett (1995) who found it to cluster in the Euascomycetes. Possibly *Calcarisporium*-like contaminants were isolated rather than *Endomyces* strains.

Comments on the genus

A further species, *Endomyces parasiticus* Fayod (1885), has been described as a parasite on carpophores of *Tricholomopsis rutilans* and has not been reported since. The type specimen in the Herbarium of Geneva contains the original drawing but no specimen. The species formed small synnemata on the gills of the agaric and had monopodial, broadly clavate asci. The ascospore shape was described as ellipsoidal, without brim.

31. Endomycete-like genera of mycoparasitic fungi
Helicogonium W.L. White, *Myriogonium* Cain,
Trichomonascus H.S. Jackson, *Phialoascus* Redhead & Malloch

D. Malloch and G.S. de Hoog

Contents

<i>Helicogonium jacksonii</i> 197	<i>Myriogonium odontiae</i> 198	<i>Trichomonascus mycophagus</i> 199
		<i>Phialoascus borealis</i> 200

31.1. *Helicogonium* W.L. White

Diagnosis of the genus

The genus is mycoparasitic. Colonies on natural substrates are composed of branched hyphae. Antheridia are undifferentiated; the ascogonium is loosely coiled and inflates unilaterally to produce a single ascus. Asci are clavate and contain 8 ascospores which are continuous with the ascogonium and open by distal deterioration. Ascospores are hyaline, thin-walled, fusiform, one- or two-celled, and bud within the ascus.

Type species

Helicogonium jacksonii W.L. White

Species accepted

1. *Helicogonium jacksonii* W.L. White (1942)

Systematic discussion of the species

31.1.1. *Helicogonium jacksonii* W.L. White (1942)

Colonies on natural substrates: Colonies have a scanty mycelium composed of branched hyphae (1.8–2.5) μm in diameter. The antheridium is an undifferentiated hyphal cell; the ascogonium is loosely coiled and inflates unilaterally to produce a single ascus. Asci contain 8 ascospores and are sessile, clavate, (7.5–10) \times (28–45) μm , slightly constricted at the base but continuous with the ascogonium. The wall is slightly thickened at the non-amyloid apex and opens by apical deterioration. Ascospores are hyaline, thin-walled, fusiform, (2.5–3.0) \times (7.5–11) μm , one- or two-celled, and bud within the ascus. Secondary budding cells are elongate, (1.5–2.0) \times (3.0–4.5) μm , and finally fill the ascus (Fig. 80).

Origin of the specimens studied: TRTC 12919, corticiaceous fungus on *Ceraceomyces sublaevis* on coniferous wood, Ontario, Canada, Skolko; on the same substrate from Ontario, Jackson/White; from Russia, Parmasto.

Type specimen: TRTC 12919.

Comments: The species is only known from herbarium collections from the Northern Hemisphere. It was invariably found inside the hymenium of *Athelia sublaevis*, formerly known as *Corticium microsporum*. The host is not significantly affected by the parasite. Asci are dispersed among normally sporulating basidia. Each ascus

Fig. 80. *Helicogonium jacksonii*, TRTC 12919, on natural substrate. Asci with fusiform ascospores and budding within the ascus. Bar = 10 μm .

formation is preceded by an anisogamous fusion of hyphal cells, the fusion product immediately growing out with an ascus. Croziers are absent and hence only single asci are formed after each sexual event.

Except for the budding cells within the ascus no anamorph is produced.

31.2. *Myriogonium* Cain

Diagnosis of the genus

The genus is mycoparasitic. Colonies on natural substrates are composed of branched hyphae. Gametangia are undifferentiated; asci are formed after fusion of terminal hyphal cells; subsequent asci are produced in a cymose arrangement. Asci are clavate and contain 8 ascospores. They are separated from the crozier by a septum, which opens by distal deterioration. Ascospores are hyaline, thin-walled, elongate, and one-celled.

Type species

Myriogonium odontiae Cain

Species accepted

1. *Myriogonium odontiae* Cain (1948)

Systematic discussion of the species

31.2.1. *Myriogonium odontiae* Cain (1948)

Colonies on natural substrates: Colonies are immersed in the host hymenium and composed of hyaline, amyloid, branched, strongly contorted hyphae which measure $(1.0\text{--}2.5)\mu\text{m}$. Terminal cells become somewhat swollen and fuse; one of the cells grows out into a crozier and the penultimate cell develops into an ascus. Subsequent crozier formation leads to cymosely arranged groups of asci. Asci are clavate, $(5\text{--}7)\times(18\text{--}25)\mu\text{m}$, and contain 8 ascospores which are separated from the crozier by a septum. The wall is thickened at the non-amyloid apex and opens by a distal deterioration. Ascospores are hyaline, thin-walled, clavate to nearly cylindrical, $(1.2\text{--}1.7)\times(4.5\text{--}6.0)\mu\text{m}$, and are one-celled (Fig. 81).

Origin of the specimen studied: TRTC 51336, on the corticiaceous fungus *Dacryobolus sudans* on rotten conifer wood, Austria, Litschauer.

Type specimen: TRTC 51336.

Comments: The fungus is only known from a single herbarium specimen. The parasite grows with dispersed hyphae into the hymenium of the host without causing significant damage. *M. odontiae* invades large areas of the host fungus, occurring between normally sporulating basidia, but remaining absent from the sterile host spines which extend from the hymenium. With Melzer's reagent, the hyphae, but not the asci, show a significant amyloid reaction. In older areas the parasite becomes more abundant and then the basidiomycete tissue may be entirely replaced by the parasite. The parasite's hyphae are strongly contorted and hence septa are observed with difficulty. From initial fusion cells, the fungus spreads out

Fig. 81. *Myriogonium odontiae*, TRTC 51336, on natural substrate. Asci and ascospores; amyloid, contorted hyphae in host tissue. Bar = $10\mu\text{m}$.

with a series of asci in a cymose arrangement; each ascus is separated from the crozier by a septum. The presence of croziers suggests a relationship to Discomycetes rather than to Saccharomycetes; the species might be compared to the mycoparasitic species *Micropyxis tribidariae* (Carter and Malloch 1982). No anamorph is produced.

31.3. *Trichomonascus* H.S. Jackson

Diagnosis of the genus

The genus is mycoparasitic. Asci are immersed in host tissue and are formed terminally on undifferentiated hyphae. The initial cell cuts off a dome-shaped distal cell which is subsequently connected with the supporting hypha and develops into a sterile seta that reaches the surface of the host hymenium. The penultimate cell develops into an ascus containing one-celled ascospores.

Type species

Trichomonascus mycophagus H.S. Jackson

Species accepted

1. *Trichomonascus mycophagus* H.S. Jackson (1947)

Systematic discussion of the species

31.3.1. *Trichomonascus mycophagus* H.S. Jackson (1947)

Formation of ascospores: Asci are formed terminally on undifferentiated hyphae which are deep in host tissue. They are initially hyaline, thick-walled ellipsoidal cells, $15 \times 10 \mu\text{m}$, with a dome-shaped distal cell that is soon cut off. The distal cell is subsequently connected with the hypha immediately below the initial ascus. The connecting element is inflated to $4 \mu\text{m}$ in its distal portion. The ultimate cell grows out with a sterile seta $2 \times (60-75) \mu\text{m}$, terminally becoming corkscrew-shaped and reaching the surface of the host hymenium. The penultimate cell develops into an ascus containing four one-celled ascospores. Ascospores are subhyaline, long-ellipsoidal to fusiform, and measure $3 \times (7-8) \mu\text{m}$ (Fig. 82).

Origin of the specimens studied: TRTC 21820, on the corticiaceous fungus *Radulomyces confluens* on balsam fir wood (*Abies balsamea*), Ontario, Canada, Jackson; TRTC 32120, Ontario, Canada, Cain.

Type specimen: TRTC 21820.

Comments: The species is only known from dried herbarium collections. The karyological events leading to the formation of asci and the role of the corkscrew-shaped extensions, referred to by Jackson (1947) as 'trichogynes', can therefore only be speculated upon. The distal cell seems to be fertilized by a lateral extension and thus functions as an ascogonium, which develops a single ascus after septation. The taxonomic relationship of this peculiar

fungus remains unknown (Benny and Kimbrough 1980). TRTC 32120 also contains a *Calcarisporium* anamorph with the same hyphal structure as *Trichomonascus*, but the connection between the two fungi could not unambiguously be verified.

Fig. 82. *Trichomonascus mycophagus*, TRTC 21820, on natural substrate. Young ascogonium fertilized by lateral, tubular antheridium; mature asci with ascospores, crowned with corkscrew-shaped ultimate cell. Bar = $10 \mu\text{m}$.

31.4. *Phialoascus* Redhead & Malloch

Diagnosis of the genus

The genus is mycoparasitic. Hyphae are hyaline and branched. Ascophores are erect, hyaline, moderately thick-walled and tapering towards the apex. Asci are single, terminal on ascophores, open by apical deterioration, and eventually proliferate with new asci. Ascospores are hyaline, one-celled, and enclosed in a thin gelatinous sheath.

Type species

Phialoascus borealis Redhead & Malloch

Species accepted

1. *Phialoascus borealis* Redhead & Malloch (1977)

Systematic discussion of the species

31.4.1. *Phialoascus borealis* Redhead & Malloch (1977)

Formation of ascospores: Hyphae are immersed, hyaline, branched, and (1.5–2.0) μm wide. Ascophores are one-celled, scattered, and project from and are perpendicular to the host's hymenium. They are hyaline, moderately thick-walled, taper towards the apex, frequently bear a clamp-like structure at the base, and measure (45–77) μm long, (3.0–3.5) μm wide above, (5–7) μm wide at the base. Asci are single, terminal on ascophores, hyaline, thin-walled, ellipsoidal to clavate, (6.0–6.5) \times (14–18) μm , and open by apical deterioration. They contain four ascospores. Often new asci are formed by percurrent proliferation. Ascospores are hyaline, ellipsoidal and unilaterally flattened to bean-shaped, (2–4) \times (3.5–7.5) μm , one-celled, and enclosed in a thin gelatinous sheath (Fig. 83).

Origin of the specimen studied: TRTC 47588, on a carpophore of *Cortinarius huronensis*, Ontario, Canada, Redhead and Malloch.

Type specimen: TRTC 47588.

Comments: Diploidization of ascophores takes place at the base of the ascophores in a fashion similar to fertilization in *Helicogonium* and *Dipodascus*. Each sexual event results in a single ascophore. As in *Cephaloascus*, each ascophore may produce several asci. The asci of *Phialoascus* proliferate percurrently and hence resemble those of *Ascoidea*.

Fig. 83. *Phialoascus borealis*, TRTC 47588, on natural substrate. Ascophores with terminal, percurrent asci-liberated ascospores. Redrawn from Redhead and Malloch (1977). Bar = 10 μm .

The spores accumulate at the open ends of the asci as sticky balls, suggesting insect dispersal (Redhead and Malloch 1977). No anamorph is known.

32. *Eremothecium Borzi emend. Kurtzman*

G.S. de Hoog, C.P. Kurtzman, H.J. Phaff and M.W. Miller

Diagnosis of the genus

Budding cells are absent or present, and when present, budding is multilateral on a narrow base. Cells are globose, ovoidal, ellipsoidal or cylindrical. Enteroarthric conidia are infrequently produced by one species. Pseudohyphae and true hyphae are generally present. Colonies are smooth or floccose and white, grayish or yellow in color.

Asci, which become deliquescent, form 8–32 ascospores that are fusiform or acicular. Ascospores may have a central septum, and those of some species have a tapered, terminal extension of the cell wall.

Sugars are fermented by some species. Nitrate is not assimilated. Coenzyme Q may have 5, 6, 7, 8, or 9 isoprene units in the side chain, some of which are in minor proportions. Diazonium blue B reaction is negative.

Type species

Eremothecium cymbalariae Borzi

Species accepted

1. *Eremothecium ashbyi* (Guilliermond ex Routien) Batra (1973)
2. *Eremothecium coryli* (Peglion) Kurtzman (1995)
3. *Eremothecium cymbalariae* Borzi (1888)
4. *Eremothecium gossypii* (Ashby & Nowell) Kurtzman (1995)
5. *Eremothecium sinecaudum* (Holley) Kurtzman (1995)

Key to species

1. a Ascospores are curved and sickle-like in appearance *E. ashbyi*: p. 201
b Ascospores are linear in appearance → 2
- 2(1). a Ascospores have a long, whip-like terminal appendage *E. coryli*: p. 202
b Ascospores do not have whip-like appendages → 3
- 3(2). a Ascospores are narrowly triangular in side view with one needle-like end *E. cymbalariae*: p. 204
b Ascospores are needle-shaped; length is greater than 20 µm *E. gossypii*: p. 204
c Ascospores are needle-shaped; length is ca. 10 µm *E. sinecaudum*: p. 205

Systematic discussion of the species

32.1. *Eremothecium ashbyi* (Guilliermond ex Routien) Batra (1973)

Synonyms:

Eremothecium ashbyi Guilliermond (1935) nom. inval.
Crebrothecium ashbyi Guilliermond ex Routien (1949)
?Spermophthora gossypii Ashby & Nowell (1926)

Growth on 4% malt extract/0.5% yeast extract

agar: After 10 days at 20–22°C, colonies are 5 mm in diameter, initially tan, but later locally excreting riboflavin into the medium. Colonies are dry, initially smooth, but later develop deep radial furrows and have sharp, lobed margins. Budding cells are absent. Hyphae are dichotomously branched, 2–6 µm wide, sparingly septate, and the cells contain yellow, needle-shaped crystals. Enteroarthric conidia are rarely produced.

Growth on the surface of assimilation media: Thin pellicles are formed by some strains.

Formation of ascospores: Asci are ellipsoidal to fusiform (10–18)×(50–110) µm, and mostly intercalary and in long chains. Each ascus forms 8–16 ascospores which are liberated at maturity. The ascospores are evenly distributed in the ascus, and are hyaline, narrow, sickle-shaped, rounded at the tip, but with a basal spine (Fig. 84).

Fig. 84. *E. ashbyi*, CBS 269.75. Intercalary, disarticulating asci and sickle-shaped ascospores with cellular basal spines, after 1 week, YM agar, 25°C.

The spore body measures $(2.0\text{--}3.5)\times(20\text{--}30)\mu\text{m}$, and the spine is $2\text{--}10\mu\text{m}$ long. The species appears to be homothallic.

Ascosporeulation was observed on YM agar after 1 week at 25°C .

Co-Q: 6, CBS 106.43 and 5 additional strains (Yamada et al. 1987b).

Mol% G + C: Not determined.

Origin of the strains studied: CBS 106.43 (ex CBS 204.36 = NRRL Y-1360), from cotton, Sudan, Massey and Guilliermond; from cotton (1); from plant-parasitic insect (1).

Authentic strain: CBS 106.43.

Comments: The name *Eremothecium ashbyi* was introduced by Guilliermond (1935) without a Latin diagnosis, but the taxon was validated by Routien (1949) in the description of *Crebrothecium*. The species has been well illustrated and described by Guilliermond (1936), Mukerji (1968) and Batra (1973). The species causes cotton boll rot in various species of *Gossypium* and induces cankers on citrus fruits. *E. ashbyi* and *E. gossypii* are often used for the industrial production of riboflavin.

32.2. *Eremothecium coryli* (Peglion) Kurtzman (1995)

Synonyms:

Nematospira coryli Peglion (1897)

?*Nematospira lycopersici* Schneider (1917)

?*Nematospira phaseoli* Wingard (1922)

Nematospira nagpuri Dastur (Dastur & Singh 1930)

Growth in 5% malt extract: After 3 days at 25°C , the cells are ovoid, elongate, globose and generally polymorphic. They occur singly, in pairs, or in small chains. The relative proportions of cells of different shapes vary from strain to strain. The size of the ovoid and globose cells varies between $(1.7\text{--}13.9)\times(4.2\text{--}14.0)\mu\text{m}$. A butyrous sediment is present; some granular growth may occur.

Growth on 10% malt agar: After one month at 25°C , the streak culture is light cream colored, usually abundantly wrinkled but sometimes coarsely folded, glossy, pasty or membranous, slightly raised, and the border is fringed with mycelium.

Dalmau plate culture on corn meal agar: True hyphae with few septa are present. Arthroconidia are not formed. Pseudomycelium is usually abundant (Fig. 85). The blastoconidia are ovoid or cylindrical and form short chains in verticillated positions.

Fig. 85. *E. coryli*, CBS 2608. Ascus on V8 agar after 2 days at 20°C . Bar = $10\mu\text{m}$.

Formation of ascospores: Conjugation preceding ascospore formation is not apparent. Asci are long, curved cylindrical cells with rounded ends, or they are sometimes of irregular shape. Usually eight spores are formed per ascus (Fig. 85). Asci with two to four spores occasionally occur; rarely, 12 or 16 spores are present. Asci release the spores very soon after maturity. The spores are spindle-shaped with a long, thin, whip-like appendage at one end. SEM photomicrographs show that the surface of the spore-half carrying the appendage is smooth whereas that of the blunted half is ornamented with concentric ridges. This ornamentation is reversed from that in *E. sincaudum*. Examination under the light microscope reveals the presence of vacuoles and a difference of refringence between the two halves of the spores. Staining with the periodic-Schiff technique shows that the wall of the half to which the whip is attached takes a deep pink shade whereas the other half remains almost unstained. When stained with the Ziehl-Neelsen or the Schaeffer-Fulton malachite green technique, the half supporting the whip-like appendage is not acid fast and does not retain the malachite green; the other half is acid fast

and retains the malachite green (do Carmo-Sousa 1970a). Electron micrographs of longitudinal sections have shown that the spores lack a septum (Kreger-van Rij 1969a). The spores are usually grouped in two bundles of four within the ascus. The whip-free ends of the spore bundles are directed towards the poles of the ascus. Germination of the spores usually takes place near the equator of the spindle on the side of the whip-supporting half and gives rise either to buds or hyphae (Fig. 86).

Fig. 86. *E. coryli*, CBS 2608. Vegetative cells and germinating ascospore with a bud, after 3 days on 5% malt extract agar at 25°C. Bar = 10 µm.

Ascosporeulation was observed after 2–3 days on V8 agar at 20°C in five out of nine strains. Some strains also sporulated on malt agar and glucose–yeast extract–peptone agar.

Fermentation (30°C):

Co-Q: 5, CBS 2608, CBS 79 (Yamada et al. 1981); 6, CBS 2599, 2600, 2601, 2604; IGC 3027=UCD-FST 66-37; NRRL Y-1808=UCD-FST 68-11; IFO 0658 (Y. Yamada, personal communication).

Mol% G+C: 43.2, 43.4, IGC 3027 and CBS 2608, resp. (BD: H.J. Phaff, unpublished data).

Origin of the strains studied: CBS 2608=UCD-FST 66-36=IFO 1220, isolated by Peglion in 1897 from diseased hazelnuts in Italy; CBS 2599 from cotton bolls, Belgian Congo; CBS 2600 from cotton bolls, U.S.A.; CBS 2601 from tomatoes, British West Indies; CBS 2604, origin not known; CBS 79, from cotton bolls, India (type strain of *Nematospora nagpuri*); IGC 3027, from *Phaseolus vulgaris*, Uganda; NRRL Y-1808, from lima beans, U.S.A.; IFO 0658, from A.J. Kluyver, origin not known.

Type strain: CBS 2608 (IFO 1220) from diseased hazelnuts in Italy (Peglion 1897).

Comments: Strains of *E. coryli* grow rather poorly in YNB media but supplementation with 0.1% yeast extract (Difco) resulted in rapid and good growth with assimilable carbon sources and no significant growth in control tubes without a carbon source. Because of the high maximum temperature for growth of this species, the fermentation and assimilation tests were conducted at 30°C, which further improved the final test results. *E. sinecaudum* responded similarly to the growth-promoting activity of yeast extract in YNB media.

The question of synonymy for *Nematospora phaseoli* and *N. lycopersici* with *E. coryli* results from the lack of authentic strains of these two species. Batra (1973) recognized *N. lycopersici* as a species based on one strain isolated from tomatoes and two from beans. One of these (CMI No. 77-422 from *Phaseolus vulgaris* in Uganda) was included in our study. Since its characteristics did not differ from the other strains, we concluded, in agreement with do Carmo-Sousa (1970a), that it is conspecific with *E. coryli*. Batra reported positive nitrate reduction whereas we were unable to obtain growth of any of the strains when nitrate was used as the sole source of nitrogen in the medium.

The alternation between haplophase and diplophase in *E. coryli* is unresolved. Koopmans (1977) made a careful cytological study of *E. coryli* during vegetative growth and sporulation, but was unable to determine at which stage a cell is committed to become an ascus. She assumed that in some enlarged cells mitotic nuclei fused to form a diploid nucleus, which underwent meiosis to eight nuclei in a greatly enlarged ascus.

Fig. 87. *E. cymbalariae*, CBS 270.75. Terminal asci with inconspicuous basal septa; asymmetrically acicular ascospores. After 3 days on YM agar at 25°C.

E. coryli is parasitic on plants, causing a disease known as stigmatomycosis. The yeast has been found in many species of plants throughout subtropical and tropical areas of the world and is always associated with insect punctures of the plant tissue made by insects with piercing-sucking mouth parts. Frazer (1944) has made a detailed study of the infection of cotton bolls by the cotton stainer, *Dysdercus*. The spores of *E. coryli* appear to be harbored in the stylet pouches of *Dysdercus suturellus*.

32.3. *Eremothecium cymbalariae* Borzi (1888)

Growth on 4% malt extract/0.5% yeast extract agar:

After 10 days at 20–22°C, colonies are 20 mm in diameter, initially tan, but later may exude a yellow pigment into the medium. Colonies are dry and smooth, becoming floccose at the center, and develop a sharp, lobed margin. Budding cells are absent. Hyphae are 2–4 µm wide, fragile, and have few septa.

Growth on the surface of assimilation media: Pellicles are not formed.

Formation of ascospores: Asci are formed on hyphal tips, often without distinct basal septa, and are narrowly limoniform with a terminal elongation. They measure (12–14) × (30–65) µm, inclusive of the acuminate tip. Usually 8–16 ascospores are formed in each ascus and liberated at maturity (Fig. 87). They often adhere to

one another in rhomboid aggregations. Ascospores are hyaline, narrowly triangular and with needle-shaped ends, (2) × (13–16) µm, with the broadest part just below the apex. The ascospores develop in the ascus in two opposed groups with the needle-shaped tips toward the outside. The species appears homothallic.

Ascospores were observed on YM agar after 3 days at 20–25°C.

Fermentation: absent.

Assimilation (in yeast nitrogen base + 0.1% yeast extract):

Glucose	+	<i>N</i> -Acetyl-D-glucosamine	–
Galactose	w/–	Methanol	–
L-Sorbose	–	Ethanol	v

10% NaCl/5% glucose	–		

Co-Q: 7, CBS 270.75 (Yamada et al. 1987b).

Mol% G + C: Not determined.

Origin of the strain studied: CBS 270.75, from a plant-pathogenic insect, Iran, Ershad.

Type strain: CBS 270.75, designated here as the neotype.

Comments: No type specimen of *E. cymbalariae* is known to be preserved, consequently, CBS 270.75 is designated as the neotype. The species was reported as a pathogen of flax and other plants and was redescribed by Arnaud (1913) and Ashby and Nowell (1926). The near absence of septa in this fragile, purely hyphal fungus is remarkable. The physiological pattern of the strain was tested in yeast nitrogen base supplemented with 0.1% yeast extract to enhance growth reactions.

32.4. *Eremothecium gossypii* (Ashby & Nowell) Kurtzman (1995)

Synonyms:

Nematospira gossypii Ashby & Nowell (1926)

Ashbya gossypii (Ashby & Nowell) Guilliermond (1928)

Ashbia gossypii (Ashby & Nowell) Ciferri & Fragoso (Fragoso and Ciferri 1928)

Fig. 88. *E. gossypii*, CBS 117.28. Intercalary asci in various stages of maturation, and ascospores showing swelling of the germinating cell. After 1 week on YM agar, 25°C.

Growth on 4% malt extract/0.5% yeast extract agar:

After 10 days at 20–22°C, colonies are 20 mm in diameter, initially tan, but later exuding a yellow pigment into the medium. Colonies are smooth or finely floccose, moist, wrinkled at the center, and with a sharp, lobed margin. Hyphae (2–6 μm wide) branch dichotomously, and some cells contain yellow, needle-shaped crystals of riboflavin. Conidia, when present, are formed laterally on hyphae, either singly or in short chains, and are ellipsoidal, (2.5–3.0) × (4.5–7.0) μm.

Growth on the surface of assimilation media: Thin pellicles are formed by some strains.

Formation of ascospores: The asci, which are clavate to fusiform, (10–20) × (60–200) μm, are mostly intercalary and in long chains. They disarticulate at maturity and then release the ascospores. Asci contain 12–32 ascospores which are arranged in parallel packets (Fig. 88), and

are hyaline, and needle- or spindle-shaped; they usually become two-celled following formation of a median septum. The ascospores, which measure (2.0–3.5) × (25–35) μm, have a terminal, filiform appendage that may be as long as 100 μm. Appendages are slimy, causing the ascospores to unite in small groups. The species appears to be homothallic.

Ascospores were observed on YM agar after 1 week at 25°C.

Fermentation: absent.

Assimilation (in yeast nitrogen base + 0.1% yeast extract):

Glucose	+	<i>N</i> -Acetyl-D-glucosamine	–
Galactose	–	Methanol	–

Co-Q: 6, CBS 109.26, CBS 109.51 (Yamada et al. 1987b).

Mol% G + C: Not determined.

Origin of the strains studied: CBS 109.26, from fruit of *Asclepias* sp., Ashby, Trinidad; from cotton, South Africa (2), Trinidad (2); from unknown sources (5).

Authentic strain: CBS 109.26

Comments: Type material is not known to exist for *E. gossypii*, consequently, CBS 109.26 has been designated as an authentic strain. Pridham and Raper (1950) and Batra (1973) have provided extensive documentation of the distribution of *E. gossypii* and most other members of *Eremothecium*.

32.5. *Eremothecium sinecaudum* (Holley) Kurtzman (1995)

Synonyms:

Nematospira sinecauda Holley (Holley et al. 1984)

Holleya sinecauda (Holley) Yamada (1986b)

Growth on YM agar: After 3 days at 30°C, the cells are globose, ellipsoidal and cylindrical, and occur singly, in pairs, or in short chains. Pseudomycelium develops in older cultures. After 2 weeks the streak culture is

cream-colored, flat, semi-glossy with a lightly corrugated surface, a pasty texture, and a periphery that is entire or slightly wavy.

Growth in YM broth: After 10 days at 30°C, there is abundant sediment; a ring or pellicle is lacking. Cells are mainly cylindrical, but some are ovoidal to long ovoidal or globose or clavate, occasionally with a terminal swelling. Budding is polar (2–7) × (7–25) μm, with cells occasionally up to 30–50 μm long. Growth shows simple to extensively branched pseudomycelium.

Dalmáu plate culture on corn meal agar: After 9 days at 30°C, there is very dense and extensive pseudomycelium with elongate to short cylindrical blastoconidia formed aerobically as well as under the coverslip (Fig. 89).

Formation of ascospores: Asci arise directly from enlarged irregularly shaped vegetative cells which contain two bundles or fascicles of four ascospores each. The spores are acicular or needle-shaped and lie with their blunt ends at the ascus poles, each fascicle at opposite sides of the ascus (Fig. 90). The asci are approximately 8 × 20 μm and the ascospores 1.3–2.5 × 10 μm. Spores are released from the asci upon maturity. Individual spores have a smooth surface at the blunt end, a swollen equatorial plate collar and concentric ridges on the surface of the pointed half which terminates without an appendage (see Holley et al. 1984, Figs. 89, 90). Spores germinate by swelling of the half with the blunt end.

Sporulation occurs readily on YM or malt agar at 30°C after 3 days.

Fermentation:

Glucose	w/–	Lactose	–

Co-Q: 9 (minor, Q 8) (Yamada 1986b).

Mol% G + C: 41.8, UCD-FST 80-21 (BD: Phaff, unpublished data).

Origin of the strains studied: CBS 8199, 7233, and 7234 isolated by R.A. Holley from oriental (*Brassica juncea*) and yellow (*B. hirta*) mustard seed; UCD-FST 80-21 from mustard seed obtained from a commercial spice company, U.S.A.

Type strain: CBS 8199, isolated by Holley and Timbers (1983) from highly contaminated oriental mustard seed, *Brassica juncea*, in commercial storage.

Comments: Infection of mustard seed by a *Nematospora*-like yeast appears to be widespread (Hemmingway 1980). Holley and Timbers (1983) developed a microwave treatment to destroy contaminating yeasts inside the seed without affecting the flavor principle of mustard. Holley et al. (1984) isolated several strains of the contaminating yeast and described it as a new species of *Nematospora*,

N. sinecauda, based on the size and shape of the asci and spores and the absence of a whip-like appendage on the latter. Excellent electron micrographs of asci and spores accompanied the description. Yamada (1986b) restudied the strains that Holley had designated as *N. sinecauda*. On the basis of the presence of coenzyme Q-9 as the main ubiquinone in this species, in contrast to that of coenzyme Q-6 in most strains of *Nematospora coryli*, and the different size and morphology of their asci and ascospores, Yamada transferred *N. sinecauda* to a new genus, *Holleya*, as *H. sinecauda*. The transfer of *H. sinecauda* to *Eremothecium* is discussed under Comments on the genus.

Although Holley et al. (1984) reported the assimilation of carbon compounds in Difco yeast nitrogen base (YNB), we obtained very poor growth with this medium, especially on agar media in the presence of other yeasts. This is presumably due to the rapid drop in pH of this medium during growth and the reported sensitivity of *H. sinecauda* to pH values below 5.0. We supplemented liquid YNB with 0.1% yeast autolyzate and obtained excellent and rapid growth at 30°C with assimilable compounds, whereas controls without a carbon source gave a maximum response no greater than a weak reaction. Our results differ somewhat from those of Holley et al. (1984). Additionally, fermentation reactions differ among laboratories and this may reflect the nutrient composition of test media (Barnett et al. 1990, C.P. Kurtzman, unpublished data).

Comments on the genus

In the present treatment of *Eremothecium*, the genera *Ashbya*, *Holleya* and *Nematospora* have been placed into synonymy. The four genera are characterized by needle-shaped ascospores that may be linear or falcate. Ascospores of *Nematospora* differ further and are appended with a long flagellum-like terminal extension of cell wall material. The taxa are pathogenic to a variety of plant species (Batra 1973), and *Ashbya* and *Eremothecium* are used worldwide for production of riboflavin (vitamin B₂) (Kaplan and Demain 1970, Wickerham et al. 1946a).

Batra (1973) and von Arx et al. (1977) discussed the phenotypic similarities of *Ashbya*, *Eremothecium* and *Nematospora* and suggested that the three taxa might be congeneric. Another genus in this complex is *Spermophthora* Ashby & Nowell. There is no extant type material from *Spermophthora*, and strains of the taxon have not been isolated since its original description. Von Arx et al. (1977) suggested that *Spermophthora gossypii* Ashby & Nowell, the only known species of *Spermophthora*, represented a contaminated specimen of *Eremothecium* (*Crebrothecium* Routien) *ashbyi*. Additionally, classification of the foregoing taxa has been complicated by the perception (Lodder 1970) that genera which commonly form budding yeast cells (*Holleya*,

Nematospora) are phylogenetically separate from genera that do not ordinarily form budding cells (*Ashbya*, *Eremothecium*).

Holleya sinecauda was first described as *Nematospora sinecauda* (Holley et al. 1984). Yamada (1986b) transferred *N. sinecauda* to the new genus *Holleya* because, unlike *Nematospora coryli*, which has ascospores with long terminal appendages and coenzyme Q with either five or six isoprene units, *N. sinecauda* forms shorter ascospores without terminal appendages and produces coenzyme Q with a mixture of eight (minor component) and nine (major component) isoprene units. Yamada and Nagahama (1991) compared partial rRNA sequences from *H. sinecauda* and *N. coryli*, and suggested that the extent of divergence was great enough to justify maintaining *Holleya* and *Nematospora* as separate genera.

Phylogenetic analysis of rRNA/rDNA nucleotide sequence divergence in selected genera of ascomycetous yeasts and yeastlike fungi has indicated that the budding yeasts and yeastlike fungi represent a group of taxa that is separate from the filamentous ascomycetes (Barns et al. 1991, Berbee and Taylor 1993, Hendriks et al. 1992, Kurtzman 1993a,c, Walker 1985a). In an extension of these studies, Kurtzman and Robnett (1994a) compared partial sequences of large and small subunit rRNAs from the type species of all cultivatable genera of ascomycetous yeasts and yeastlike fungi. Results from this study demonstrated that all budding yeasts and yeastlike fungi are members of a clade separate from the filamentous ascomycetes. The analysis further demonstrated that *Ashbya*, *Eremothecium*, *Holleya* and *Nematospora* represent closely related members of a subclade that is phylogenetically separate from the subclade that includes the genus *Metschnikowia*, which is also characterized by needle-shaped ascospores.

Taken in the context of this larger data set, Kurtzman (1995) proposed the transfer of species of *Ashbya*, *Holleya* and *Nematospora* to *Eremothecium*, the genus of taxonomic priority, pointing out that the five species to be included in *Eremothecium* are members of a monophyletic lineage and that the species show relatively little interspecific divergence. At odds with this interpretation is the disparity in coenzyme Q values found among the species. Some genera show no differences in coenzyme Q contents, whereas other genera, and even some species, produce two forms, but none has the wide range seen among species of the *Ashbya/Eremothecium/Holleya/Nematospora* clade. However, because rRNA/rDNA comparisons have been reliable predictors of kinship among other groups of yeasts (Kurtzman 1992a, 1994), the sequence analysis was given precedence in defining the taxonomy of this group. Additionally, Messner et al. (1995) compared other rRNA gene sequences from *N. coryli*, *A. gossypii* and *E. ashbyi* and concluded that the three taxa are congeneric.

Species of *Eremothecium*, as noted earlier, grow poorly in yeast nitrogen base unless it is supplemented with

0.1% yeast extract. Even with this adjustment, some variability in assimilation reactions was found among the laboratories of the authors of this chapter. Furthermore, fermentation reactions have been variable between laboratories as well as between repeats in the same laboratory. Consequently, it seems more reliable to key species of *Eremothecium* on the basis of their morphological characters.

33. *Galactomyces* Redhead & Malloch

G.S. de Hoog, M.Th. Smith and E. Guého

Diagnosis of the genus

Colonies are white, farinose or hairy, and dry; hyphae are hyaline and disarticulate into rectangular arthroconidia. Septa have micropores.

Gametangia are formed laterally on profusely septate parts of hyphae on opposite sides of septa. Asci are subspherical, containing 1 ascospore which is liberated by disintegration of the entire ascus wall. Ascospores are round, pale brownish, with a rough outer wall layer and with an exosporium and an equatorial furrow.

Fermentation is weak or absent. Nitrate is not assimilated. Extracellular starch is not produced. Diazonium blue B reaction is negative.

Anamorph genus is *Geotrichum*.

Type species

Galactomyces geotrichum (E.E. Butler & L.J. Petersen) Redhead & Malloch

Species accepted

1. *Galactomyces citri-aurantii* E.E. Butler (1988)
2. *Galactomyces geotrichum* (E.E. Butler & L.J. Petersen) Redhead & Malloch (1977)
3. *Galactomyces reessii* (van der Walt) Redhead & Malloch (1977)

Key to species

See Table 24.

Morphological key:

1. a Ascospores echinulate, longest dimensions 7–10 µm *G. geotrichum*: p. 210
b Ascospores finely verrucose, longest dimensions 6–9 µm → 2
- 2(1). a Ascospores (5–6)×(6–7) µm; species homothallic *G. reessii*: p. 212
b Ascospores (5–7)×(7–9) µm; species heterothallic *G. citri-aurantii*: p. 209

Physiological key:

1. a Growth without vitamins *G. geotrichum*: p. 210
b Absence of growth without vitamins → 2
- 2(1). a Growth with ribitol or mannitol *G. citri-aurantii*: p. 209
b Absence of growth with ribitol or mannitol *G. reessii*: p. 212

Table 24
Key characters of species in the genus *Galactomyces*

Species	Fermentation of glucose	Assimilation			Growth in vitamin-free medium	Mating system
		Ribitol	Mannitol	Glucono-δ-lactone		
<i>Galactomyces citri-aurantii</i>	–	+	+	v	–	Heterothallic
<i>G. geotrichum</i>	v	v	v	v	+	Heterothallic
<i>G. reessii</i>	w/–	–	–	–	–	Homothallic

Systematic discussion of the species

33.1. *Galactomyces citri-aurantii* E.E. Butler (Butler et al. 1988)

Anamorph: *Geotrichum citri-aurantii* (Ferraris) E.E. Butler

Synonyms:

Oidium citri-aurantii Ferraris (1899)

Oospora citri-aurantii (Ferraris) Saccardo & Sydow (1902)

Geotrichum citri-aurantii (Ferraris) E.E. Butler (Butler et al. 1988)

Geotrichum candidum Link var. *citri-aurantii* (Ferraris) R. Ciferri &

F. Ciferri (Ciferri 1955a)

Growth on 4% malt extract/0.5% yeast extract

agar: After 10 days at 20–22°C, colonies are 70–80 mm in diameter, white, flat, dry, and powdery to finely hairy. Hyphae are 2.5–10.0 µm wide, with frequent dichotomous branching at the apex, with early disarticulation into cubic arthroconidia. Arthroconidia are hyaline and slightly inflating to (4–6)×(5–17) µm.

Formation of ascospores: Gametangia are formed in dense clusters laterally on fertile hyphae; gametangia are located on opposite sides of septa or on separate hyphae. Asci are subspherical, (7–12)×(6–9) µm, and contain

Fig. 91. *G. citri-aurantii*, CBS 175.89×176.89, PDA, 22°C, 2 weeks. Asci with mature ascospores.

one ascospore. Ascospores are broadly ellipsoidal, (5–7)×(7–9) µm, hyaline, with a smooth or verruculose inner wall and an irregular exosporium, often with a hyaline equatorial furrow and a central lipid droplet (Fig. 91). The species is heterothallic.

Fermentation: absent.

Assimilation:

Glucose	+	<i>N</i> -Acetyl-D-glucosamine	n
Galactose	+	Methanol	n
L-Sorbose	+	Ethanol	+
Sucrose	–	Glycerol	+
Maltose	–	Erythritol	–
Cellobiose	–	Ribitol	+
Trehalose	–	Galactitol	–
Lactose	–	D-Mannitol	+

Additional assimilation tests and other growth characteristics:

Arbutin – Growth at 37°C –

Co-Q: Not determined.

Mol% G+C: 37.9–39.2, 5 strains (T_m : Smith et al. 1995c).

Origin of the strains studied: CBS 175.89, from soil of an orange orchard, Zimbabwe, Butler; CBS 176.89, from soil of an orange orchard, California; from citrus (3); from soil (4).

Complementary mating types: Mating type *A1*: CBS 228.38, CBS 175.89, CBS 604.85, Butler 564B, Butler 594A; mating type *A2*: CBS 176.89, CBS 605.85, Butler 564C, Butler 594B.

Type strain: CBS 175.89×176.89, the tester strains of *Galactomyces citri-aurantii*.

Comments: The species was segregated from *Galactomyces geotrichum*/*Geotrichum candidum* for a taxon causing sour rot on citrus. Smith et al. (1995c) confirmed this conclusion by obtaining low DNA/DNA homology values for the species with both *Galactomyces geotrichum* and *G. reessii*.

33.2. *Galactomyces geotrichum* (E.E. Butler & L.J. Petersen) Redhead & Malloch (1977)

Anamorph: *Geotrichum candidum* Link:Fries

Synonyms:

Endomyces lactis Windisch (1951)

Geotrichum novakii El-Masry & Zsolt (1968)

Geotrichum pseudocandidum Saëz (1968b)

Growth on 4% malt extract/0.5% yeast extract agar:

After 10 days at 20–22°C, colonies are 50–80 mm in diameter, white, flat, dry, and powdery to finely hairy. Odor is insignificant or fruity. Expanding hyphae are parallel, often with dichotomous branching; the main branches are 7–12 µm wide, with firm walls, and lateral branches are 2.5–4.0 µm wide, with early disarticulation into cubic arthroconidia. Arthroconidia are hyaline and slightly inflating to (5–6) × (5–17) µm.

Formation of ascospores: Gametangia are formed laterally on densely septate parts of fertile hyphae which arise after mating; gametangia are located on opposite sides of the septa. Asci are subspherical, (7–10) × (6–9) µm, and contain one ascospore. Ascospores are broadly ellipsoidal, (6–9) × (7–10) µm, pale golden-brown, with an echinulate inner wall and an irregular exosporium, often

with a hyaline equatorial furrow (Fig. 92). The species is heterothallic.

Mol% G+C: 42.9–45.2, 11 strains (T_m : de Hoog et al. 1986); 40.7–42.3, 4 strains (BD: Guého et al. 1985).

Origin of the strains studied: CBS 110.12, probably authentic for *Oidium humi*; CBS 122.22, authentic for *Oospora fragrans* var. *minuta*, from banana, Berkhout; CBS 114.23, authentic for *Oidium nubilum*, Berkhout; CBS 116.23, authentic for *Oospora lactis* var. *parasitica*, from rotten tomato, Pritchard and Porte, Maryland; CBS 149.26, authentic for *Oidium asteroides*, Castellani; CBS 178.30, type strain of *Oospora lactis* var. *exuberans*, from *Populus* sap, Stautz; CBS 180.33, authentic for *Geotrichum matalense* var. *chapmanii*; CBS 182.33, type strain of *Geotrichum javanense*, from yoghurt, Verona; CBS 193.34, type strain of *Geotrichum versiforme*, Moore; CBS 195.35, authentic for *Geotrichum matalense*, Castellani; CBS 178.53, type strain of *Endomyces lactis*, Windisch; CBS 772.71 (ATCC 22600), from soil, Puerto Rico, Butler; CBS 557.83, type strain of *Geotrichum novakii*, from prune, Egypt, Zsolt; CBS 626.83, type strain of *Geotrichum pseudocandidum*, from stomach of elk, Paris, Saëz; CBS 279.84, type strain of *Geotrichum redaellii*, Saëz; additional strains isolated from milk (1), *Hyacinthus* bulb (1), tomato (1), human nail (1), light oil (2), human tongue (1), grain (1), cheese (2), soil (2), paper pulp (1), red beet (1) and insect (1).

Complementary mating types: Mating type α : CBS 357.86, CBS 774.71 (tester strain), CBS 557.83, CBS 606.85. Mating type α : CBS 267.79, CBS 180.33, CBS 775.71 (tester strain), CBS 626.83, CBS 607.85.

Fig. 92. *G. geotrichum*, CBS 772.71, MEYA, 22°C, 2 weeks. Hyphal tips with di- and trichotomous branching. Mature main branches and disarticulating lateral branches from various cultures; asci with ascospores.

Type strain: CBS 772.71, type strain of *Galactomyces geotrichum* and neotype strain of *Geotrichum candidum*.

Comments: *Galactomyces geotrichum*, better known under the anamorph name *Geotrichum candidum*, is common in all kinds of moist substrates, particularly in citrus fruits and tomatoes, and mainly as a rotter of ripe fruits. The species may occur in a relatively early stage of fruit development and hence it has been presumed to be a weak pathogen. In other nutrient-rich substrates it unambiguously occurs as a saprophyte, e.g., in liquid pig's fodder and in lipid-containing materials such as milk and cheese. Thirdly, *G. geotrichum* is occasionally associated with human pulmonaceous disease. Probably deep, saprophytic colonization is of concern rather than pathogenicity.

The species is reported to be heterothallic. Crossed strains are fertilized and subsequently fertile hyphae develop which locally become profusely septate with cells often wider than long. On both sides of the septa gametangia develop which fuse and give rise to subglobose asci.

De Hoog et al. (1986) and Smith et al. (1995c), using DNA/DNA reassociation techniques found several groups within the species separated by low or intermediate relatedness. The two tester strains showed intermediate reassociation with remaining groups, which are therefore interpreted as varieties.

Geotrichum candidum is morphologically recognized by its rapid expansion growth, very wide main branches and often dichotomously branched ends of expanding hyphae; in contrast to the anamorphs of *Galactomyces reessii* and *G. citri-aurantii*, it is able to grow on media without vitamins.

33.3. *Galactomyces reessii* (van der Walt) Redhead & Malloch (1977)

Synonyms:

Endomyces reessii van der Walt (1959c)

Dipodascus reessii (van der Walt) von Arx (1977a)

Growth on 4% malt extract/0.5% yeast extract agar: After 10 days at 20–22°C, colonies are 65 mm in diameter, flat, white, dry and cottony. Expanding hyphae are submerged, and without dichotomous branching. Main branches are 6–9 µm wide, with lateral branches 4–6 µm wide, which soon disarticulate into rectangular arthroconidia (3.5–4.5) × (6–15) µm.

Formation of ascospores: Hyphae with local, profuse septation develop gametangia on opposite sides of septa. Asci are subspherical, (7–10) × (6–8) µm, and contain one ascospore. Ascospores are broadly ellipsoidal, (5–6) × (6–7) µm, pale golden-brown, finely warted, with irregular, locally inflated exosporium, and often with a hyaline median furrow (Fig. 93). The species is homothallic.

Origin of the strains studied: CBS 179.60, from water-rotted *Hibiscus*; from fodder (2).

Type strain: CBS 179.60.

Comments: The species is close to *Galactomyces geotrichum* but differentiated by having a smaller micromorphology; the hyphae are less than 9 µm wide and are without dichotomous branching. *G. geotrichum* mostly shows weak fermentation of glucose, and usually growth with D-mannitol, D-glucono-δ-lactone and on media without vitamins. The two species are clearly different in their nuclear DNA G+C content.

Comments on the genus

Kurtzman and Robnett (1995) demonstrated from comparisons of nucleotide sequence divergence in the 5' end of large subunit rDNA that *Galactomyces* appears congeneric with *Dipodascus*.

34. *Hanseniaspora* Zikes

M.Th. Smith

Diagnosis of the genus

Asexual reproduction is by bipolar budding in basipetal succession on a narrow base. Cells are apiculate, ovoidal to long-ovoidal or elongate. Pseudohyphae are absent or present, usually rudimentary and rarely well-developed. Vegetative cells are diploid.

Asci arise without conjugation. Ascospores are 1–4 per ascus, hat- or helmet-shaped, or spheroidal with warts only, or smooth or warty with an equatorial ledge. Asci are persistent or deliquescent.

Glucose is fermented. Nitrate is not assimilated. Inositol and pantothenate are required for growth. Acetic acid is not produced. Diazonium blue B reaction is negative.

Type species

Hanseniaspora valbyensis Klöcker

Species accepted

1. *Hanseniaspora guilliermondii* Pijper (1928)
2. *Hanseniaspora occidentalis* M.Th. Smith (1974)
3. *Hanseniaspora osmophila* (Niehaus) Phaff, M.W. Miller & Shifrine ex M.Th. Smith (1984)
4. *Hanseniaspora uvarum* (Niehaus) Shehata, Mrak & Phaff ex M.Th. Smith (1984)
5. *Hanseniaspora valbyensis* Klöcker (1912)
6. *Hanseniaspora vineae* van der Walt & Tscheuschner (1957)

Key to species

See Table 25. A key to all described species based entirely on physiological reactions is given under the genus *Kloeckera*.

1. a Ascospores hat-shaped → 2
b Ascospores spheroidal → 3
- 2(1). a Growth at 37°C *H. guilliermondii*: p. 215
b Absence of growth at 37°C *H. valbyensis*: p. 218
- 3(1). a Maltose assimilated → 4
b Maltose not assimilated → 5
- 4(3). a Growth at 34°C *H. vineae*: p. 219
b Absence of growth at 34°C *H. osmophila*: p. 216
- 5(3). a Sucrose assimilated *H. occidentalis*: p. 215
b Sucrose not assimilated *H. uvarum*: p. 217

Table 25
Key characters of species in the genus *Hanseniaspora*

Species	Assimilation		Growth		Ascospores	
	Sucrose	Maltose	at 34°C	at 37°C	Shape	Number ^a
<i>Hanseniaspora valbyensis</i>	–	–	–	–	hat	1–4(2)
<i>H. guilliermondii</i>	–	–	+	+	hat	1–4(4)
<i>H. uvarum</i>	–	–	n	–	spherical, warty + equatorial ledge	1–2
<i>H. occidentalis</i>	+	–	n	–	spherical, smooth + equatorial ledge	1–2
<i>H. osmophila</i>	v	+	–	–	spherical, warty	1–2
<i>H. vineae</i>	v	+	+	–	spherical, warty	1–2

^a The numbers in parentheses refer to the number of spores per ascus most frequently observed.

Systematic discussion of the species

34.1. *Hanseniaspora guilliermondii* Pijper (1928)

Anamorph: *Kloeckera apis* Lavie ex M.Th. Smith, Simone & S.A. Meyer

Synonyms:

Hanseniaspora melligeri Lodder (1932)

Hanseniaspora apuliensis Castelli (1948)

Kloeckera apiculata (Reess) Janke var. *apis* Lavie (1954)

Kloeckera apis Lavie ex M.Th. Smith, Simone & S.A. Meyer (1977)

Growth in glucose–yeast extract–peptone water:

After 2 days at 25°C, the cells are apiculate, ovoidal or elongate, (2.2–5.8)×(4.5–10.2)µm, or occasionally longer, and single or in pairs. Reproduction is by bipolar budding. A sediment is present. After one month a thin ring is formed.

Growth on glucose–yeast extract–peptone agar:

After one month at 25°C, the streak culture is white to cream-colored, smooth, glossy, and slightly raised at the center.

Dalmou plate cultures on potato agar: Pseudomycelium is rudimentary or absent.

Formation of ascospores: One to four, mostly four, hat-to helmet-shaped ascospores, which are normally released at maturity from the ascus (Fig. 94), often aggregate after liberation.

Abundant sporulation is usually observed on 5% Difco malt extract agar and on potato dextrose agar at low temperature (15°C) after 7 or more days.

Co-Q: 6 (Yamada et al. 1976a, Billon-Grand 1987).

Mol% G + C: 32.9–34.2, 11 strains, including CBS 95, CBS 465, CBS

Fig. 94. *H. guilliermondii*. Asci with ascospores on 5% malt extract agar after 7 days at 25°C. Bar = 10 µm (from H.J. Phaff 1970a).

466, CBS 1972, CBS 2574, CBS 2591, CBS 5060 (T_m : Meyer et al. 1978).

Origin of the strains studied: CBS 465, diseased nail, Pijper; CBS 95, fermenting bottled tomatoes, van Rhee; CBS 466, dates, Chodat, type strain of *H. melligeri*; CBS 1972, grape juice, Castelli, authentic strain of *H. apuliensis*; CBS 2567, grape must, Capriotti; CBS 2574, grape juice, Capriotti; CBS 2591, bee trachea, Chauvin, type strain of *Kloeckera apis*; CBS 4378, caecum of baboon, do Carmo-Sousa; CBS 5060, culture contaminant, Phaff; CBS 6619, CBS 6707, unknown, Nakase.

Type strain: CBS 465 (ATCC 10630, NRRL Y-1625), isolated by Pijper.

Comments: The species *H. apuliensis*, *H. guilliermondii* and *H. melligeri*, which were placed in synonymy with and maintained as synonyms of *H. valbyensis* by Lodder and Kreger-van Rij (1952) and Phaff (1970a), respectively, were separated from *H. valbyensis* by Meyer et al. (1978) on the basis of low DNA homology. A high degree of reassociation was revealed between *H. apuliensis*, *H. guilliermondii*, *H. melligeri* and *Kloeckera apis*.

34.2. *Hanseniaspora occidentalis* M.Th. Smith (1974)

Anamorph: *Kloeckera javanica* (Klöcker) Janke

Synonyms:

Pseudosaccharomyces antillarum Klöcker (1912b)

Kloeckera antillarum (Klöcker) Janke (1928)

Hanseniaspora antillarum Kudryavtsev (1960)

Pseudosaccharomyces willi Klöcker (1912b)

Kloeckera willi (Klöcker) Janke (1928)

?*Kloeckera cacaoicola* Ciferri (1931b)

Growth in glucose–yeast extract–peptone water:

After 2 days at 25°C, the cells are lemon-shaped, ovoidal or sometimes spheroidal, (1.8–6.2) × (3.0–11.0) µm, and single or in pairs. Sediment is formed. After one month a very thin ring is present.

Growth on glucose–yeast extract–peptone agar:

After one month at 25°C, the streak culture is white to cream-colored, smooth, glossy, and with a raised center and a flat periphery.

Dalmou plate culture on potato agar: Pseudomycelium is generally lacking, but some strains produce a rudimentary or well-developed pseudomycelium.

Formation of ascospores: One or two ascospores are formed per ascus and are spheroidal and smooth with an equatorial ledge. Ascospores are not released from the ascus.

Sporulation occurs on 5% Difco malt extract agar at 25°C after 7 or more days.

34.6. *Hanseniaspora vineae* van der Walt & Tscheuschner (1957b)

Anamorph: *Kloeckera africana* (Klöcker) Janke

Synonyms:

Pseudosaccharomyces africanus Klöcker (1912b)

Kloeckera africana (Klöcker) Janke (1928)

Vanderwaltia vineae (van der Walt & Tscheuschner) Novák & Zsolt (1961)

Hanseniaspora nodinigris Lachance (1981)

Kloeckeraspora vineae (van der Walt & Tscheuschner) Y. Yamada, Maeda & Banno (1992e)

Growth in glucose–yeast extract–peptone water:

After 2 days at 25°C, the cells are apiculate, spheroidal to ovoidal or elongate, (2.0–7.5) × (4.0–14.5) μm, and mostly single or sometimes in pairs. Sediment is formed. After one month a very thin ring may be present.

Growth on glucose–yeast extract–peptone agar:

After one month at 25°C, the streak culture is white to cream-colored, smooth and glossy; the center is raised, and the periphery is flat.

Dalmu plate cultures on potato agar: A pseudomycelium is formed, that may be rudimentary or well-developed with or without clusters of blastospores.

Formation of ascospores: One to two spheroidal, warty ascospores are produced per ascus (Fig. 98). Ascospores are not released from the ascus.

Sporulation was observed on 5% Difco malt extract agar and YM agar after 7 days or more at 25°C.

Fermentation:

Glucose	+	Lactose	–

Co-Q: 6 (Yamada et al. 1976a, Billon-Grand 1987).

Mol% G + C: 38.8–40.7, 9 strains, including CBS 277, CBS 2171, CBS 6555 (T_m : Meyer et al. 1978); 39.6, CBS 8031 (T_m : Smith and Poot 1985).

Origin of the strain studied: CBS 2171 (ATCC 58436), vinyard soil, van der Walt; CBS 277 (ATCC 24232) soil, Klöcker, type strain of *Pseudosaccharomyces africanus*; CBS 2568, *Drosophila persimilis*, Phaff; CBS 2827, soil, Capriotti; CBS 5068, unknown, Verona; CBS 6555 (ATCC 20109), unknown, Takeda Chem. Ind.; CBS 6706, unknown, Nakase; CBS 8031 (ATCC 46412), black knot gall *Dibotryon morbosum* on *Prunus virginiana*, Lachance, type strain of *H. nodinigris*; ATCC 10632, sour *Calimyrma* fig; ATCC 16512, unknown, Kyowa Ferm. Ind. Co., Ltd.

Type strain: CBS 2171, isolated by van der Walt, South Africa.

Comments: *Hanseniaspora vineae* was placed in synonymy with *H. osmophila* by Miller and Phaff (1958) and maintained as a synonym by Phaff (1970a). However, Meyer et al. (1978) separated the two species since the average DNA reassociation value was 48%. In view of more recent interpretations of DNA relatedness (Kurtzman and Phaff 1987), these values would suggest these two taxa to be sibling species or possible varieties of the same species. The conspecificity of *H. nodinigris* and *H. vineae* was shown by DNA homology studies (Smith and Poot 1985).

Comments on the genus

Miller and Phaff (1958) published a detailed study of the history, nomenclature, physiology, morphology and life cycle of all *Hanseniaspora* species. Antigenic analyses of some *Kloeckera* and *Hanseniaspora* species were carried out by Tsuchiya et al. (1966) and Tsuchiya and Imai (1968). In the former study, 3 serological groups were found, viz. *K. javanica*, *K. africana* and *K. apiculata*, and the relationship of *K. apiculata* with *H. valbyensis*

was recognized. In addition, *K. javanica* appeared to be a hybrid species of *K. apiculata* and *K. africana*. In the latter study, the authors concluded that (1) *K. apiculata* was the anamorph of *H. uwarum* and *H. guilliermondii*; and (2) *K. africana* was the anamorph of *H. osmophila* and *H. vineae*.

A comparative study on the ultrastructure of the different types of ascospores in *Hanseniaspora* species was performed by Kreger-van Rij and Ahearn (1968) and by Kreger-van Rij (1977b). These studies showed the presence of three types of ascospores: (a) hat-shaped in *H. guilliermondii* and *H. valbyensis*; (b) spheroidal with an equatorial or sub-equatorial ledge, and smooth or warty in *H. occidentalis* and *H. uwarum*; (c) spheroidal with warts in *H. osmophila* and *H. vineae*. Spencer and Gorin (1968) carried out PMR spectrometric studies of mannans isolated from species of the genera *Hanseniaspora* and *Kloeckera*. Yamada et al. (1976a) studied the coenzyme Q systems in apiculate yeast genera, namely *Hanseniaspora*, *Kloeckera*, *Nadsonia*, *Saccharomyces* and *Wickerhamia*. The Co Q-6 system was found in all species analyzed except for *Wickerhamia*, which had a Co Q-9 system. The authors discussed their results in relation to other criteria, such as PMR spectra of cell wall polysaccharides, DNA base composition and serological characteristics. Billon-Grand (1987) investigated the occurrence of minor components of coenzyme Q systems in *Hanseniaspora* and *Kloeckera*. In addition to the major component Co Q-6, this author found Co Q-7 as a minor component in *H. uwarum*, *H. valbyensis* and *H. nodinigri*. Fiol and Billon-Grand (1978a) examined the production of intracellular oxidases, nitrite and nitrate reductases in some species of *Hanseniaspora* and *Kloeckera* and discussed the taxonomic relationships between the two genera.

The significance of DNA base composition in the classification of *Hanseniaspora* was studied by Nakase and Komagata (1970a) and Meyer et al. (1978). The latter authors established the status of various *Hanseniaspora* species by DNA-DNA reassociation experiments and correlated *Hanseniaspora* teleomorphs with *Kloeckera* anamorphs. Yamada et al. (1992c) estimated the phylogenetic relationships of the teleomorphic apiculate yeast genera *Hanseniaspora*, *Nadsonia* and *Saccharomyces* on the basis of partial rRNA sequences. Their data demonstrated the three genera to be distinct from each other. However, the six species of the genus *Hanseniaspora* were divided into two clusters, one cluster consisted of *H. guilliermondii*, *H. uwarum* and *H. valbyensis*, the second cluster consisted of *H. occidentalis*, *H. osmophila* and *H. vineae*. Yamada et al. (1992c) considered the two clusters as genera and reinstated the genus *Kloeckeraspora* to accommodate the latter three species, which are characterized by spheroidal, warty ascospores. This genus, introduced by Niehaus (1932) to accommodate apiculate species producing spheroidal ascospores, was considered a synonym of *Hanseniaspora* by various authors (Lodder and Kreger-van Rij 1952, Phaff 1970a, Meyer et al. 1978, Smith 1984).

A second phylogenetic study on *Hanseniaspora* and possible related genera (Boekhout et al. 1994) based on partial 26S rDNA nucleotide sequences, demonstrated that the genus *Hanseniaspora* is monophyletic and could be divided into the same subgroups as in the study of Yamada et al. (1992c,e). However, Boekhout et al. argued for maintenance of all species in *Hanseniaspora* on the basis of both the heterogeneous distribution of phenetic properties among species of this genus as well as the low statistical support in the 26S rDNA tree for separation of the two subgroups.

35. *Issatchenkia* Kudryavtsev emend. Kurtzman, Smiley & Johnson

C.P. Kurtzman

Diagnosis of the genus

Asexual reproduction is by multilateral budding on a narrow base. Cells are spheroidal, ellipsoidal or elongate, and pseudohyphae are present.

Asci are unconjugated when formed from diploid cells or may be conjugated if formed by the pairing of complementary mating types. Asci are persistent and form 1–4 roughened spheroidal ascospores. The protuberances causing ascospore roughness may not be visible under the light microscope.

Glucose is fermented. Nitrate is not assimilated. Early formation of pellicles on liquid media. Diazonium blue B reaction is negative.

Type species

Issatchenkia orientalis Kudryavtsev

Species accepted

1. *Issatchenkia occidentalis* Kurtzman, Smiley & Johnson (1980)
2. *Issatchenkia orientalis* Kudryavtsev (1960)
3. *Issatchenkia scutulata* (Phaff, M.W. Miller & Miranda) Kurtzman, Smiley & Johnson (1980)
 - a. *Issatchenkia scutulata* (Phaff, M.W. Miller & Miranda) Kurtzman, Smiley & Johnson var. *scutulata* (1980)
 - b. *Issatchenkia scutulata* var. *exigua* (Phaff, M.W. Miller & Miranda) Kurtzman, Smiley & Johnson (1980)
4. *Issatchenkia terricola* (van der Walt) Kurtzman, Smiley & Johnson (1980)

Systematic discussion of the species

35.1. *Issatchenkia occidentalis* Kurtzman, Smiley & Johnson (1980b)

Anamorph: *Candida sorbosa* Hedrick & Burke ex van Uden & H.R. Buckley

Synonyms:

Candida sorbosa Hedrick & Burke (1951) nom. nud.

Candida sorbosa Hedrick & Burke ex van Uden & H.R. Buckley (1970)

Candida soli Okuma & S. Goto (Goto et al. 1987b)

Growth on 5% malt extract agar: After 3 days at 25°C, the cells are ovoidal to elongate, (2.2–4.3)×(3.2–9.3) μm, and single or in pairs. Growth is butyrous and light cream colored.

Growth on the surface of assimilation media: Dry climbing pellicles are formed.

Dalmau plate culture on morphology agar: After 7 days at 25°C, growth under the coverglass shows abundant and moderately well-branched pseudohyphae. Aerobic

growth is white to tannish-white, dull, butyrous, striated, and slightly raised with a flattened center. The margin is smooth, finely serrate, or with small lobes. Colonies are fringed with pseudohyphae. A faintly acidic odor is present.

Formation of ascospores: Asci are unconjugated, persistent, and form one or two roughened ascospores (Fig. 99). Electron microscopy may be required to discern the protuberances on spore walls (Kurtzman and Smiley 1974, Kurtzman et al. 1980b). Isolation of single spores demonstrated this species to be heterothallic (Kurtzman and Smiley 1976). Following conjugation of complementary mating types, zygotes usually give rise to a succession of diploid cells that sporulate; consequently, conjugated asci are rarely, if ever, observed.

Ascospores were observed on autoclaved cucumber and carrot wedges after 3–6 weeks at 25°C. Sporulation is usually sparse.

Co-Q: 7 (CBS 5459, Y. Yamada, personal communication).

Mol% G+C: 40.9–41.1, two strains, CBS 5459, CBS 1910 (BD: Kurtzman et al. 1980b).

Origin of the strains studied: NRRL Y-7552 (CBS 5459), spoiled figs?, Phaff, U.S.A., originally identified as a citrate-negative strain of *Pichia kudriavzevii* (Kreger-van Rij 1970c); NRRL Y-7767 (CBS 1910), type strain

Fig. 99. *I. occidentalis*, CBS 5459. Unconjugated ascus with ascospores, after 1 month on an autoclaved cucumber wedge at 25°C. Bar = 5 μ m.

of *Candida sorbosa* from feces of a fly (*Drosophila crucigera*), Hedrick, Hawaii, U.S.A.; NRRL Y-7768 (CBS 2107), ‘tea fungus’, Boedijn, Indonesia.

Complementary mating types: NRRL Y-7552-61 (CBS 6887) and NRRL Y-7552-62 (CBS 6888), both single-ascospore isolates from the type strain.

Type strain: CBS 5459 (NRRL Y-7552), a diploid strain received from Phaff, U.S.A.

Comments: *I. occidentalis* was initially classified as a strain of *I. orientalis*, but Kreger-van Rij (1970c) noted that this strain (CBS 5459) differed from the others in being sorbose-positive and citrate-negative. Kurtzman and Smiley (1976) demonstrated this strain to be heterothallic and that one of the mating types conjugated with the type strain of *Candida sorbosa* and formed ascospores. The other strains of *I. orientalis* and several strains of *Candida krusei* also conjugated with one of the mating types, but the frequency was quite low and no ascospores formed.

DNA reassociation studies by Kurtzman et al. (1980b) showed *I. occidentalis* and *C. sorbosa* to have 98% base sequence complementarity, thus confirming the teleomorph–anamorph relationship demonstrated by mating tests. The extent of DNA reassociation among strains of *I. orientalis* and *C. krusei* was 93–100%, but when DNA from these strains was compared with that from *I. occidentalis*, only 8% common sequences were detected. Consequently, evidence from both mating tests and DNA studies shows the presence of two taxa, but a close relationship is suggested. The heterothallic diploid type strain of *I. occidentalis* was shown to be heterozygous for L-sorbose assimilation; therefore, this compound is of questionable utility for separating *I. occidentalis* from *I. orientalis*.

35.2. *Issatchenkia orientalis* Kudryavtsev (1960)

Anamorph: *Candida krusei* (Castellani) Berkhout

Synonyms:

Saccharomyces krusei Castellani (1910?)

Endomyces krusei Castellani (1912b)

Monilia krusei (Castellani) Castellani & Chalmers (1913)

Procandida tamarindii (Lewis & Johar) Novák & Zsolt (1961)
Candida lobata Batista & Silveira (1959c)
Endoblastomyces thermophilus Odincova ex Kudryavtsev (1960)
Candida requinyii Szép & Novák (1963)
Candida soosii Novák (1964)
Pichia orientalis (Kudryavtsev) Kreger-van Rij (1964b) [non *Saccharomyces orientalis* Beijerinck (1898a) nec *Pichia orientalis* (Beijerinck) Guilliermond (1912)]
Pichia kudriavzevii Boidin, Pignat & Besson (1965b)
Candida acidothermophilum Masuda, Kato, Takayama, Kida & Nakanishi (1975)
Candida brassicae Amano, S. Goto & Kagami (1975)
Candida ethanothermophilum Masuda, Kato, Takayama, Kida & Nakanishi (1975)
 ?*Candida melinii* Diddens & Lodder var. *melobiosica* Nowakowska-Waszczyk & Pietka (1983)
Candida hinoensis Iwasaki & S. Goto (Goto et al. 1987b)
Candida solicola Endo, Okuma & S. Goto (Goto et al. 1987b)

Growth on 5% malt extract agar: After 3 days at 25°C, the cells are ovoidal to elongate, (1.3–6.0) × (3.3–14.0) µm, and single or in pairs. Growth is butyrous and light cream colored.

Growth on the surface of assimilation media: Heavy, dry climbing pellicles are formed.

Dalmau plate culture on morphology agar: After 7 days at 25°C, growth under the coverglass shows abundant and moderately branched pseudohyphae. Aerobic growth is tannish-white, dull to occasionally almost powdery, butyrous, low convex with a flattened center, margin varying from smooth to lobed, and fringed with pseudohyphae. Some cultures have a faintly acidic odor.

Formation of ascospores: Ascospores were not observed in the present study. Kudryavtsev (1960) reported the spores to be spheroidal, smooth under the light microscope, and one per ascus. Asci were persistent. Two of the three strains observed by Kreger-van Rij (1970c)

had occasional asci with one to two spheroidal ascospores, but the infrequency of spores prevented their observation under the electron microscope.

Fermentation:

Glucose	+	Lactose	–
Galactose	–	Raffinose	–

5-Keto-D-gluconate	–	Gelatin liquefaction	w/–
Saccharate	–	Growth at 37°C	+
10% NaCl/5% glucose	+	Growth at 40°C	+

Co-Q: 7 (Yamada et al. 1973a).

Mol% G + C: 39.7–40.3, CBS 5147, CBS 573 and four other strains (BD: Kurtzman et al. 1980b).

Origin of the strains studied: Isolates originally reported to form ascospores: CBS 5147, fruit juice or berries, Kudryavtsev, Russia; CBS 2911, tea beer, Netherlands; CBS 5590, unknown, Suomalainen, Finland. Isolates received as *Candida krusei*: bronchomycosis (1); vaginitis (1); human feces (1); human urine (1); mastitic cow (2); animal feces (4); fruit flies (*Drosophila* spp.) (5); ginger beer (1); apple cider (1); stored rice (1); stored corn (2); bread (1); fermented foods (3); dairy products (3); industrial fermentation (1); yeast cake (1); tree exudates (2); seawater (1); unknown (15).

Type strain: CBS 5147 (NRRL Y-5396), received from Kudryavtsev, Russia.

Comments: *Candida krusei* is considered to represent the anamorphic form of *I. orientalis* because the type strains, as well as other isolates of both species, showed significant (93–100%) DNA base sequence complementarity (Kurtzman et al. 1980b). *C. requinyii* also showed significant base sequence relatedness with *C. krusei* and *I. orientalis* but not with *I. occidentalis*. The relationship between *I. orientalis* and *I. occidentalis* is discussed in the section on the latter species.

I. orientalis and its anamorph *C. krusei* are isolated

from a wide variety of habitats including humans and animals. Hurley et al. (1987) summarized clinical evidence supporting the concept that *C. krusei* should be considered pathogenic rather than a transient saprophyte.

35.3. *Issatchenkia scutulata* (Phaff, M.W. Miller & Miranda) Kurtzman, Smiley & Johnson (1980b)

This species has two varieties:

***Issatchenkia scutulata* (Phaff, M.W. Miller & Miranda) Kurtzman, Smiley & Johnson var. *scutulata* (1980)**

Synonym:

Pichia scutulata Phaff, M.W. Miller & Miranda var. *scutulata* (1976)

***Issatchenkia scutulata* var. *exigua* (Phaff, M.W. Miller & Miranda) Kurtzman, Smiley & Johnson (1980)**

Synonym:

Pichia scutulata var. *exigua* Phaff, M.W. Miller & Miranda (1976)

Growth on 5% malt extract agar: After 3 days at 25°C, the cells are ovoidal to elongate, (2.9–5.5) × (3.5–10.0) µm, and single or in short chains. Growth is butyrous and tannish-white in color.

Growth on the surface of assimilation media: Moderate to heavy, dry climbing pellicles are formed.

Dalmay plate culture on morphology agar: After 7 days at 25°C, growth under the coverglass is composed of moderately branched pseudohyphae. Aerobic growth is tannish-white, butyrous, low convex with a depressed center, and with a finely lobed margin. There is a faintly acidic odor.

Formation of ascospores: Asci are persistent, unconjugated and usually form four (one to four) spheroidal, roughened spores in diamond-shaped tetrads (Fig. 100). The species is heterothallic and four-spored asci give two spores of each mating type. Asci arising from a mixture of complementary mating types are generally unconjugated because of proliferation of diplophase cells before sporulation. Ascospore roughness is visible only under the electron microscope and results from small pro-

tuberances originating in the inner spore wall (Kurtzman et al. 1980b).

Ascospores were observed for both varieties on YM- and 5% Difco malt extract agar after 1–2 weeks at 25°C.

Fermentation:

Glucose	+	Lactose	–
Galactose	–	Raffinose	–
Sucrose	–	Trehalose	–
Maltose	–

Additional assimilation tests and other growth characteristics:

2-Keto-D-gluconate	–	Starch formation	–
5-Keto-D-gluconate	–	Gelatin liquefaction	–
Saccharate	–	Growth at 37°C	–
10% NaCl/5% glucose	+		

Co-Q: 7 (Y. Yamada, personal communication).

Mol% G+C: 32.6–33.0, three strains of the variety *scutulata*; 32.4–32.6, three strains of the variety *exigua* (BD: Phaff et al. 1976).

Supplementary description of *I. scutulata* var. *exigua*:

The variety *exigua* does not assimilate glycerol or grow in osmotic medium (10% NaCl/5% glucose) but does assimilate *N*-acetyl-D-glucosamine, and these differences allow it to be separated from the variety *scutulata* using standard growth tests. Furthermore, glucose fermentation is slow or weak. Morphologically, the varieties are similar. Asci of the variety *exigua* are frequently diamond-shaped, but a linear arrangement of ascospores is not uncommon. Ascospore ultrastructure is similar to that of the variety *scutulata* except that the protuberances seem to arise from the outer layer of the spore wall. The variety *exigua* is also heterothallic.

Origin of the strains belonging to the variety *scutulata*: Slime flux of sandalwood (*Myoporum sandwicense*), Hawaii, U.S.A. (3).

Complementary mating types: NRRL Y-7663-2 (CBS 6672) and NRRL Y-7663-3 (CBS 6673), both single-ascospore isolates from the type strain.

Type strain: CBS 6670 (UCD-FST 71-102, NRRL Y-7663) received from Phaff.

Fig. 100. *I. scutulata* var. *scutulata*, CBS 6670. Unconjugated ascus with ascospores after 2 weeks on YM agar at 25°C. Bar = 5 µm.

Origin of the strains belonging to the variety *exigua*: Insect boring in sitka spruce (*Picea sitchensis*), Washington, U.S.A. (1); slime flux of black cottonwood (*Populus trichocarpa*), British Columbia, Canada (1); slime flux of willow (*Salix* sp.), British Columbia, Canada (1).

Complementary mating types: NRRL Y-10920-3 (CBS 8067) and NRRL Y-10920-4 (CBS 8068), both obtained as single-ascospore isolates from the type strain.

Type strain: CBS 6836 (UCD-FST 68-979B1, NRRL Y-10920), isolated from an insect boring in sitka spruce, Washington, U.S.A.; received from Phaff.

Comments: Phaff et al. (1976) separated the two varieties because of the physiological differences enumerated above and on the basis of geographically separate habitats. Kurtzman et al. (1980b) determined the extent of nuclear DNA base sequence complementarity between the two varieties to be only 25%, and this would suggest that they are separate species (Price et al. 1978, and references cited therein). However, intervarietal matings gave asci with spores that appeared normal and a small number of the spores proved viable. Sib-matings between these progeny gave viable spores. On the basis of this intervarietal fertility, the variety designations have been maintained.

35.4. *Issatchenkia terricola* (van der Walt) Kurtzman, Smiley & Johnson (1980b)

Synonyms:

Pichia terricola van der Walt (1957)

Saccharomyces terricolus (van der Walt) Novák & Zsolt (1961)

Growth on 5% malt extract agar: After 3 days at 25°C, the cells are ovoidal to elongate, (2.4–5.8) × (3.0–14.7) μm, and single or in pairs. Growth is butyrous and tannish-cream in color.

Growth on the surface of assimilation media: Moderate to heavy, dry climbing pellicles are formed.

Dalmau plate culture on morphology agar: After 7 days at 25°C, growth under the coverglass shows poorly to moderately branched pseudohyphae. Aerobic growth is white to tannish-white, dull to faintly glistening, butyrous, low convex with a flattened center, and a lobed margin. The odor is faintly acidic.

Formation of ascospores: Asci are unconjugated, persistent and contain one to four, but usually two, spheroidal spores. Ascospores are roughened as a result of protuberances which originate in the outer spore wall, and this roughness can usually be perceived in the light microscope (Fig. 101). Kurtzman and Smiley (1976) demonstrated this species to be heterothallic. During laboratory cultivation, diploid cultures frequently become haploid to the exclusion of one mating type, and the type strain as well as several other cultures are now asporogenous haploids. Asci arising from a mixture of complementary mating types are usually unconjugated because of the proliferation of diploid cells before sporulation.

Fig. 101. *I. terricola*, CBS 2617 × CBS 6893. Cluster of 2-spored unconjugated asci after 3 weeks on 5% malt extract agar at 25°C. Bar = 5 μm.

Ascospores were observed on YM-, 5% Difco malt extract-, and V8 agar after 1–3 weeks at 25°C.

Mol% G + C: 37.9, 38.2, CBS 2617, NRRL Y-8218 (BD: Kurtzman et al. 1980b).

Origin of the strains studied: Soil, South Africa (1); soil, Italy (1); soil, Louisiana, U.S.A. (2); cherry juice (1); dregs of pressed grapes, Italy (1); sea water (1); spoiled figs, U.S.A. (1); old wine (1).

Complementary mating types: NRRL YB-4310 (CBS 2617) and NRRL Y-7549-25 (CBS 6893).

Type strain: CBS 2617 (NRRL YB-4310), soil isolate received from van der Walt, South Africa.

Comments on the genus

Kudryavtsev (1960) described the monotypic genus *Issatchenkia* on the basis of certain strains isolated from berries and fruit juices. The cultures formed spores that were spheroidal and smooth when observed with the light microscope. Asci were persistent and contained one spore. Kreger-van Rij (1964b) transferred the single species to the genus *Pichia* as *P. orientalis*, but Boidin et al. (1965b) pointed out that the name had been used previously and proposed the new name *P. kudriavzevii*.

Pichia terricola and *P. scutulata* were two other species phenotypically similar to *P. kudriavzevii*. Scanning electron microscopy showed the former two species and *I. occidentalis* to have warty ascospore walls, and in this respect, to differ from other spheroidal-spored species of *Pichia* which have essentially smooth spore walls (Kurtzman and Smiley 1974, Phaff et al. 1976).

Despite their similarity in ascospore surface structure to species of *Debaryomyces* and *Torulaspota* (Kurtzman et al. 1975), these three species do not exhibit the cell–bud conjugation typical of *Debaryomyces* or the protuberances on asci that are associated with sporulation in *Torulaspota*. Furthermore, all species now assigned to *Issatchenkia* have Q-7 ubiquinone in the electron transport system while all *Saccharomyces* and *Torulaspota* species have Q-6 ubiquinone. Species of *Debaryomyces* and the remainder of the *Pichia* species with spheroidal spores have Q-9 ubiquinone (Yamada et al. 1973a, 1976b, 1977; Yamada, personal communication). Peterson and Kurtzman (1990) estimated phylogenetic relatedness among *Issatchenkia* spp. from extent of nucleotide substitution in three regions of rRNA. *I. terricola* was the most divergent member of the group.

36. *Kluyveromyces* van der Walt emend. van der Walt

M.A. Lachance

Diagnosis of the genus

Asexual reproduction is by multilateral budding on a narrow base. Cells are ovoidal, ellipsoidal, cylindrical to elongate. Pseudomycelium may be formed. True hyphae are not produced.

Conjugation may or may not precede ascus formation. The ascospores are smooth, reniform, bacilliform, ellipsoidal or spheroidal, tending to agglutinate after liberation. One to four, or in some species, many ascospores are formed per ascus.

Glucose is fermented vigorously. Nitrate is not assimilated. Diazonium blue B reaction is negative.

Type species

Kluyveromyces polysporus van der Walt

Systematic discussion of the species

36.1. *Kluyveromyces aestuarii* (Fell) van der Walt (1971)

Synonyms:

Saccharomyces aestuarii Fell (1961)

Kluyveromyces aestuarii (Fell) van der Walt (1965c) nom. inval.

Zygofabospora aestuarii (Fell) Naumov (1987b)

Growth on YM agar: After 3 days at 25°C, the cells are globose to ellipsoidal, (2–6) × (3–7) μm, single, in pairs or in short chains. Growth is butyrous, white to deep ochre because of pulcherrimin production, and glossy or dull.

Growth in glucose–yeast extract broth: A sediment and a thin pellicle are formed.

Dalmau plate culture on corn meal agar: After two weeks a rudimentary pseudomycelium is formed.

Formation of ascospores: Conjugation between cells of the same culture or between bud and parent-cell usually precedes ascus formation. One to four spheroidal to ellipsoidal ascospores with central refringent globules are formed (Fig. 102). The spores are liberated from the ascus soon after formation and tend to agglutinate.

Abundant sporulation occurs after 2–4 days at 17–25°C on most commonly used media. Both strains studied were sporogenous.

Fermentation:

Glucose	+	Lactose	–
Galactose	v	Raffinose	+
Sucrose	+	Trehalose	–
Maltose	–	Inulin	–

Assimilation:

Glucose	+	<i>N</i> -Acetyl-D-glucosamine	–
Galactose	+	Methanol	–
L-Sorbose	+	Ethanol	+
Sucrose	+	Glycerol	+
Maltose	w/–	Erythritol	–
Cellobiose	+	Ribitol	–
Trehalose	w/–	Galactitol	–
Lactose	+	D-Mannitol	+
Melibiose	–	D-Glucitol	+

Co-Q: Not determined.

Mol% G+C: 39.8–39.9, 2 strains, CBS 4438 and CBS 4904 (BD: Fuson et al. 1987).

Fig. 102. Asci of *K. aestuarii*, CBS 4438, after 2 weeks on YM agar. Bar = 5 μm.

Origin of the strains studied: CBS 4438, marine mud, Biscayne Bay, Fell, U.S.A.; CBS 4904, sea water, Torres Strait, van Uden, Portugal.

Type strain: CBS 4438, isolated by Fell from marine mud.

Comments: *K. aestuarii* is presumed to be a marine species, although special physiological adaptations to saline environments have not been fully documented. Growth characteristics are not substantially different from those of several other typical members of the genus whose habitats are terrestrial plants or animals, except that in the presence of 5 or 10% sodium chloride on YM agar, growth and pulcherrimin production are particularly abundant, whereas no growth occurs on 50% glucose. Van der Walt and Johannsen (1984) reported variation in the utilization of maltose, trehalose and D-xylose. In this laboratory, the type strain grew weakly on the first two sugars after 3 weeks, but neither strain was seen to assimilate D-xylose.

A moderately close relationship between *K. aestuarii* and certain other *Kluyveromyces* species has long been suspected on the basis of similarity in morphology and physiology (van der Walt 1970c, Martini et al. 1972, Poncet 1973b, Johannsen 1980), including β-galactosidase activity and abundant pulcherrimin formation. *K. aestuarii*, although homothallic, reacts to the α mating pheromone of *K. lactis* and forms zygotes with haploid cells of that mating type (Herman 1970). Attempts to document a measurable degree of relatedness by DNA reassociation (Martini 1973, Vaughan-Martini and Martini 1987b, Fuson et al. 1987), immunological cross-reactivity of β-glucanase (Lachance and Phaff 1979), or prototrophic hybrid selection (Johannsen 1980) had negative results, but some recent studies provided such evidence. *K. aestuarii* possesses, in its ribosomal DNA, a *Bam*HI restriction site shared only with *K. lactis*, *K. marxianus*, and *K. wickerhamii*, and a *Kpn*I site shared only with *K. lactis*, *K. marxianus*, *K. dobzhanskii*, *K. delphensis*, and the multisporous *Kluyveromyces* species (Lachance 1989). Also, electrokaryograms of *K. aestuarii* are quite typical

of those of various *K. marxianus* or *K. lactis* strains (Kock et al. 1988, Sor and Fukuhara 1989).

Lactose assimilation combined with lack of growth in the presence of 100 mg/l cycloheximide separate *K. aestuarii* from the rest of the genus.

36.2. *Kluyveromyces africanus* van der Walt (1956b)

Growth on YM agar: After 3 days at 25°C, the cells are ovoidal, (2–5)×(3–8)µm, single, in pairs or in short chains. Conjugating cells may be present. Growth is butyrous, glossy, white to cream-colored.

Growth in glucose–yeast extract broth: A sediment is formed.

Dalmou plate culture on corn meal agar: After two weeks a few chains of cells may be formed.

Formation of ascospores: Asci arise directly from diploid cells. One to 16 or more oblong or reniform ascospores are formed. The spores are liberated from the ascus soon after formation and tend to agglutinate. Early conjugation may be observed.

Asci are formed on YM or malt extract agar after 2–5 days at 17–25°C, but mature ascospores may be difficult to see.

Fermentation:

Glucose	+	Lactose	–
Galactose	+	Raffinose	–
Sucrose	–	Trehalose	–
Maltose	–	Inulin	–

Assimilation:

Glucose	+	<i>N</i> -Acetyl-D-glucosamine	–
Galactose	+/w	Methanol	–
L-Sorbose	–	Ethanol	–
Sucrose	–	Glycerol	w/–
Maltose	–	Erythritol	–

Additional assimilation tests and other growth characteristics:

2-Keto-D-gluconate	–	Gelatin liquefaction	–
Cadaverine	–	Cycloheximide 100 mg/l	–
L-Lysine	–	Amino acid-free	w
Ethylamine-HCl	–	Growth at 37°C	w/–
50% Glucose	–		

Co-Q: Not determined.

Mol% G+C: 38.5, CBS 2517 (BD: Fuson et al. 1987).

Origin of the strains studied: CBS 2517, NRRL

Y-2404, NRRL Y-2405, NRRL Y-2406, soil, van der Walt, South Africa.

Type strain: CBS 2517, isolated by van der Walt from soil.

Comments: *K. africanus* is represented by four similar strains recovered from South African soil samples. In addition to sharing many phenotypic features with other *Kluyveromyces* species, *K. africanus* is strikingly similar to *Saccharomyces transvaalensis* and *S. dairenensis* when examined by phenetic analysis. A Co-Q 6 yeast isolated from South African soil, *S. transvaalensis* differs by about 4% G+C from *K. africanus* and *S. dairenensis*. Unlike *S. dairenensis*, *K. africanus* grows weakly on most culture media. In particular, very weak growth is observed on amino acid-free yeast nitrogen base. Growth is stimulated by methionine, less by cysteine.

In addition to the formation of asci with up to 16 (or more) spores, *K. africanus* is resolved from other *Kluyveromyces* species by absence of growth on sucrose, trehalose, and 2-keto-D-gluconate. Separation from *K. phaffii* and *K. yarrowii* by physiological traits is tenuous. *K. phaffii* grows slowly on D-gluconate or ethanol, *K. yarrowii* utilizes ethanol, and *K. africanus* utilizes neither.

36.3. *Kluyveromyces bacillisporus* Lachance, Phaff & Starmer (1993)

Growth on YM agar: After 3 days at 25°C, the cells are ovoidal to elongate, (2–5)×(4–7)µm, single or in pairs. Growth is butyrous, glabrous, and white.

Growth in glucose–yeast extract broth: A sediment is formed.

Dalmou plate culture on corn meal agar: No pseudomycelium is formed.

Formation of ascospores: Asci arise directly from diploid cells (Fig. 103). Four, occasionally 6 to 8 cylindrical to bacilliform ascospores are formed. The spores are liberated from the ascus 1 week after formation and tend to agglutinate.

Fig. 103. Asci of *K. bacillisporus*, CBS 7720, after 1 week on McClary's acetate agar. Bar = 5 µm. (Lachance et al. 1993, with permission of the publisher.)

Asci are formed on McClary's acetate agar after 2–5 days at 17–25°C.

Fermentation:

Glucose	+	Lactose	–
Galactose	–	Raffinose	–
Sucrose	–	Trehalose	–
Maltose	–	Inulin	–

Assimilation:

50% Glucose	–		

Co-Q: Not determined.

Mol% G + C: 37.9–38.1, 2 strains, including CBS 7720 (BD: Lachance et al. 1993).

Origin of the strains studied: CBS 7720 and 2 other strains, exudate, Emory oak (*Quercus emoryi* Torr.), Arizona, U.S.A.

Type strain: CBS 7720, isolated from Emory oak exudate.

Comments: *K. bacillisporus* is represented by three strains recovered from exudates of Emory oak in the vicinity of Tucson, Arizona. These trees were in close proximity to cottonwoods (*Populus fremontii* Wats.) and to various species of prickly pear cacti (*Opuntia* L. spp.), and were being visited by flies (*Drosophila carbonaria* Patterson & Wheeler) that also carried yeasts (Lachance et al. 1993). In view of the fact that these habitats were sampled very extensively, the small number of isolates suggests that the true habitat of *K. bacillisporus* may be another insect or plant. *K. bacillisporus* contains an unusual amount (ca. one half) of mitochondrial DNA. The significance of that observation is not clear.

K. bacillisporus differs from other *Kluyveromyces* species by the utilization of 2-keto-D-gluconate, shared only with *K. blattae*, and the absence of growth on galactose, shared only with *K. delphensis* and *K. waltii*.

36.4. *Kluyveromyces blattae* Henninger & Windisch (1976a)

Growth on YM agar: After 3 days at 25°C, the cells are globose to ellipsoidal, (3–9) × (4–10) μ m, single, in pairs or in short chains. Growth is butyrous, glossy, and white to cream-colored.

Growth in glucose–yeast extract broth: A sediment is formed.

Dalmat plate culture on corn meal agar: No pseudomycelium is formed.

Formation of ascospores: Asci arise directly from diploid cells. One to 8 or more spheroidal to ellipsoidal ascospores, occasionally of variable sizes, are formed (Fig. 104). The spores are liberated from the ascus soon after formation and tend to agglutinate.

Immature asci are observed on YM and malt extract agar after 2–5 days at 17–25°C. Ascospores may be seen after 3 weeks.

Fermentation:

Glucose	+	Lactose	–
Galactose	+	Raffinose	–
Sucrose	–	Trehalose	–
Maltose	–	Inulin	–

Assimilation:

Glucose	+	<i>N</i> -Acetyl-D-glucosamine	–
Galactose	+	Methanol	–
L-Sorbose	–	Ethanol	–
Sucrose	–	Glycerol	w/–
Maltose	–	Erythritol	–
Cellobiose	–	Ribitol	–
Trehalose	–	Galactitol	–
Lactose	–	D-Mannitol	–
Melibiose	–	D-Glucitol	–
Raffinose	–	α -Methyl-D-glucoside	–
Melezitose	–	Salicin	–
Inulin	–	D-Gluconate	–
Soluble starch	–	DL-Lactate	–
D-Xylose	–	Succinate	–
L-Arabinose	–	Citrate	–
D-Arabinose	–	Inositol	–
D-Ribose	–	Hexadecane	–
L-Rhamnose	–	Nitrate	–
D-Glucosamine	–	Vitamin-free	–

Additional assimilation tests and other growth characteristics:

2-Keto-D-gluconate	+	Gelatin liquefaction	–
Cadaverine	–	Cycloheximide 100 mg/l	–
L-Lysine	–	Amino acid-free	–
Ethylamine-HCl	–	Growth at 37°C	–
50% Glucose	–		

Co-Q: Not determined.

Mol% G + C: 34.2, CBS 6284 (BD: Fuson et al. 1987).

Origin of the strains studied: CBS 6284 and CBS 6285, cockroach (*Blatta orientalis* L.), Henninger and Windisch (1976a).

Type strain: CBS 6284, isolated by Henninger and Windisch from a cockroach.

Fig. 104. Ascus of *K. blattae*, CBS 6284, after 3 weeks on YM agar. Bar = 5 μ m.

Comments: Henninger and Windisch (1976a) described *K. blattae* based on the isolation of two strains from the oriental cockroach (*Blatta orientalis* L.). An unusual feature of this yeast is the complete failure to grow on minimal medium without amino acids, due to a requirement for histidine. Growth (delayed) has been reported on D-ribose (Barnett et al. 1990), but the observation could not be confirmed in the present study. *K. blattae* shares with *K. bacillisporus* the relatively rare ability to assimilate 2-keto-D-gluconate, but differs from the latter by the absence of galactose assimilation.

36.5. *Kluyveromyces delphensis* (van der Walt & Tseuschner) van der Walt (1971)

Synonyms:

Saccharomyces delphensis van der Walt & Tseuschner (1956b)

Dekkeroomyces delphensis (van der Walt & Tseuschner) Novák & Zsolt (1961) nom. inval.

Guilliermondella delphensis (van der Walt & Tseuschner) Boidin, Abadie, J.L. Jacob & Pignal (1962)

Kluyveromyces delphensis (van der Walt & Tseuschner) van der Walt (1965c) nom. inval.

Zygofabospora delphensis (van der Walt & Tseuschner) Naumov (1987b)

Growth on YM agar: After 3 days at 25°C, the cells are ellipsoidal, (1–4) × (2–6) μ m, single, in pairs or in short chains. Growth is butyrous, glossy, and cream-colored.

Growth in glucose-yeast extract broth: A sediment and a slight ring are formed.

Dalmou plate culture on corn meal agar: No pseudomycelium is formed.

Formation of ascospores: Asci arise from the conjugation of haploid cells in the same culture. One to four reniform ascospores are formed. The spores are liberated from the ascus soon after formation and tend to agglutinate.

Sporulation occurs after 2–5 days at 17–25°C on YM or malt extract agar.

Fermentation:

Glucose	+	Lactose	–
Galactose	–	Raffinose	–
Sucrose	–	Trehalose	–
Maltose	–	Inulin	–

Assimilation:

50% Glucose	ws		

Co-Q: Not determined.

Mol% G + C: 40.2, CBS 2170 (BD: Fuson et al. 1987).

Origin of the strain studied: CBS 2170, dried figs, van der Walt and Tseuschner.

Type strain: CBS 2170, isolated by van der Walt and Tseuschner from dried figs.

Comments: Van der Walt and Tseuschner (1956b) isolated *K. delphensis* from dried figs. Due to the availability of only a single strain, it is difficult to comment further on the ecology of this organism. Lachance and Phaff (1979) reported a high degree of similarity between the β -glucanase of that yeast and that of *K. lactis*. Although this has not been investigated further, the possibility of gene flow between different *Kluyveromyces* species is not without precedent (e.g., Johannsen 1980) and should not be discounted. However, genetic exchange probably would not follow the normal path of zygote formation, as evidenced by the negative results obtained by Herman (1970) who showed that mating pheromones of *K. lactis* have no effect on *K. delphensis*.

Phenetically, *K. delphensis* is closest to *K. bacillisporus* and to a lesser extent to other group A species, bearing in addition a superficial resemblance with various nutritionally specialized species of *Saccharomyces*. A previous report of glycerol utilization (van der Walt 1970c) was not confirmed. The combined absence of assimilation of galactose, 2-keto-D-gluconate, and ethylamine sets *K. delphensis* apart from any other *Kluyveromyces* species. Separation from *Saccharomyces* species is based primarily on ascus persistence and ascospore morphology.

36.6. *Kluyveromyces dobzhanskii* (Shehata, Mrak & Phaff) van der Walt (1971)

Synonyms:

Saccharomyces dobzhanskii Shehata, Mrak & Phaff (1955)

Dekkeromyces dobzhanskii (Shehata, Mrak & Phaff) Novák & Zsolt (1961) nom. inval.

Kluyveromyces dobzhanskii (Shehata, Mrak & Phaff) Santa María & Sanchez (1970) nom. inval.

Guilliermondella dobzhanskii (Shehata, Mrak & Phaff) Boidin, Abadie, J.L. Jacob & Pignal (1962)

Kluyveromyces dobzhanskii (van der Walt & Tscheuschner) van der Walt (1965c) nom. inval.

Kluyveromyces marxianus (E.C. Hansen) van der Walt var. *dobzhanskii* (Shehata, Mrak & Phaff) E. Johannsen & van der Walt (Johannsen 1980)

Zygofabospora dobzhanskii (Shehata, Mrak & Phaff) Naumov (1987b)

Growth on YM agar: After 3 days at 25°C, the cells are spheroidal, ellipsoidal to cylindrical, (2–6) × (3–11) µm, single, in pairs or in short clusters. Growth is butyrous, glossy, and cream-colored or pink due to pulcherrimin production.

Growth in glucose–yeast extract broth: A sediment and a slight ring are formed.

Dalmou plate culture on corn meal agar: Well ramified pseudomycelium is formed abundantly.

Formation of ascospores: Conjugation of haploid cells in the same culture or bud–parent cell conjugation may precede ascus formation, or asci may arise directly from diploid cells. One to four reniform ascospores are formed. The spores are liberated from the ascus soon after formation and tend to agglutinate.

Sporulation occurs abundantly after 2–5 days at 17–25°C on YM, malt extract, or McClary's acetate agar. Most strains are sporogenous.

50% Glucose	v		

Co-Q: Not determined.

Mol% G+C: 42.6, 2 strains, including CBS 2104 (BD: Fuson et al. 1987).

Origin of the strains studied: CBS 2104, *Drosophila pseudoobscura* Frolova, Shehata et al. (1955); CBS 5061 and CBS 5062, oak white pocket rot mushroom [*Hymenochaeta ruboginosa* (Dickson:Fr.) Lèv.] and brown oak mushroom *Fistulina hepatica* Huds. ex Fr., Boidin, France; climbing shrub [*Actinidia arguta* (Sieb. & Zucc.) Planch. ex Miq.], herbaceous perennial (*Chloranthus japonicus* Sieb.), white nut tree [*Kalopanax septemlobus* (Thunb.) Koidz.], and magnolia vine [*Schisandra chinensis* (Turcz.) Baill.], near Vladivostok, Golubev, USSR; numerous strains from black knot [*Dibotryon morbosum* (Schw.) Theissen & Sydow] of chokecherry (*Prunus virginiana* L.), and from *Drosophila* Fallén spp., Ontario, Canada.

Type strain: CBS 2104, isolated by Shehata et al. (1955) from *Drosophila pseudoobscura*.

Comments: *K. dobzhanskii* is associated with *Drosophila* and related insect habitats such as plants and macrofungi. Very similar in many ways to *K. lactis* var. *drosophilorum*, it nevertheless represents a fully speciated entity, as evidenced by DNA reassociation (Martini 1973, Fuson et al. 1987, Vaughan-Martini and Martini 1987b), by immunological distances of β-glucanases (Lachance and Phaff 1979), and by isoenzyme electrophoresis (Sidenberg and Lachance 1986). *K. dobzhanskii* can be distinguished from other *Kluyveromyces* species by weak growth or absence of growth at 37°C, lack of utilization of lactose, and good growth on β-glucosides (cellobiose and salicin).

36.7. *Kluyveromyces lactis* (Dombrowski) van der Walt (1971)

This species has two varieties:

Kluyveromyces lactis (Dombrowski) van der Walt var. *lactis* (1986)

Anamorph: *Candida spherica* (Hammer & Cordes) S.A. Meyer & Yarrow

Synonyms:

Saccharomyces lactis Dombrowski (1910)

Zygosaccharomyces lactis Dombrowski (1910)

Zygoenospora lactis (Dombrowski) Krasil'nikov (1954a)

Guilliermondella lactis (Dombrowski) Boidin, Abadie, J.L. Jacob & Pignal (1962)

Dekkeromyces lactis (Dombrowski) Santa María & Sanchez (1970) nom. inval.

Kluyveromyces lactis (Dombrowski) van der Walt (1965c) nom. inval.

Kluyveromyces lactis (Dombrowski) van der Walt (1971)

Kluyveromyces marxianus (E.C. Hansen) van der Walt var. *lactis* (Dombrowski) E. Johannsen & van der Walt (Johannsen 1980)

Zygosaccharomyces casei Sacchetti (1932a,b)
Zygosaccharomyces versicolor Sacchetti (1933)
Saccharomyces sociasii C. Ramirez (1954)
Zygofabospora lactis (Dombrowski) Naumov (1987b)
 ?*Mycoderma lactis* Dombrowski (1910)
Torula sphaerica Hammer & Cordes (1920)
Torulopsis sphaerica (Hammer & Cordes) Lodder (1934)
Cryptococcus sphaericus (Hammer & Cordes) Anderson & Skinner (1947)
Candida spherica (Hammer & Cordes) S.A. Meyer & Yarrow (Yarrow and Meyer 1978)

***Kluyveromyces lactis* var. *drosophilum* (Shehata, Mrak & Phaff) Sidenberg & Lachance (1986)**

Synonyms:

Zygofabospora phaseoluspora (Shehata, Mrak & Phaff) Naumov (1987b)
Zygofabospora krassilnikovii Kudryavtsev (1960)
Dekkeromyces krassilnikovii Kudryavtsev (1960)
Saccharomyces vanudenii van der Walt & Nel (1963)
Kluyveromyces vanudenii (van der Walt & Nel) van der Walt (1965c) nom. inval.
Kluyveromyces vanudenii (van der Walt & Nel) van der Walt (1971)
Kluyveromyces marxianus (E.C. Hansen) van der Walt var. *vanudenii* (van der Walt & Nel) E. Johannsen & van der Walt (Johannsen 1980)

Growth on YM agar: After 3 days at 25°C, the cells are ellipsoidal, (2–6) × (2–8) µm, single, in pairs or in short chains. Growth is butyrous, glossy, cream-colored or pinkish due to pulcherrimin production.

Growth in glucose–yeast extract broth: A sediment and a ring are formed. A thin pellicle is usually formed.

Dalmu plate culture on corn meal agar: A rudimentary pseudomycelium is usually formed.

Formation of ascospores: Conjugation of haploid cells

or bud–parent cell conjugation may precede ascus formation, or asci may arise directly from diploid cells. One to four ascospores are formed. The spores range in shape from spheroidal to ellipsoidal to reniform. Sporulating strains of the variety *lactis* are heterothallic, whereas those in the variety *drosophilum* are homothallic. The spores are liberated from the ascus soon after formation and tend to agglutinate.

Sporulation occurs after 2–5 days at 17–25°C on YM, malt extract, or McClary's acetate agar. Most strains are sporogenous.

Fermentation:

In the fermentation, assimilation and other characteristics, the superscript numbers indicate (1) characteristics that may differ in *K. lactis* var. *drosophilum*, and (2) characteristics that differ in strain CBS 4693.

Co-Q: 6 (Yamada et al. 1976b).

Mol% G + C: 39.9–40.8, 12 strains, including CBS 683 and CBS 2105 (BD: Fuson et al. 1987).

Supplementary description of *K. lactis* var. *drosophilum*: The variety *drosophilum* does not ferment or assimilate lactose. Some strains may ferment inulin or assimilate L-arabinose. Some strains fail to assimilate cellobiose, trehalose, melezitose, mannitol, or salicin. Some strains utilize citrate. All strains grow well at 37°C. The variety *lactis* is heterothallic and the variety *drosophilum* is homothallic.

Origin of the strains belonging to the variety *lactis*: CBS 683, gassy cheese, Allen and Thornley (1929); CBS

4693, received by CBS from Brust; numerous strains from cheese, Schmidt, France.

Complementary mating types: CBS 683 (*α*) and CBS 739 (*α*).

Type strain: CBS 683, isolated by Allen and Thornley from gassy cheese.

Origin of the strains belonging to the variety *drosophilum*: CBS 2105, *Drosophila azteca* Sturtevant & Dobzhansky, Shehata et al. (1955); CBS 4372, type strain of *K. vanudenii*, winery equipment, van der Walt and Nel (1963); CBS 2103, type strain of *K. phaseolosporus*, *Drosophila pseudoobscura* Frolova, Shehata and Mrak (1952); numerous strains from *Drosophila* spp., black knot [*Dibotryon morbosum* (Schw.) Theissen & Sydow] of chokecherry (*Prunus virginiana* L.), exudate of red oak (*Quercus rubra* L.), Ontario, Canada; *Drosophila carbonaria* Patterson & Wheeler, exudates of Emory oak (*Quercus emoryi* Torr.) and Fremont cottonwood (*Populus fremontii* Wats.), Arizona, Ganter et al. (1986).

Type strain: CBS 2105, isolated by Shehata et al. (1955) from *Drosophila azteca*.

Comments: *K. lactis* exhibits many similarities with several other *Kluyveromyces* species, and is even able, under certain conditions, to form hybrids with them, leading van der Walt and Johannsen (1984) to consider it a variety of *K. marxianus*. The rationale for restoring its full species status is discussed in later sections. On the basis of interfertility and genetic affinities, the former taxa *K. drosophilum*, *K. phaseolosporus*, and *K. vanudenii* are considered conspecific with *K. lactis*.

The division of *K. lactis* into the two varieties *lactis* and *drosophilum* was proposed by Sidenberg and Lachance (1986) and is maintained. It is arbitrarily based on physiological and ecological criteria. Lactose utilizers have arisen almost exclusively in samples from dairy products, whereas lactose-negative strains originate mostly from *Drosophila* or materials known to be *Drosophila* habitats, such as exudates and fungal pathogens of trees. That the same varietal lines seem to be followed by mating compatibility systems may or may not be accidental, but nonetheless adds another basis for maintaining the two infraspecific taxa. A clear genetic partitioning of the species is lacking, and as pointed out by Naumov (1988), division into varieties on the basis of lactose assimilation is not natural. However, until more information is available, a correct genetic definition of varieties within *K. lactis* is not possible. The maintenance of three separate species under the epithets *lactis*, *drosophilum*, and *phaseolosporus*, as suggested by Naumov (1988), would not be consistent with the DNA reassociation values ranging from 64 to 100% (Martini 1973, Fuson et al. 1987) among representatives of these taxa and of the former designation *K. vanudenii*. The reassociation values are independent of former taxonomic assignments. For example, two strains previously assigned to *K. vanudenii* gave, respectively, 98% and 68% heteroduplex formation

with the type of *K. lactis* var. *lactis* (Fuson et al. 1987). The type strain of *K. phaseolosporus* gave 90% reassociation with the type of the variety *lactis* and 83% with the type of the variety *drosophilum*. Seven strains formerly designated as *K. drosophilum* had reassociation values ranging from 64 to 80% with the type of the variety *lactis*, and from 64% to 86% with the type of the variety *drosophilum*. The type cultures of the two recognized varieties formed 77% and 80% heteroduplexes in reciprocal experiments. Electrokarotypes (Sor and Fukuhara 1989) are equally perplexing. Although different strains have important differences in chromosome size distributions between the varieties, significant variation exists within the varieties as well.

The conspecificity of *Candida spherica* and *K. lactis*, recognized by van der Walt (1970c), has been confirmed by Vaughan-Martini and Martini (1985) by means of DNA reassociation.

K. lactis is rapidly becoming a serious competitor to *Saccharomyces cerevisiae* and *Schizosaccharomyces pombe* as a model organism. A European-based, international group of geneticists interested in *K. lactis* has met in 1990 and agreed to adopt a standard nomenclature of mutations and chromosomes for the species (H. Fukuhara and B.J.M. Zonneveld, personal communications). They have chosen strain CBS 2359 as standard for genetic analysis. As an example of the work being done with *K. lactis*, a circular plasmid of the so-called 2 μ family has been isolated from *K. lactis* var. *drosophilum* (Falcone et al. 1986), and used to create a gene cloning system for *K. lactis* (Chen et al. 1988). Interestingly, the plasmid could be replicated in both varieties of *K. lactis*, but not in *K. marxianus*. Linear killer plasmids of *K. lactis* have also been used to construct vectors (Kamper et al. 1989).

K. lactis has also been explored for its industrial potential. For example, the β -galactosidase from *K. lactis* can be used to reduce the lactose content of milk (Hussein et al. 1989).

For identification purposes, *K. lactis* var. *lactis* is unique in the genus in assimilating both lactose and α -glucosides. *K. lactis* var. *drosophilum* is best recognized, among lactose-negative species that utilize ethylamine and L-lysine strongly, by its vigorous growth at 37°C.

36.8. *Kluyveromyces lodderae* (van der Walt & Tscheuschner) van der Walt (1971)

Synonyms:

Saccharomyces lodderae (as *S. lodderi*) van der Walt & Tscheuschner (1957a)

Dekkeroomyces lodderi (van der Walt & Tscheuschner) Novák & Zsolt (1961) nom. inval.

Guilliermondella lodderi (van der Walt & Tscheuschner) Boidin, Abadie, J.L. Jacob & Pignal (1962)

Kluyveromyces lodderi (van der Walt & Tscheuschner) van der Walt (1965c) nom. inval.

Zygoabospora lodderi (van der Walt & Tscheuschner) Naumov (1987b)

Growth on YM agar: After 3 days at 25°C, the cells

are ellipsoidal to cylindrical, (2–6) × (3–11) μm, single, in pairs or in small clusters. Growth is butyrous, glossy to dull, and cream-colored.

Growth in glucose–yeast extract broth: A sediment and a slight ring are formed.

Dalmau plate culture on corn meal agar: A rudimentary pseudomycelium is formed.

Formation of ascospores: Conjugation of haploid cells or bud–parent cell conjugation may precede ascus formation, or asci may arise directly from diploid cells. One to four reniform or bacilliform ascospores are formed. The spores are liberated from the ascus soon after formation and tend to agglutinate.

Sporulation occurs after 1 week at 17–25°C on 1% malt extract agar and McClary's acetate agar. Strain UCD-FST 70-3, a subculture of the type, sporulates better than other cultures examined.

Fermentation:

Glucose	+	Lactose	–
Galactose	+	Raffinose	+

¹A slow, but positive reaction was observed in the type culture.

Co-Q: Not determined.

Mol% G + C: 35.4–35.7, 2 strains, including CBS 2757 (BD: Fuson et al. 1987).

Origin of the strains studied: CBS 2757 [UCD-FST 70-3], soil, van der Walt and Tscheuschner, NRRL YB-4303, NRRL YB-4304, NRRL YB-4305, NRRL YB-4306, soil, van der Walt, South Africa.

Type strain: CBS 2757, isolated by van der Walt and Tscheuschner from soil.

Comments: This species was originally described as

K. lodderi, but, as pointed out by Barnett et al. (1983), and in accordance to Article 73 of the Botanical Code (Greuter et al. 1988), the correct Latin orthography of the epithet *lodderae* should be used. *K. lodderae* was recovered from soil, but its true habitat is not known. *K. lodderae* is phenetically similar in many ways with *K. polysporus*, but the two are easily distinguished on the basis of ascospore numbers. In addition, unlike *K. polysporus*, *K. lodderae* assimilates cadaverine vigorously, albeit slowly. Strain NRRL YB-4306 gave weaker reactions than the type for the assimilation of glycerol, lactic and succinic acids, and growth in the absence of amino acids. The slow assimilation of inulin reported by van der Walt (1970c) could not be confirmed. The utilization of ethylamine as sole nitrogen source, reported as positive by Barnett et al. 1990, was only observed in the type culture, and growth on lysine, reported as variable by these authors, was negative.

K. lodderae differs from species of *Kluyveromyces* that fail to grow on both ethylamine and L-lysine by the utilization of the β-fructosides sucrose and raffinose, and the ability to grow in the presence of 100 mg/l cycloheximide.

36.9. *Kluyveromyces marxianus* (E.C. Hansen) van der Walt (1971)

Anamorph: *Candida kefyr* (Beijerinck) van Uden & H.R. Buckley

Synonyms:

- Pseudomycoderma mazzae* Dodge (1935)

Growth on YM agar: After 3 days at 25°C, the cells are globose, ellipsoidal, to cylindrical, (2–6) × (3–11) μm , single, in pairs or in short chains. Growth is butyrous, glossy, cream-colored to brown, rarely pinkish due to pulcherrimin production.

Growth in glucose–yeast extract broth: A sediment and a ring are formed. A thin pellicle may be formed.

Dalmat plate culture on corn meal agar: A rudimentary to highly branched pseudomycelium with a few blastospores may be formed.

Formation of ascospores: Conjugation of haploid cells or bud–parent cell conjugation may precede ascus formation, or asci may arise directly from diploid cells. One to four ascospores are formed. The spores range in shape from spheroidal to ellipsoidal to reniform. Sporulating cultures appear to be homothallic. The spores are liberated from the ascus soon after formation and tend to agglutinate.

Sporulation occurs after 2–5 days at 17–25°C on 1% malt extract agar and McClary's acetate agar. Most strains sporulate well.

Co-Q: 6 (Yamada et al. 1976b).

Mol% G+C: 41.1–41.5, 12 strains, including CBS 712 (BD: Fuson et al. 1987).

Origin of the strains studied: CBS 712, Schnegg; CBS 2762, type strain of *K. bulgaricus*, yogurt, Santa María; CBS 4857, type strain of *K. cicerisporus*; CBS 397, type strain of *K. fragilis*, yogurt; CBS 5671, type strain of *K. wikenii*, sorghum beer, van der Walt et al. (1966); numerous strains from cheese, Schmidt, France; one strain from prickly pear (*Opuntia phaeacantha* Engelm), and one from *Drosophila carbonaria* Patterson & Wheeler, Arizona, Ganter et al. (1986).

Type strain: CBS 712 (neotype), Schnegg.

Comments: In the last monograph on *Kluyveromyces* (van der Walt and Johannsen 1984), the definition of *K. marxianus* was altered to reflect the ability of certain species to hybridize. Following that view, *K. marxianus* encompassed several varieties, among which were taxa recognized here as either distinct species (*K. dobzhanskii*, *K. lactis*), or synonyms of *K. lactis* or *K. marxianus*. The species definition used in the present treatment takes into account hybridization ability in combination with the genetic structure of populations. Because species delineation in *K. marxianus* has been controversial, these criteria are now given explicitly.

The biological species concept is unequivocally applicable to yeasts only when they are heterothallic. The majority of *Kluyveromyces* species are homothallic and thus facultatively self-fertile. For such yeasts, whether or not populations effectively share a common gene pool depends not only on mating potential, but also on numerous other factors that are difficult to ascertain. However, the end result of evolution can be examined to see whether genes are patterned consistently with a history of phyletic divergence, or whether they exhibit a diffuse genetic clustering indicative of panmixia (random mating). The available information on physiological properties, isoenzyme distributions, ecological affinities, and nuclear genome DNA heteroduplex formation (see Comments on the genus) clearly indicates that *K. marxianus* is evolutionarily indistinct from taxa once designated by the epithets *bulgaricus*, *cicerisporus*, *fragilis*, or *wikenii*, and that it has speciated fully from *K. dobzhanskii* and *K. lactis*. The distinct nature of *K. marxianus* and *K. lactis* has received further substantiation most recently from the work of Steensma et al. (1988), who examined, by electrokaryotyping and phenotype analysis, hybrids of the two species and single spore isolates obtained from the hybrids. The spores had low viability, but more importantly, the few viable spores grew into cultures that were identical, in karyotype or genotype, to either the hybrid or one of the parents. Balanced genetic recombination was not taking place.

If *K. lactis* is rapidly stealing from *Saccharomyces cerevisiae* its place in the limelight of molecular genetics, *K. marxianus* is competing for the status of most celebrated domestic microbe. The examples given below should be viewed as a minute sampling of a vast literature. The lactose hydrolysing properties of *K. marxianus* (and *K. lactis*) have long been known for their potential in the food industry. Interestingly, Algeri et al. (1978) observed that lactose uptake and β -galactosidase activity in *K. marxianus* are induced by lactose whereas they are constitutive in *K. lactis*, based on an examination of one strain of each species. Carvalho-Silva and Spencer-Martins (1990) compared several strains of *K. marxianus* and *K. lactis* on the basis of several features of their lactose uptake, and found that they could be assigned to three different groups that were unfortunately not congruent with their species assignments.

Many publications in the last ten years describe studies of inulin utilization by *K. marxianus*. Interest in this area stems from the abundance of inulin in certain easily grown crop plants such as the Jerusalem artichoke (*Helianthus tuberosus*). At the risk of being unjust to all others, a single recent study will be cited in which several key reports are reviewed. Strain CBS 6556, originally described as *Hansenula pozolis* by Herrera et al. (1973), was found to combine thermotolerance with higher productivity when compared with other inulinase-producing strains of *K. lactis* (including representatives of former taxon *K. vanudenii*) and *K. marxianus* (Rouwenhorst et al. 1988). Inulinase, in that yeast, is bound to the cell envelope, but can be released at higher pH or under reducing conditions. Its synthesis is repressed by glucose or lactose, and reaches a maximum at high temperatures (37–42°C).

The extracellular pectinolytic activity of *K. marxianus* endows it with the potential to be both useful and detrimental to human activity. In the first instance, the endo-polygalacturonase of this yeast has been used experimentally to eliminate the pectin haze of apple juice (Gomez-Ruiz et al. 1988). *K. marxianus* has also been identified as the agent of a soft rot in onion (Johnson et al. 1988). *K. marxianus* is able to produce glycerol from lactose when grown in whey permeate if the medium is supplemented with 1% Na₂SO₃ (Jeng et al. 1989).

The thermotolerance of *K. marxianus* allows it to be used in very rapid processes of ethanol production, which might compensate for its lower tolerance to ethanol compared to *S. cerevisiae*. Anderson et al. (1986) obtained 6% ethanol at 43°C in one day with isolates selected from sugar mill effluents. Interestingly, the better isolates keyed to *K. marxianus* var. *marxianus* (*sensu* van der Walt & Johannsen 1984). The type culture of the former *K. bulgaricus* gave less satisfactory results, and those of *K. lactis* and *K. wickerhamii* gave poor results.

Bak and Stenderup (1969) demonstrated the existence of a high degree of genetic relatedness between *K. fragilis* (syn. *K. marxianus*) and *Candida pseudotropicalis*, now considered a synonym of *Candida kefyr*. Vaughan-Martini and Martini (1985) confirmed the very high genetic relatedness of these taxa.

Yeasts with significant biotechnological interest are particularly difficult to characterize ecologically. The β -galactosidase activity of *K. marxianus* is likely to explain its frequent recovery from samples of materials associated with warm-blooded animals, including dairy products. A number of isolates, some of which do not utilize lactose, originate from natural fermentations.

The fact that *K. marxianus* was once represented by five different nomenclatural species reflects the phenetic heterogeneity of the species, and explains why it is difficult to distinguish from other related taxa, especially *K. lactis*. However, *K. marxianus* is the only inulin-assimilating *Kluyveromyces* species that does not assimilate or ferment α -glucoside and grows well at 37°C.

36.10. *Kluyveromyces phaffii* (van der Walt) van der Walt (1971)

Synonyms:

Fabospora phaffii van der Walt (1963)

Kluyveromyces phaffii (van der Walt & Tschuschner) van der Walt (1965c) nom. inval.

Growth on YM agar: After 3 days at 25°C, the cells are ellipsoidal to cylindrical, (2–4) × (3–8) μm, single, in pairs or in small clusters. Growth is butyrous, glossy to dull, and cream-colored.

Growth in glucose–yeast extract broth: A sediment is formed.

Dalmu plate culture on corn meal agar: Short chains of cells may be formed.

Formation of ascospores: Asci arise directly from diploid cells. One to four reniform or bacilliform ascospores are formed. The spores are liberated from the ascus soon after formation and tend to agglutinate.

Sporulation occurs after 2–5 days at 17–25°C on YM, malt extract, or McClary's acetate agar.

Fermentation:

Glucose	+	Lactose	–
Galactose	+	Raffinose	–
Sucrose	–	Trehalose	–
Maltose	–	Inulin	–

Assimilation:

Glucose	+	<i>N</i> -Acetyl-D-glucosamine	–
Galactose	+	Methanol	–
L-Sorbose	–	Ethanol	v
Sucrose	–	Glycerol	+
Maltose	–	Erythritol	–

Cadaverine	–	Cycloheximide 100 mg/l	–
L-Lysine	–	Amino acid-free	+
Ethylamine-HCl	–	Growth at 37°C	–
50% Glucose	–		

Co-Q: Not determined.

Mol% G + C: 35.3, CBS 4417 (BD: Fuson et al. 1987).

Origin of the strain studied: CBS 4417, soil, van der Walt.

Type strain: CBS 4417, isolated by van der Walt from soil.

Comments: *K. phaffii* differs from *K. africanus* and *K. blattae* mostly by ascospore numbers and from

K. yarrowii and others largely by ploidy of the natural isolates. These two characters were considered sufficient by Naumov (1987b) to propose the reclassification of *K. phaffii* in a separate genus. However, taking into account all the phenetic and genetic data available, it is clear that the current classification is satisfactory.

Physiologically, lack of ethylamine utilization, absence of growth on β-fructosides, and assimilation of D-gluconate, set *K. phaffii* apart from other galactose-utilizing *Kluyveromyces* species.

36.11. *Kluyveromyces polysporus* van der Walt (1956a)

Synonym:

Saccharomyces polysporus (van der Walt) Campbell (1972)

Growth on YM agar: After 3 days at 25°C, the cells are globose to cylindrical, (2–5) × (3–7) μm, single, in pairs or in short chains. Conjugating cells and large zygotes may be present. Growth is butyrous, glossy, cream-colored to brownish.

Growth in glucose–yeast extract broth: A sediment and a thin pellicle are formed.

Dalmu plate culture on corn meal agar: Chains of cells or rudimentary pseudomycelium may be formed.

Formation of ascospores: Asci arise from the conjugation of haploid cells. Large numbers of oblong to reniform ascospores are formed (Fig. 105). The spores are liberated from the ascus soon after formation and tend to agglutinate.

The type culture forms abundant asci after 1 week at 17–25°C on YM agar. It is difficult to observe mature asci because the ascospores are released easily.

Fermentation:

Glucose	+	Lactose	–
Galactose	+	Raffinose	+
Sucrose	+	Trehalose	s
Maltose	–	Inulin	–

Fig. 105. Lysed ascus of *K. polysporus*, CBS 2163, after 1 week on YM agar. Bar = 5 μm.

Assimilation:

Glucose	+	<i>N</i> -Acetyl-D-glucosamine	–
Galactose	+	Methanol	–
L-Sorbose	–	Ethanol	v
Sucrose	+	Glycerol	+
Maltose	–	Erythritol	–
Cellobiose	–	Ribitol	–
Trehalose	s	Galactitol	–
Lactose	–	D-Mannitol	–
Melibiose	–	D-Glucitol	–
Raffinose	+	α-Methyl-D-glucoside	–

D-Glucosamine	–	Vitamin-free	–

Additional assimilation tests and other growth characteristics:

2-Keto-D-gluconate	–	Gelatin liquefaction	–
Cadaverine	–	Cycloheximide 100 mg/l	–
L-Lysine	–	Amino acid-free	+
Ethylamine-HCl	–	Growth at 37°C	w/–
50% Glucose	–		

Co-Q: Not determined.**Mol% G+C:** 35.3, CBS 2163 (BD: Fuson et al. 1987).**Origin of the strains studied:** CBS 2163, soil, South Africa; NRRL Y-2397, NRRL Y-2400, van der Walt.**Type strain:** CBS 2163, isolated by van der Walt from soil.

Comments: The type species of *Kluyveromyces*, *K. polysporus* is unique among yeasts because of its ability to produce up to 100 ascospores due to supernumerary mitoses in the ascus parent cell (Roberts and van der Walt 1958). Van der Walt (1956a) hypothesized that the multispored state was an evolutionary carry-over from more developed fungi into the realm of yeasts, but that the vigorously fermentative uninucleate nature of *K. polysporus* made it a bona fide member of the Endomycetales. The later realization that other yeast species are phenetically close to *K. polysporus* confirmed the correctness of the assignment.

Physiologically, *K. polysporus* exhibits a particularly high degree of similarity to *K. lodderae*, but differs from the latter by growth on citric and D-gluconic acids, and failure to grow in the presence of cycloheximide (100 mg/l). *K. polysporus* differs from all other ethylamine-negative *Kluyveromyces* species by the utilization of β-fructosides and absence of growth on 2-keto-D-gluconate.

36.12. *Kluyveromyces thermotolerans* (Filippov) Yarrow (1972)**Synonyms:**

- Zygosaccharomyces thermotolerans* Filippov (1932)
Saccharomyces thermotolerans (Filippov) Campbell (1972)
Zygofabospora thermotolerans (Filippov) Naumov (1987b)
Torula dattila Kluyver (1914) (see van der Walt and E. Johannsen 1974)
Mycotorula dattila (Kluyver) Harrison (1928)

- Torulopsis dattila* (Kluyver) Lodder (1934)
Cryptococcus dattilus (Kluyver) Skinner (1947a)
Candida dattila (Kluyver) S.A. Meyer & Yarrow (Yarrow and Meyer 1978)
Saccharomyces veronae Lodder & Kreger-van Rij (1952)
Kluyveromyces veronae (Lodder & Kreger-van Rij) van der Walt (1970c) nom. inval.
Kluyveromyces veronae (Lodder & Kreger-van Rij) van der Walt (1971)

Zygosaccharomyces drosophilae Shehata & Mrak (1952) nom. inval.

Growth on YM agar: After 3 days at 25°C, the cells are spheroidal to ellipsoidal, (3–6) × (6–8) μm, single, in pairs or in short clusters. Growth is butyrous, glossy, and cream-colored.

Growth in glucose–yeast extract broth: A sediment and a slight ring are formed. Occasionally, growth may be very flocculent.

Dalmat plate culture on corn meal agar: Pseudomycelium may be formed. When present, it ranges from very rudimentary to highly branched with blastospores.

Formation of ascospores: Conjugation of haploid cells in the same culture or bud–parent cell conjugation may precede ascus formation, or asci may arise directly from diploid cells. One to four spherical ascospores with conspicuous lipid globules are formed. The spores are liberated from the ascus soon after formation and tend to agglutinate.

Sporeulation occurs abundantly in most strains after 2–5 days at 17–25°C on YM, malt extract, or McClary's acetate agar.

L-Lysine	+	Amino acid-free	+
Ethylamine-HCl	+	Growth at 37°C	v
50% Glucose	+		

Co-Q: 6 (Yamada et al. 1976b).**Mol% G+C:** 46.2, CBS 2803 (BD: Fuson et al. 1987).

Origin of the strains studied: CBS 6340, plum jam, Filippov (1932); CBS 2803, type of *Kluyveromyces veronae* (van der Walt 1971), grapes, Verona; CBS 137, type of *Candida dattila*; many strains from black knot [*Dibotryon morbosum* (Schw.) Theissen & Sydow] of sand cherry (*Prunus pumila* L.) and chokecherry (*Prunus virginiana* L.), *Drosophila* Fallén spp., and insect galls of red oak (*Quercus rubra* L.), Ontario, Canada; black knot of black cherry (*Prunus serotina* Ehrh.), Québec, Canada; fruit of prickly pear (*Opuntia* L. sp.), Big Pine Key, Florida; fruit of a cereoid cactus, Shroud Cay, Exuma Cays, Bahamas; a drosophilid (*Gitona americana* Patterson) collected near decaying prickly pear (*Opuntia stricta* Haworth) somatic tissue, Cayman Islands; *Drosophila carbonaria* Patterson & Wheeler, Arizona (Ganter et al. 1986).

Type strain: CBS 6340, isolated by Filippov from fermenting plum jam.

Comments: *Saccharomyces veronae* was transferred to *Kluyveromyces* “provisionally and for purely practical reasons” by van der Walt (1970c). When Yarrow (1972) later studied authentic strains of *Zygosaccharomyces thermotolerans* and found them to be indistinguishable from *K. veronae*, he assigned the fused species to *Kluyveromyces* because he observed ascus deliquescence. This does not alter the fact that *K. thermotolerans* has obvious natural affinities with *Saccharomyces* and *Zygosaccharomyces*, a property that is shared with *K. waltii*. They are retained in *Kluyveromyces* monothetically on the basis of ascus deliquescence. Ascospore ultrastructure in *K. thermotolerans* and *K. waltii* is similar to that of certain *Zygosaccharomyces* species and different from that of *K. marxianus*, but equally important differences are observed within the genus *Zygosaccharomyces* itself (Kreger-van Rij 1979). Phenetically, *K. thermotolerans* is very similar not only to *Zygosaccharomyces florentinus* and *Zygosaccharomyces cidri*, but also to *Saccharomyces kluyveri*. However, an equally high degree of similarity exists between *Zygosaccharomyces fermentati* and *K. dobzhanskii*, and to a lesser extent between *Z. fermentati* and *K. lactis* or *K. marxianus*. Although it is possible that *K. thermotolerans* may one day return to one of its genera of origin, carrying along with it *K. waltii*, the choice of which genus is not at all obvious. The arguments in favor of transferring them at this time are not at all compelling.

Candida dattila was found by van der Walt and Johannsen (1974) to produce ascospores after a suitable heat treatment. They noted the very high phenetic similarity between *C. dattila* and *K. thermotolerans*, and concluded that the two taxa were synonyms. Vaughan-Martini and Martini (1985) demonstrated a high degree of DNA reassociation between these taxa.

K. thermotolerans is associated with fruit, *Drosophila* species, and possibly other insects that use plants for feeding purposes. Two unusual strains were recovered from drosophilid flies collected near decaying prickly

pear tissue in the Cayman Islands. Both strains utilized melibiose, and one strain grew vigorously at 37°C. The utilization of 2-keto-D-gluconate by some strains (including the type) and not by others is unusual, as that compound generally appears to be taxonomically stable.

For identification purposes, *K. thermotolerans* can be recognized among species that utilize ethylamine and L-lysine, by its combined lack of growth on β -glucosides or in the presence of 100 mg/l cycloheximide.

36.13. *Kluyveromyces waltii* K. Kodama (1974)

Synonym:

Zygofabospora waltii (K. Kodama) Naumov (1986a)

Growth on YM agar: After 3 days at 25°C, the cells are spheroidal to ellipsoidal, (3–6) × (4–10) μ m, single, in pairs or in short clusters. Growth is butyrous, glossy, and cream-colored.

Growth in glucose–yeast extract broth: A sediment is formed.

Dalmau plate culture on corn meal agar: Pseudomycelium may be formed. When present, it ranges from very rudimentary to highly branched with blastospores.

Formation of ascospores: Conjugation of haploid cells in the same culture or bud–parent cell conjugation precedes ascus formation. One to four spherical ascospores with lipid globules are formed. The spores are liberated slowly from the ascus and tend to agglutinate.

Sporulation occurs after 2–5 days at 17–25°C on YM, malt extract, or McClary’s acetate agar. All strains sporulate moderately well.

Fermentation:

Glucose	+	Lactose	–
Galactose	–	Raffinose	+
Sucrose	+	Trehalose	–

Cadaverine	+	Cycloheximide 100 mg/l	+
L-Lysine	+	Amino acid-free	+
Ethylamine-HCl	+	Growth at 37°C	w/–
50% Glucose	ws		

Co-Q: Not determined.

Mol% G + C: 45.7, CBS 6430 (BD: Fuson et al. 1987).

Origin of the strains studied: CBS 6430 [UCD-FST 72-13], exudate of holly (*Ilex* L. sp.), Kodama, Japan; several strains were recovered from *Drosophila* Fallén spp., black knot [*Dibotryon morbosum* (Schw.) Theissen & Sydow] of chokecherry (*Prunus virginiana* L.), and insect galls of red oak (*Quercus rubra* L.), Ontario, Canada.

Type strain: CBS 6430, isolated by Kodama from holly exudate.

Comments: As noted for *K. thermotolerans*, the inclusion of *K. waltii* in *Kluyveromyces* is not based on solid evidence of monophyly. *K. waltii* exhibits greater phenetic resemblance to *Zygosaccharomyces mrakii* and *Zygosaccharomyces microellipsoides* than to any *Kluyveromyces* species. Deliquescence of its asci requires considerably more time compared to other species, including *K. thermotolerans*. Notwithstanding these considerations, the current classification is retained, because revisions should hinge on compelling evidence which is not currently available.

K. waltii is probably insect associated, having been recovered from plant injuries known or suspected to serve as feeding sites for *Drosophila* species and other insects. *K. waltii* differs from other ethylamine- and L-lysine-assimilating species of *Kluyveromyces* by the inability to assimilate galactose and the ability to grow in the presence of 100 mg/l cycloheximide.

36.14. *Kluyveromyces wickerhamii* (Phaff, M.W. Miller & Shifrine) van der Walt (1971)

Synonyms:

Saccharomyces wickerhamii Phaff, M.W. Miller & Shifrine (1956)

Dekkeroomyces wickerhamii (Phaff, M.W. Miller & Shifrine) Novák & Zsolt (1961) nom. inval.

Guilliermondella wickerhamii (Phaff, M.W. Miller & Shifrine) Boidin, Abadie, J.L. Jacob & Pignal (1962)

Dekkeroomyces wickerhamii (Phaff, M.W. Miller & Shifrine) Santa Maria & Sanchez (1970) nom. inval.

Kluyveromyces wickerhamii (Phaff, M.W. Miller & Shifrine) van der Walt (1965c) nom. inval.

Zygojabospora wickerhamii (Phaff, M.W. Miller & Shifrine) Naumov (1986a)

Growth on YM agar: After 3 days at 25°C, the cells are spheroidal to cylindrical, (2–4) × (3–6) μm, single, in pairs or in short clusters. Growth is butyrous, glossy, and cream-colored or pink to brown because of abundant pulcherrimin production.

Growth in glucose-yeast extract broth: A sediment and a thin, dull pellicle are formed.

Dalmau plate culture on corn meal agar: A rudimentary pseudomycelium is formed.

Fig. 106. Asci and free ascospores of *K. wickerhamii*, UWO(PS)91-127.2, after 2 weeks on YM agar. Bar = 5 μm.

Formation of ascospores: Conjugation of haploid cells in the same culture may precede ascus formation, or asci may arise directly from diploid cells. One to four reniform to crescentiform ascospores are formed (Fig. 106). The spores are liberated from the ascus soon after formation and tend to agglutinate.

Sporulation is abundant for most strains after 2–5 days at 17–25°C on YM, malt extract, or McClary's acetate agar.

Fermentation:

Glucose	+	Lactose	–

50% Glucose	–		

Co-Q: Not determined.

Mol% G + C: 41.9–42.4, 5 strains, including CBS 2745 (BD: Fuson et al. 1987).

Origin of the strains studied: CBS 2745 [NRRL Y-8286, UCD-FST 54-210], *Drosophila pinicola* Sturtevant, Sierra Nevada Mountains, California, Phaff, USA; NRRL Y-5973 [UCD-FST 56-40], slime flux of fir tree (*Abies* L. sp.), Miller, USA; UWO(PS)85-330.5, exudate of Fremont cottonwood (*Populus fremontii* Wats.), UWO(PS)85-379.1 and UWO(PS)85-384.1, *Drosophila brooksae* Pipkin, Ganter et al. (1986); UWO(PS)91-127.2, exudate of red oak (*Quercus rubra* L.), Ontario, Canada.

Type strain: CBS 2745, isolated by Phaff et al. (1956), from *Drosophila pinicola*.

Comments: In nature, *K. wickerhamii* is confined to *Drosophila* species and to tree exudates that probably act as *Drosophila* habitats. Certain *K. wickerhamii* strains produce broad spectrum killer factors, effective not only against other *Kluyveromyces* and related species (Lehmann et al. 1987b, Vaughan-Martini and Rosini 1989), but also against a very wide array of unrelated yeasts (M.A. Lachance, unpublished results).

K. wickerhamii would easily be confused with other lactose-assimilating species of *Kluyveromyces* were it not for its inability to assimilate inulin and its resistance to 100 mg/l cycloheximide.

36.15. *Kluyveromyces yarrowii* van der Walt, E. Johannsen, Opperman & Halland (1986b)

Synonyms:

Torulopsis tannotolerans F.H. Jacob (1970)

Candida tannotolerans (F.H. Jacob) S.A. Meyer & Yarrow (Yarrow and Meyer 1978)

Growth on YM agar: After 3 days at 25°C, the cells are spheroidal to ovoid, (3–6)×(4–9)µm, single, in pairs or in short chains. Growth is butyrous, glossy, and cream-colored.

Growth in glucose-yeast extract broth: A sediment and a partial ring are formed.

Dalmau plate culture on corn meal agar: Pseudomycelium is not formed.

Formation of ascospores: Ascus formation follows the conjugation of haploid cells of complementary mating types or asci may arise directly from stable diploid cells. One to four spheroidal ascospores are formed. The spores are liberated from the ascus soon after formation and tend to agglutinate.

The diploid strain CBS 8242 sporulates well after 2–5 days at 17–25°C on YM, malt extract, or McClary's acetate agar.

Fermentation:

Glucose	+	Lactose	–
Galactose	+	Raffinose	–
Sucrose	–	Trehalose	–
Maltose	–	Inulin	–

Assimilation:

Glucose	+	<i>N</i> -Acetyl-D-glucosamine	–

Ethylamine-HCl	–	Growth at 37°C	–
50% Glucose	–		

Co-Q: 6 (Y. Yamada in: van der Walt et al. 1986b).

Mol% G+C: 34.5 (Stenderup et al. 1972).

Origin of the strains studied: CBS 2684, type strain of *Candida tannotolerans* and CBS 6070, both from tanning liquors containing tree bark, Jacob, France; CBS 8242, a diploid strain.

Complementary mating types: CBS 2684 and CBS 6070.

Type strain: CBS 8242, a stable diploid obtained by crossing auxotrophic subcultures of CBS 2684 (*α*) and CBS 6070 (*a*) (van der Walt et al. 1986b).

Comments: *Candida tannotolerans* was isolated from tanning liquors by Jacob (1970). After Yarrow observed ascospore formation in mixtures of strains of *Candida tannotolerans*, van der Walt et al. (1986b) described the teleomorph as *K. yarrowii*. This yeast is very similar in DNA base composition and physiological profile to *K. africanus* and *K. phaffii*. Unlike these, however, *K. yarrowii* is heterothallic and forms spherical ascospores.

The designation of an artificial diploid strain created from two mutagenized parents as the type strain of a species may be questionable as a biological practice, but it follows the rules of the International Code of Botanical Nomenclature (Greuter et al. 1988) and must be accepted. This is all the more unfortunate because the diploid construct exhibits a certain amount of hybrid vigor, whereby growth on ethanol, glycerol, xylitol, glucono-δ-lactone, 10 mg/l cycloheximide, and YM agar with 40 mM HCl (the last four are not standard tests used in this chapter) was noticeably stronger for the diploid than for either haploid strain.

The liquors from which strains of *K. yarrowii* were isolated contained approximately 6% tannins extracted from the bark of various trees (Jacob 1970). Whether or not this is significant in defining the niche of this yeast remains to be seen. The 3 strains examined grew well on yeast nitrogen base agar supplemented with 0.5% tannic acid as the carbon source, which is not particularly unusual. Several other yeasts, including most *Kluyveromyces* species, grow on that medium.

Physiologically, *K. yarrowii* may be distinguished from other ethylamine-negative, four-spored *Kluyveromyces* species by its absence of growth on β-fructosides, 2-keto-D-gluconate, D-gluconate, and at 37°C.

Comments on the genus

The history of the taxonomy of *Kluyveromyces* is characterized by a series of interesting developments from the creation of the genus, prompted by the discovery

of *K. polysporus* (van der Walt 1956a), to the later inclusion (van der Walt 1965c) of several species at one time considered members of *Saccharomyces sensu lato* (van der Walt 1970d). The reader is referred to van der Walt's treatment (1970c) for details up to that point. Here, the discussion will emphasize the most recent reassessments of the boundaries of the genus based on phenetic, genetic, or molecular approaches, which are not without a number of fascinating peripeties. To facilitate the discussion, the genus is conveniently divided into three groups each representing species known to exhibit a number of properties in common (see Tables 27 and 28). Group A comprises *K. africanus*, *K. bacillisporus*, *K. blattae*, *K. delphensis*, *K. lodderae*, *K. phaffii*, *K. polysporus*, and *K. yarrowii*. Group B is made up of *K. aestuarii*, *K. dozhanskii*, *K. lactis*, *K. marxianus*, and *K. wickerhamii*. Group C comprises *K. thermotolerans* and *K. waltii*.

Wickerham and Burton (1956a,b) divided species now considered as members of the genus *Kluyveromyces* with regard to sexual compatibility and ascospore shape, suggesting that they had evolved along two "lines of development". Van der Walt (1970c) extended this idea further, viewing the nutritionally specialized reniform spored species that produce four spores as primitive progenitors from which emerged more advanced species characterized either by the formation of larger ascospore numbers, or the acquisition of β -glucosidase, β -galactosidase or α -glucosidase activities. Another line of development, in which ascospores are spheroidal instead of reniform, was presumed to have undergone an analogous nutritional radiation. Ascospore shape was, in those cases, given considerable importance. Kock et al. (1988) reviewed this theme and extended it in the light of published molecular comparisons. In addition to placing much less emphasis on ascospore morphology, they reached the conclusion that ancestral members of the genus were in fact those that produce abundant pseudomycelium, assimilate a wider spectrum of nutrients, produce certain specific fatty acids, and possess diverse ascospore morphologies.

Because of the widespread ability of many *Kluyveromyces* species to be self-fertile (homothallic), a classical concept of biological species based on mating compatibility alone would be difficult to formulate. Hybridization between members of various taxa, including *K. dozhanskii* and species now regarded as synonyms of *K. marxianus* or *K. lactis* was subjected to diverse interpretations and generated a fair amount of controversy. Wickerham and Burton (1956a,b) obtained interspecific hybrids of these yeasts. Bicknell and Douglas (1970) later showed that hybrids involving *K. marxianus* (syn. *K. fragilis*) and *K. lactis* or *K. dozhanskii* were in fact allopolyploids. The potential for limited gene flow was demonstrated (Johannsen 1980) among all taxa later regarded by van der Walt and Johannsen (1984) as varieties of the single species, *K. marxianus*, as well as with *K. wickerhamii*. Limited hybridization was also

reported between these and *K. waltii* or *K. thermotolerans*. Gene flow between species is not entirely surprising. It serves as a mechanism by which new species may arise, and thus accounts for reticulate evolution. The significance of interspecific hybridization involving *K. thermotolerans* was examined by Vaughan-Martini et al. (1987), who studied a single-spore isolate previously obtained by mass-mating of *K. marxianus* and *K. thermotolerans* (Johannsen and van der Walt 1978). The putative recombinant was phenotypically and genetically unstable, and could be made to revert to one parental state, that of *K. marxianus*. The significance of the results was complicated by the observation that the strain used to construct this hybrid may not have been an authentic representative of *K. thermotolerans*. Interspecific hybridization was most recently addressed by Steensma et al. (1988) whose results leave no doubt that *K. marxianus* and *K. lactis* represent different biological species, in spite of their propensity towards forming sporulating hybrids. One very obvious conclusion is wanting to be drawn regarding mating compatibility in the group B *Kluyveromyces* species: given that those yeasts have diverged into at least 5 fully distinct species and yet have conserved almost unaltered their sexual compatibility, it follows that the various gene products involved in this mating system must be extremely efficient at performing their function. A last thought on the difficulty of assessing the taxonomic significance of hybridization can be drawn from the following study. Witte et al. (1989) have obtained, by protoplast fusion, hybrids between *K. marxianus* and *Saccharomyces cerevisiae*, and between *K. thermotolerans* and *S. cerevisiae*. No one would argue that these could be anything but interspecific crosses. Electro-karyotypes of the hybrids demonstrated the presence of hybrid chromosomes, illustrating that once the hurdle of pre-zygotic isolation is sidestepped, speciation does not necessarily provide a complete barrier to gene recombination. While this does not ease our task of identifying species boundaries, it does urge us to exercise caution in interpreting out-of-context data that we deem taxonomically significant.

Because all the factors contributing to genetic isolation of yeast populations cannot be assessed in every case, the question of species delimitation is advantageously examined ex post facto, by measuring genetic divergence. The question of species delineation in *Kluyveromyces* has been addressed extensively by such methods. Nucleic acid reassociations will be considered first.

The molecular taxonomy of *Kluyveromyces* was pioneered by Bicknell and Douglas (1970), who obtained high degrees of heteroduplex formation between the non-repetitive DNAs of *K. marxianus* and the former taxon *K. fragilis*, hinting on their conspecificity. *K. dozhanskii* and *K. wickerhamii* were found to be genetically distinct from *K. marxianus* and *K. lactis*, and the last two were recognized as distinct from each other. Based on rRNA-DNA duplex formation, these four taxa were shown, in addition, to have speciated fairly recently. The rRNA relatedness

of *K. delphensis* or *K. thermotolerans* to *K. lactis* was comparable to the relatedness of members of the genera *Saccharomyces*, *Torulaspota*, or *Zygosaccharomyces* to *K. lactis*. When compared to *Saccharomyces cerevisiae*, those *Kluyveromyces* species appeared heterogeneous in their rRNAs, but always distinct from *Saccharomyces*, *Torulaspota*, or *Zygosaccharomyces*. Martini (1973) confirmed that *K. marxianus*, *K. lactis*, *K. wickerhamii*, *K. thermotolerans*, *K. dobzhanskii*, and *K. delphensis* were genetically disjoint as assessed by heterologous DNA renaturation rates. In addition, he compared many pairs of DNAs from every *Kluyveromyces* species sensu van der Walt (1970c), setting the foundation for our current understanding of genetic relatedness in the genus. Fiol and Poncet (1980) performed DNA reassociations on certain strains. Their reassociation values were not in general agreement with those already in the literature, or with preliminary results to be published later by other workers. Specifically, they found relatively high amounts of reassociation between *K. marxianus* and *K. africanus*, *K. phaffii*, *K. dobzhanskii*, or *K. wickerhamii*. A likely interpretation of their findings is that the DNA used as tracer may have been enriched for certain conserved sequences, possibly ribosomal DNA, thus extending the useful range of DNA reassociation beyond the usual level of closely related species. The recent DNA reassociation studies of *Kluyveromyces* by Fuson et al. (1987) and Vaughan-Martini and Martini (1987b) are altogether sufficiently exhaustive to resolve most uncertainties about species boundaries. Lachance et al. (1993) ascertained the species status of *K. bacillisporus* by DNA reassociation with their putative nearest relatives among group A species. Taken all together, the results of these studies are consistent with the classification presented here.

Many authors have contributed to the determination of DNA base composition in *Kluyveromyces* (Bicknell and Douglas 1970, Nakase and Komagata 1971e, Martini et al. 1972, Poncet and Fiol 1972, Stenderup et al. 1972, Fuson et al. 1987, Vaughan-Martini and Martini 1987b, Lachance et al. 1993). While a broad agreement exists between data from different laboratories, a few exceptions should be noted and taken into account when making comparisons. The values of Poncet and Fiol (1972) tended to be lower than others, except for *K. polysporus*, for which the lowest value (33%) was from Nakase and Komagata (1971e). Because the publication of Fuson et al. (1987) is the most comprehensive and reports data uniformly based on the buoyant density method, only those values have been included in this chapter, with the exception of the value for *K. bacillisporus*. Base composition values are consistent with the separation of the genus *Kluyveromyces* into three natural groups. Group A species range from 34 to 40, group B species from 40 to 43, and group C species both have 46 mol% G + C.

Other molecular approaches have focused on patterns of protein or nucleic acid divergence assessed by various indirect methods. Lachance and Phaff (1979) clarified

the species boundaries in group B species through an immunological comparison of β -glucanases. They showed that *K. marxianus*, *K. fragilis*, *K. bulgaricus*, *K. cicerisporus*, and *K. wikenii* should be considered synonyms, and that *K. lactis*, *K. vanudenii*, *K. drosophilorum*, and *K. phaseolosporus* were also probably conspecific, in spite of their heterogeneity of ascospore morphology. Sidenberg and Lachance (1983, 1986) pursued the question by means of isoenzyme electrophoresis. They confirmed the patterns elicited by DNA reassociation, concluding that introgression, if present among *Kluyveromyces* species shown to mate at high frequencies, had in fact been sufficiently rare to allow them to maintain separate gene pools. *K. thermotolerans* and *K. waltii* were clearly identified as distinct from each other and from group B species. Their ability to undergo some form of rare genetic interaction with other *Kluyveromyces* species must be considered a vestige of their evolutionary history, and not evidence that they represent "incipient species" (Kock et al. 1988). Restriction endonuclease mapping of the ribosomal DNA clusters of the type strains of *Kluyveromyces* (Lachance 1989) confirmed the cohesive nature of group B species, all of which shared some synapomorphic restriction sites with other members of the group. Group A species, not surprisingly, were less cohesive, but their respective rDNAs each shared some synapomorphic sites with other members of the group. Our inexperience with the significance of the variation in size and numbers of yeast chromosomes renders difficult the task of evaluating electrokaryography and its application to the systematics of *Kluyveromyces*. The available data (Kock et al. 1988, Sor and Fukuhara 1989) have usually confirmed the species boundaries proposed here, but have not provided new insight on their interrelatedness. Restriction analysis of mitochondrial DNA (Ragnini and Fukuhara 1988) revealed a great deal of polymorphism among the mitochondrial genomes of *Kluyveromyces* species. Particularly interesting was the observation that mtDNAs of most group B species contained an unusually high number of *SacII* (CCGCGG) and *HpaII* (CCGG) restriction sites. *K. marxianus* (five strains of *K. marxianus sensu stricto* and three strains of the synonym *K. bulgaricus*), group C species, and most group A species had few or no such sites. *K. aestuarii*, *K. africanus*, *K. delphensis*, *K. lodderae* occupied an intermediate position, with many *HpaII* sites, but few, if any *SacII* sites. Again, these data support the distinct status of *K. marxianus* and *K. lactis*, and the complex inter-relationships linking species in groups A, B, and C.

The poor success of numerical taxonomy in recognizing natural groups among yeasts probably derives from our inability to measure many genetically independent phenotypes in them. On the basis of cluster analysis, Campbell (1972) proposed the transfer of all *Kluyveromyces* species to *Saccharomyces* (*sensu* van der Walt 1970d), which has not met with much agreement in the taxonomic community. The physiological profiles of all ascogenous

yeasts listed in Barnett et al. (1990) have been analyzed by a similar method (M.A. Lachance, unpublished results) and the analysis has been used here to assess possible relationships and phenetic homogeneity of taxa. Taxa thought to be monophyletic on the basis of genetic or molecular data rarely arranged themselves into phylogenetically consistent patterns. Although intergeneric relationships may not be attainable by such methods, an ordination analysis performed by Poncet (1973b) on *Kluyveromyces* species gave results that were remarkably consistent with those of molecular studies conducted years after the publication of her paper. She identified the existence of groups A and B, and the distinct nature of *K. thermotolerans* (group C; *K. waltii* was not known at that time). Within group B, she correctly recognized the conspecificity of taxa now known to be synonyms of *K. marxianus*, and their independence from taxa known to be synonyms of *K. lactis*.

A number of novel properties thought to be potentially useful in the taxonomy of the genus *Kluyveromyces* have been examined. Gorin and Spencer (1970) examined proton magnetic resonance spectra of outer cell wall components. Their analyses properly identified kinships between *K. fragilis* and *K. marxianus*, and between *K. lactis* and *K. drosophilorum*, but also suggested significant degrees of relatedness between *K. thermotolerans* and *K. delphensis*, *K. polysporus* and *K. aestuarii*, and could not elicit any particular resemblance between *K. phaseolusporus* and other synonyms of *K. lactis*. Also targeting outer wall surface components, Campbell (1972) reported on antigenic characterizations of whole cells. Four antigenic classes were identified. Three antigenic determinants (A, B, and C) had little, if any predictive value with respect to phyletic relatedness. A fourth antigen (D) was unique to three species in group A, namely *K. delphensis*, *K. polysporus* and *K. lodderae*. Fiol and Claisse (1982) studied the spectrophotometric properties of whole cell cytochromes. The low temperature spectra were purported to separate *Kluyveromyces* groups A and B, and within group B, to elicit *K. aestuarii* and *K. wickerhamii* as distinct from the rest. Furthermore, groups A and B were said probably to constitute a monophyletic entity. Although these conclusions are in general agreement with the views presented here, it is not at all clear how they were arrived at on the basis of the data presented by those authors. Lehmann et al. (1987b) and Vaughan-Martini and Rosini (1989) demonstrated killer activity in some strains of every group B species, and in strains of *K. lodderae* and *K. phaffii*. The toxins are effective against yeasts from other genera as well as species of *Kluyveromyces*. Reciprocal killing is even possible (Lehmann et al. 1987b). Both studies indicated that killer patterns might be useful in biotype identification, but Vaughan-Martini and Rosini (1989) reached the general conclusion that killer patterns had little value in delineating species. Kock et al. (1988) found a correlation between long-chain fatty acid distribution

in *Kluyveromyces* species and their broad evolutionary affinities as understood by most students of the genus. In particular, group B and C species were found to differ from most group A species by the presence of linoleic and linolenic acids among their long-chain fatty acids. The exception was *K. yarrowii*, which contains both acids, and *K. africanus*, which contains linoleic acid only. Perhaps inspired by the work of Carvalho-Silva and Spencer-Martins (1990) on the significance of lactose proton symports in *K. marxianus* and relatives, Kilian and coworkers (1991) surveyed the distribution of symports for five sugars in a strain of every *Kluyveromyces* species. Evidence that transport patterns are in good agreement with natural affinities is difficult to bring into focus, given that, in terms of symports, *K. lodderae* and *K. yarrowii* clustered closer to *K. marxianus* and *K. dobzhanskii* than to other group A species, and three synonyms of *K. lactis* clustered closer to group A than to *K. lactis* var. *drosophilorum*. The most unexpected result was the presence of four symports in *K. yarrowii* and the absence of symports in *K. phaffii*, in sharp contrast with the very similar physiologies of these two species. Last, a correlation is claimed between the number of symports and the number of compounds utilized. Careful examination of the data (Fig. 2 in Kilian et al. 1991) shows that the postulated trend arose to a large part out of errors made in rearranging the carbon source utilization profiles from a diagram taken from Kock et al. (1988).

Naumov (1987b) emended the genus *Zygofabospora* Kudryavtsev to accommodate certain species of *Kluyveromyces*, proposing that the latter name should apply only to the multisporous species, and that possibly a separate genus should be erected for *K. phaffii* because of its diplontic life cycle. The rationale for this proposed reorganization (Naumov 1986a) was that the original descriptions of *Kluyveromyces* and *Zygofabospora* were clearly distinct, and that many species currently assigned to *Kluyveromyces* apparently fit the description of *Zygofabospora* better. When van der Walt (1965c) chose to combine multisporous *Kluyveromyces* species together with others in a single genus, he did so on the basis that ascus deliquescence correlated better than spore number with other characteristics of the species, and thus was a better basis for defining a genus monothetically. By contrast, the two major genera created by Naumov's proposals would be clearly polyphyletic. Indeed, *K. lodderae* and *K. delphensis*, which are proposed members of *Zygofabospora*, bear considerably less resemblance to *K. marxianus*, *K. lactis*, or other putative "*Zygofabospora*" species than to *K. phaffii* or to the multisporous, "true" *Kluyveromyces* species. By many criteria (Poncet 1973b, Kock et al. 1988), Group A species are phenetically homogeneous. The most recently discovered species, *K. bacillisporus*, is diplontic, like *K. phaffii*, but also fits well within group A, which serves as additional evidence against splitting group A species. Until the phylogenetic affinities of group C species are clarified, it is not unreasonable

to think that *Kluyveromyces*, as currently defined, might be monophyletic. Alternatively, group C species might be classified better elsewhere, but evidence of polyphyly in *Kluyveromyces* is simply lacking, and their transfer at this point would be unjustified. A fortiori, the reassignment of these and other *Kluyveromyces* species into one monotypic and two polyphyletic genera is to be rejected outright.

Morikawa et al. (1985) reported the isolation of a new yeast species capable of fermenting D-xylose to relatively large amounts (3%) of ethanol. The yeast reportedly resembled *K. lactis* in its assimilation patterns, and was provisionally named *K. cellobiovorus* pending a formal description. Strain CBS 7153 was examined and ascospores were not found. Unlike any *Kluyveromyces* species, this yeast assimilates *N*-acetyl-D-glucosamine, ethyl acetate, and hexadecane vigorously, utilizes D-glucosamine slowly but strongly, and exhibits very strong and rapid growth in YM agar supplemented with 40 mM hydrochloric acid. Strain CBS 7153 was studied by means of rDNA restriction mapping (Lachance 1989), electrokaryotyping (Sor and Fukuhara 1989), and killer sensitivity patterns (Vaughan-Martini and Rosini 1989). In all cases it was clear that the strain cannot be assigned to the genus *Kluyveromyces*. In fact, Martini

and Vaughan-Martini (1992) showed, by means of DNA reassociation, a high degree of genetic similarity between strain CBS 7153 and the type culture of *Candida intermedia*, a Q-9 species thought by some to be related to the genus *Debaryomyces*.

Weber et al. (1992) recently described two soil isolates as *K. piceae*, reported to differ from other group A species by the utilization of ethylamine and lysine as nitrogen sources, and galactitol as carbon source. DNA reassociation suggested that these strains represent a distinct species, possibly related to *K. lodderae*. Strains CBS 7738 and CBS 7739 were examined both in this laboratory and at the Centraalbureau voor Schimmelcultures (D. Yarrow, personal communication). Neither strain utilized the three aforementioned compounds. Although the two strains appeared strikingly similar in many ways, the second strain (type) had apparently lost the ability to sporulate or to grow on yeast nitrogen base agar with any simple carbon source (including glucose). Scant growth was observed after supplementing the medium with leucine. In view of this perplexing instability, it appears advisable to defer recognition of this species until these problems are clarified.

37. *Lipomyces* Lodder & Kreger-van Rij

M.Th. Smith

Diagnosis of the genus

Cells are ellipsoidal or globose, reproducing by multilateral budding. Oval to cylindrical giant cells may occur. Pseudomycelium is absent. Cells of most strains are surrounded by a thick mucoid capsule. Most strains form starch-like polysaccharides in this capsule. Cells in older cultures usually include a large fat globule.

Fig. 107. *L. starkeyi*, CBS 1807. Various ways of conjugation and of formation of asci (see text) (Slooff 1970a).

Asci develop in various ways; an “active bud” is most frequently involved in formation of the ascus. This may or may not be preceded by a discernable conjugation.

(1) When the asci develop from active buds only, they often enlarge to an elongate pear shape (Fig. 107a,c,d). The wall of this type of ascus is thin. Two asci or more may arise from one parent cell (Fig. 107b). The entire ascus may liberate itself from the cell when mature (Fig. 107f). The number of spores may be up to 16 or more per ascus; in some species the number of spores is eight to four or less per ascus.

(2) When the ascus is the result of conjugation of an active bud and a protuberance of a cell, the ascus wall is thicker (Fig. 107g, j). Complicated groups of these cell–bud conjugations are frequently present on sporulation media.

(3) A parent cell, after having produced an ascus through an active bud, may itself turn into an ascus. Fully grown cells containing ascospores have been observed. These asci possess thick walls.

Ascospores are globose, ellipsoidal to oblong-ellipsoidal, generally liberated at maturity. The pigmented walls are of a light amber to brown color. The ascospore wall may be warty, smooth, or it bears ridges running longitudinally on the surface.

Germination of ascospores is by swelling to the size of a small cell followed by budding. Conjugation of swollen spores has been observed.

Fermentation is absent. Nitrate is not assimilated. Diazonium blue B reaction is negative.

Type species

Lipomyces starkeyi Lodder & Kreger-van Rij

Species accepted

1. *Lipomyces japonicus* van der Walt, M.Th. Smith, Y. Yamada & Nakase (1989)
2. *Lipomyces kononenkoeae* Nieuwdorp, Bos & Slooff (1974)
 - a. *Lipomyces kononenkoeae* Nieuwdorp, Bos & Slooff subspecies¹ *kononenkoeae* (1995)
 - b. *Lipomyces kononenkoeae* subspecies *spencer-martinsiae* van der Walt & M.Th.Smith (1995)
3. *Lipomyces lipofer* Lodder & Kreger-van Rij ex Slooff (1970)
4. *Lipomyces starkeyi* Lodder & Kreger-van Rij (1952)
5. *Lipomyces tetrasporus* Nieuwdorp, Bos & Slooff (1974)

¹ Editor's note: In this book the extent of genetic divergence between subspecies and between varieties of a species is considered comparable.

Systematic discussion of the species

**37.1. *Lipomyces japonicus* van der Walt,
 M.Th. Smith, Y. Yamada & Nakase (van
 der Walt et al. 1989c)**

Synonym:

Smithiozyma japonica (van der Walt, M.Th. Smith, Y. Yamada & Nakase) Kock, van der Walt & Y. Yamada (1995)

Growth in malt extract: After 3 days at 25°C, cells are globose, 3.5–7.0 µm in diameter, rarely subglobose, ellipsoidal or ovoidal, encapsulated, contain lipid globules, and occur singly or in pairs. Growth is scant. After one month, a sediment and an incomplete ring are formed.

Growth on malt agar: After 3 days at 25°C, the cells have the same appearance as observed in malt extract. The streak culture is watery to viscous, creamish-opaque, glistening, and smooth with an entire margin.

Dalmay plate culture on corn meal agar: After 10 days at 25°C, neither hyphae nor pseudohyphae are formed.

Formation of ascospores: Asci are saccate, (7.0–13.0×3.0–6.0) µm, persistent, as a rule attached, with 1–4 spores, and arise from the fusion of protuberances of adjacent or non-adjacent cells, or from enlarging protuberances of single cells, or infrequently by automixis. Ascospores are globose, (2.0–3.5) µm, warty, amber or brown when mature, and contain a lipid globule. Actively sporulating cultures turn brown.

Sporulation was observed on 2% malt- and V8 agars at 18°C, after 7–14 days.

Fermentation: absent.

Assimilation:

Glucose	+	<i>N</i> -Acetyl-D-glucosamine	n

Co-Q: 9 (van der Walt et al. 1989c).

Mol% G+C: 41.5–42.2, CBS 7319, CBS 7549, CBS 7550 (T_m : Smith et al. 1995a).

Origin of the strains studied: CBS 7319 (NRRL Y-17357), garden soil, Kanagawa Prefecture, Japan, J.P. van der Walt; CBS 7549, uncultivated soil, Bronkhorst-spruit District, Transvaal, South Africa, E.L. Jansen van Rensburg; CBS 7550, uncultivated soil, Frankfort, Orange Free State, South Africa, E.L. Jansen van Rensburg.

Type strain: CBS 7319 (NRRL Y-17357), isolated by J.P. van der Walt.

37.2. *Lipomyces kononenkoae* Nieuwdorp, Bos & Slooff (1974)

This species has two subspecies:

Lipomyces kononenkoae Nieuwdorp, Bos & Slooff ssp. *kononenkoae* (1995)

Lipomyces kononenkoae ssp. *spencer-martinsiae* van der Walt & M.Th. Smith (Smith et al. 1995a)

Growth in malt extract: After 7 days at 25°C, the cells are predominately globose, 5.0–8.5 µm in diameter, or rarely ellipsoidal, (4–5.8×5.5–8.5) µm. The cell walls and contents are faintly refractile, except those of the larger cells. Only a few small oil globules are present. After one month a sediment, a ring, and occasionally a thin, moist pellicle are present.

Growth on malt agar: After 7 days at 25°C, cells are mostly globose, 4–10 µm in diameter, or rarely ellipsoidal, (4.0–6.0×6.2–8.0) µm. Some cells produce a single bud. After one month, the streak culture is creamy-white, glistening and mucoid.

Dalmau plate culture on corn meal agar: Neither hyphae, nor pseudohyphae are formed.

Formation of ascospores: Conjugation of two “active” buds (Slooff 1970a), initiated on one parent cell, frequently precedes the formation of very thin-walled asci. Globose spores are formed and free spores often lie in a cluster in close contact with the parent cell (Fig. 108). Pear-shaped asci also occur, possibly arising from diploidized single buds. Two or more asci may occur on one parent cell. YM agar stimulates the development of protuberances; fully grown cells with protuberances may be transformed directly into asci. The usual number of spores per ascus is 8, but varies from 2 to 16.

Fig. 108. *L. kononenkoae* ssp. *kononenkoae*, CBS 2514 (Phaff and Kurtzman 1984). Globose spores within asci.

Sporeulation was observed on corn meal-, 1/10 V8, YM and 1/10 YM agars after 7 days at 25°C.

Fermentation: absent.

Assimilation:

Co-Q: 9 (Yamada et al. 1986c, Billon-Grand 1987).

Mol% G+C: 48.3, CBS 2514 (BD: Phaff and Holzschu, in Phaff and Kurtzman 1984); 47.0–48.0, CBS 2514, CBS 7535, CBS 8113, CBS 8114 (*T_m*: Smith et al. 1995a).

Supplementary description of *L. kononenkoae* ssp. *spencer-martinsiae*:

The subspecies *spencer-martinsiae* differs from the subspecies *kononenkoae* by its failure to assimilate D-xylose, galactitol and succinic acid. The assimilation of trehalose and ethanol is variable, and of glycerol is positive. The subspecies is able to grow at 40°C.

Origin of the strains of ssp. *kononenkoae* studied:

CBS 2514 (IFO 10375, NRRL Y-11553), soil of citrus orchard, Los Lomas, Trinidad, J.H. Becking; CBS 7535, soil, Magoeba's Kloof, Transvaal, South Africa, J.P. van der Walt; CBS 8113, CBS 8114, soil, South Africa, J.P. van der Walt.

Type strain: CBS 2514, isolated by J.H. Becking.

Origin of the strains of ssp. *spencer-martinsiae* studied:

CBS 5608 (ATCC 44833; NRRL Y-11554), soil, Nigeria, E. Drouhet; CBS 7534, soil, Pretoria district, Transvaal, South Africa, J.P. van der Walt; CBS 7543, soil, Kwa-Mbonambi State Forest Reserve, Natal, South Africa, J.P. van der Walt; CBS 7681, CBS 7682, soil, Bronkhorstspuit District, Transvaal, South Africa, J.P. van der Walt.

Type strain: CBS 5608, isolated by E. Drouhet.

Comments: In a study of species delimitation in the genus *Lipomyces* by genome comparisons (Smith et al. 1995a), it was shown that strains assigned to *L. kononenkoae* comprised two genetically discernable

entities characterized by an average nDNA relatedness of 47%. The heterogeneity of *L. kononenkoae* was first observed by Hossack and Spencer-Martins (1978) and Spencer-Martins (1983) who noted differences in lipid composition, amylolytic complexes, optimal growth temperature and utilization of β -cyclodextrin and D-deoxyglucose. Since the two taxa are phenotypically distinguishable, Smith et al. (1995a) proposed to subdivide *L. kononenkoae* into subspecies.

37.3. *Lipomyces lipofer* Lodder & Kreger-van Rij ex Slooff (1970a)

Synonyms:

Torulula lipofera den Dooren de Jong (1927)

Torulopsis lipofera (den Dooren de Jong) Lodder (1934)

Cryptococcus lipoferus (den Dooren de Jong) Skinner (1947b)

Waltomyces lipofer (Lodder & Kreger-van Rij ex Slooff) Y. Yamada & Nakase (1985)

Growth in malt extract: After 7 days at 25°C, growth is scant. The cells are granular, sometimes vacuolated, and globose to ellipsoidal, (3.2–8.0×5.0–12.0) μm . Walls and cells are faintly refractile, and sometimes contain a few small lipid globules. A thin ring may be present. After one month, some sediment forms and a few slimy islets may be present.

Growth on malt agar: After 7 days at 25°C, the cells are globose to ellipsoidal (4.0–8.0×5.0–14.0) μm , and contain vacuoles and small lipid granules. Large spheroidal cells that contain one large lipid globule may occur. After one month, the streak culture is white to cream-colored, glistening and pasty or mucoid.

Dalmau plate cultures on corn meal agar: Neither hyphae nor pseudohyphae are formed.

Formation of ascospores: Active buds that are formed on lipid-containing cells become transformed into asci as follows (Fig. 109):

(1) An active bud enlarges and the contents turn granular and divide into spores. The number of spores is 4 to 20, but sometimes less than 4.

(2) Two active buds on one cell fuse; the fusion product enlarges and develops into an ascus. The number of spores is 3 to 16.

(3) Two active buds on separate cells or on neighboring cells copulate; this case is infrequently observed in *L. lipofer*.

(4) An active bud, growing lengthwise, fuses with the conjugation tube of another cell; the two cells joined by a conjugation tube turn into one ascus. In this case the recipient cell frequently contains the greater part of the ascospores: 8–12 per ascus. Ascospores are ellipsoidal and contain an oil droplet. The color is olive-green to light amber. Malachite green is readily taken by the spores. The spore wall is smooth.

Fig. 109. *L. lipofer*, CBS 944. Asci with ascospores on Starkey's ethanol agar (Slooff 1970a).

Sporulation is observed on corn meal-, V8-, 1/10 V8, YM, 1/10 YM agars after one to two weeks.

Fermentation: absent.

Mol% G+C: 49.3, CBS 944 (BD: Phaff and Holzschu, in Phaff and Kurtzman 1984); 46.9–48.5, CBS 944, CBS 2513, CBS 5841, CBS 7603 (T_m : Smith et al. 1995a).

Origin of the strains studied: CBS 944 (ATCC 32031, IFO 1288, NRRL Y-2542), garden soil, Netherlands, L.E. den Dooren de Jong; CBS 2513 (IFO 10378, NRRL Y-11556), soil botanic garden, Leiden, Netherlands, J.H. Becking; CBS 5841 (ATCC 10742, IFO 10379, NRRL Y-1351), A.C. Thaysen; CBS 5842 (ATCC 32371, IFO 10380, NRRL Y-6333), soil, Wales, U.K., D. Jones; CBS 7602, cultivated podzolic soil, Biological Station of Perm University, Russia, I.P. Bab'eva; CBS 7603, cultivated meadow soil, Kirghiz, Armenia, I.P. Bab'eva.

Type strain: CBS 944, isolated by L.E. den Dooren de Jong.

Comments: *Lipomyces lipofer* is the only species in *Lipomyces* with the coenzyme Q-10 system. On the basis of this chemotaxonomic character, as well as ultrastructural differences in ascospore morphology (Smith and Batenburg-van der Vegte 1984), Yamada and Nakase (1985) transferred this species to the new genus *Waltomyces*. However, Kurtzman and Liu (1990) showed by molecular studies that *W. lipofer* and the remaining *Lipomyces* species are congeneric.

37.4. *Lipomyces starkeyi* Lodder & Kreger-van Rij (1952)

Growth in malt extract: After 7 days at 25°C, growth is scant. Cells are granular and some have vacuoles; lipid globules are scarce and small; cells are globose to ellipsoidal, (4–7×5–11)µm. Cell walls and contents are faintly refractile, except in some large globose cells and those cells that contain a single large lipid globule. A thin ring may be present. After one month, there are some small moist islets on the surface.

Growth on malt agar: After one week, the cells are similar as in malt extract, except that occasional large round cells with a single large lipid globule occur and the cells are only moderately granulated. After one month, the streak culture is white to light cream-colored, glistening, smooth, and very mucoid.

Dalmat plate culture on corn meal agar: Neither hyphae nor pseudohyphae are produced.

Formation of ascospores: Active buds developed by lipid-containing cells are transformed into asci by the same four processes as described for *L. lipofer*. The highest numbers of spores were found in asci derived from one active bud or from the fusion of two active buds (Fig. 107e,h) and may be 16 or more per ascus. The usual number in the type strain was 8 spores, but it may vary from 4–20. Other strains develop 2–6 spores per ascus, the usual number being 4. Starkey's strain number 72, which formerly sporulated with 1–4 spores per ascus, could no longer be induced to sporulate. In those cases where conjugation between bud and cell was involved, the number of spores did not exceed 8. Ascospores are ellipsoidal and contain an oil drop. The color is light amber to brown. Malachite green readily stains the spores. The spore wall is warty.

Sporulation was observed on Starkey's ethanol-, corn meal-, V8-, 1/10 V8-, YM-, 1/10 YM agars after two weeks.

Fermentation: absent.

Seigle-Murandi; and 12 strains more, isolated from soil of various locations in South Africa.

Type strain: CBS 1807, isolated by R.L. Starkey.

37.5. *Lipomyces tetrasporus* Nieuwdorp, Bos & Slooff (1974)

Synonyms:

Zygotipomyces tetrasporus Krasil'nikov, Bab'eva & Meavadh (1967) nom. nud.

Zygotipomyces lactosus Krasil'nikov, Bab'eva & Meavadh (1967) nom. nud.

Growth in malt extract: After 7 days at 25°C, the cells are globose to short-ellipsoidal, (4–7×4–9)µm, and occur singly, in pairs or in small clusters. A thin ring may be present. After one month, there is usually a ring and sometimes a mucoid pellicle as well as a small amount of sediment.

Growth on malt agar: The cells are similar to those in malt extract. After one month, the streak culture is

Fig. 110. *L. tetrasporus*, CBS 5910. Budding cells and asci with ascospores (Phaff and Kurtzman 1984).

white to light cream-colored, glistening, smooth, and very mucoid.

Dalmau plate culture on corn meal agar: Neither hyphae nor pseudohyphae are formed.

Formation of ascospores: The ascus develops from “active buds” or, more frequently, from a young cell conjugating by a tube with a bud from another cell. Often, fully grown cells develop ascospores without evident previous conjugation. There are 1–4 spores per ascus (Fig. 110). At maturity, the spores are released from the ascus. Ascospores are amber to brown and have lengthwise ridges.

Sporulation was observed on Starkey’s ethanol-, corn meal-, YM-, 1/10 YM agars after two weeks.

Fermentation: absent.

Type strain: CBS 5910, isolated by I.P. Bab’eva.

Comments on the genus

Since the treatment of Phaff and Kurtzman in the last edition of “The Yeasts” (1984), the genus *Lipomyces* and related genera of the Lipomycetaceae have been the subject of many morphological, biochemical and molecular studies. Morphological examinations concerned the ultrastructure of ascospore walls and septa (Smith and Batenburg-van der Vege 1984, Smith et al. 1995b). Biochemical studies were related to electrophoretic comparisons of enzymes (Yamazaki and Goto 1985, Yamada and Matsumoto 1988b), coenzyme Q systems (Yamada et al. 1986c, Billon-Grand 1987), carbohydrate profiles of whole-cell hydrolyzates (Weijman and van der Walt 1989), fatty acids and eicosanoids (Botha and Kock 1993, Cottrell et al. 1986, Cottrell and Kock 1989, Lomascola et al. 1994), electrophoretic karyotypes (Cottrell and Kock 1990), ferrichrome production (van der Walt et al. 1990a) and arachidonic acid metabolism (Kock et al. 1992). Molecular studies were focused on mtDNA analyses (Lodolo et al. 1990), ribosomal RNA sequence divergence (Kurtzman and Liu 1990, Yamada and Nogawa 1990b) and genome comparisons (Smith et al. 1995a).

The most relevant taxonomic proposals concerned two species. *Lipomyces anomalus* was transferred to the new genus *Babjevia* as *B. anomala* by Smith et al. (1995b) on the basis of molecular data from Kurtzman and Liu (1990) and Yamada and Nogawa (1990b), as well as because of the ultrastructure of septa and ascospore walls. *L. lipofer* was transferred to the new genus *Waltomyces* by Yamada and Nakase (1985) because it is the only species with coenzyme Q-10, a characteristic considered by some investigators to be important on the genus level. However, this transfer is not accepted in this treatment since Kurtzman and Liu (1990) showed *Waltomyces* and *Lipomyces* to be congeneric on basis of rRNA sequence divergence. For similar reasons, the proposed transfer of *L. japonicus* to *Smithiozyma* by Kock et al. (1995) has not been accepted.

38. *Lodderomyces* van der Walt

C.P. Kurtzman

Diagnosis of the genus

Asexual reproduction is by multilateral budding on a narrow base. Cells are spheroidal, ovoidal or elongate. True hyphae are not produced, but pseudohyphae are present.

Asci are unconjugated, persistent, and produce one, or rarely two, ellipsoidal to elongate ascospores.

Glucose and certain other sugars are fermented. Nitrate is not assimilated. Pellicles are not formed on the surface of liquid media. Coenzyme Q-9 is produced. Diazonium blue B reaction is negative.

Type species

Lodderomyces elongisporus (Recca & Mrak) van der Walt

Species accepted

1. *Lodderomyces elongisporus* (Recca & Mrak) van der Walt (1971)

Systematic discussion of the species

38.1. *Lodderomyces elongisporus* (Recca & Mrak) van der Walt (1971)

Synonyms:

Saccharomyces elongisporus (as *S. elongasporus*) Recca & Mrak (1952)

Lodderomyces elongisporus (Recca & Mrak) van der Walt (1966a) nom. inval.

Growth on 5% malt extract agar: After 3 days at 25°C, the cells may occasionally be spheroidal but they usually are ellipsoidal to elongate (2.6–6.3) × (4.0–7.4) μm, and occur singly, in pairs, or in small clusters. Growth is butyrous, faintly glistening, and tannish-white in color.

Growth on the surface of assimilation media: Pellicles are not formed.

Dalmou plate culture on morphology agar: After 7 days at 25°C, growth under the coverglass shows abundant well-branched pseudohyphae with blastoconidia. True hyphae are not formed. Aerobic growth is tannish-white, butyrous, smooth and glistening. Single colonies are low convex with a raised center. A faintly acidic odor is present.

Formation of ascospores: Asci are unconjugated, persistent, and transformed from vegetative cells. Each ascus forms one, rarely two, long-ellipsoid shaped ascospores (Fig. 111). Van der Walt (1984b) reported heat-treated ascosporeogenous cultures to give only colonies that were ascosporeogenous. However, it is not certain that this species is homothallic because the ploidy of the ascospores is unknown.

Ascospores were observed on V8 agar after 7–10 days at 25°C.

Mol% G+C: 39.9, 39.5, CBS 2605, CBS 2606 (T_m : Meyer and Phaff 1969).

Origin of the strains studied: CBS 2605 (NRRL YB-4239), type strain of *Saccharomyces elongasporus*, from concentrated orange juice; CBS 2606 (NRRL YB-4240), soil, South Africa, from J.P. van der Walt; CBS 5912 (NRRL Y-7681), from a finger nail, Finland; CBS 6182 (NRRL Y-7682), from baby cream, Netherlands.

Type strain: CBS 2605, from concentrated orange juice.

Comments on the genus

Recca and Mrak (1952) described *Saccharomyces elongasporus* for a strain isolated from concentrated orange juice. Van der Walt (1966a) pointed out that *S. elongasporus* was unique among species of *Saccharomyces*

because of its elongated ascospores and capability to assimilate higher paraffins such as decane and hexadecane. Because of these unique properties, van der Walt (1966a) described the genus *Lodderomyces* for *S. elongasporus*, and then later revalidated the genus (van der Walt 1971).

Because of phenotypic similarities, *L. elongisporus* had been considered the teleomorph of *Candida parapsilosis*. Meyer and Phaff (1972) demonstrated from comparisons of nDNA relatedness that the two taxa are separate species. Nakase et al. (1979) reported that isolates designated *C. parapsilosis* form II represented the anamorph of *L. elongisporus*, and the isozyme comparisons of Yamazaki and Komagata (1982a) supported this proposal. Hamajima et al. (1987) confirmed from nDNA complementarity that strains of *C. parapsilosis* form II represent the anamorph of *L. elongisporus*. Interspecific relationships among members of the *Lodderomyces* complex have been assessed from comparisons of 18S rRNA/rDNA sequences. Barns et al. (1991) showed a close relationship between *C. parapsilosis*, *C. tropicalis*, *C. viswanathii* and *C. albicans*, and James et al. (1994a) reported *L. elongisporus* to be closely related to *C. parapsilosis*.

39. *Metschnikowia* Kamienski

M.W. Miller and H.J. Phaff

Diagnosis of the genus

Vegetative reproduction is by multilateral budding. Cells are spheroidal to ellipsoidal, as well as pyriform, cylindroid, or lunate. Pseudomycelium is rudimentary, rarely lacking.

Asci are elongate: clavate, sphaeropedunculate or ellipsoidopedunculate. Ascospores are needle-shaped, attenuate at one or both ends, and without a whip-like appendage. One or two spores form per ascus, depending on the species.

Some species are parasitic in invertebrates, as well as free-living in aquatic habitats; others are terrestrial, free-living, and often associated with flowers.

Sugars are fermented by most species. Nitrate is not assimilated. Ubiquinone system is Co-Q 9. Diazonium blue B reaction is negative.

^b Ploidy of vegetative cells.

^c Number of spores per ascus.

Systematic discussion of the species

39.1. *Metschnikowia agaves*¹ Lachance (1993)

Growth in glucose (2%) yeast extract (0.5%) broth:

After 3 days at 25°C, the cells are ovoidal to ellipsoidal, occur singly, in parent–bud pairs, or occasionally in short chains and measure (2–4)×(3–7) μm. A sediment and a diffuse but thick ring are formed after one month.

Growth on 5% malt agar: After 2 weeks at 17°C, colonies are small, low convex, glabrous, smooth, white and butyrous to chalky.

Dalmau plate cultures on corn meal agar: After 2 weeks, no pseudohyphae or true hyphae are formed.

Formation of ascospores: After 1 day on Yeast Carbon Base agar (without added nitrogen source), mixed strains of complementary mating types give rise to long (several cell lengths) conjugation tubes, or elongated cells. Conjugated pairs and zygotes are also present. After 3 days at 25°C, mature asci are present, pleiomorphic in shape but usually quasi-cylindrical and conjugated. Two acicular ascospores, 15–20 μm in length, are formed in one of the two conjugated parent cells forming the ascus (Fig. 112). In some cases the spores stretch the ascus into a single tubular shape. Ascospores are not liberated at maturity.

Co-Q: Not determined.

Mol% G+C: Not determined.

Origin of the strains studied: Both type and isotype strains were isolated from basal rots of leaves of blue agave plants (*Agave tequilana* var. *azul*), Jalisco, Mexico.

¹ The original spelling of the species name as *agaveae* has been treated as an orthographic error.

Fig. 112. Phase contrast micrographs of *M. agaves*. One day after mixing compatible strains on Yeast Carbon Base agar (with no added nitrogen), cells with conjugation tubes or elongated cells (a) fuse to form zygotes (b), which after three days give rise to asci (c,d) containing two (d) acicular ascospores. Bar = 5 μ m. Courtesy Lachance (1993).

Complementary mating types: CBS 7744, mating type h^+ and CBS 7745 (UWO(PS) 92-210.1), mating type h^- .

Type strain: CBS 7744 (UWO(PS) 92-207.1, designated as mating type h^+).

Comments: The characteristics of this species are from Lachance (1993) as the culture was not available for study. *Metschnikowia agaves*, like *M. hawaiiensis* and *M. australis*, occurs in nature in the form of separate haploid mating types. Lachance mixed the mating types of *M. hawaiiensis* and of *M. agaves* in all possible combinations on Yeast Carbon Base and examined the mixtures after 3 and 7 days. He observed intraspecific crosses in both species, resulting in abundant asci and spores, whereas the four interspecific crosses showed no sign of mating activity. He considered this as evidence that *M. agaves* represented a distinct species. *M. agaves* grows well at 37°C in contrast to other haploid *Metschnikowia* species and is unable to assimilate glycerol.

39.2. *Metschnikowia australis* (Fell & I.L. Hunter) Mendonça-Hagler, Phaff & Tredick (1985)

Synonym:

Metschnikowia bicuspidata var. *australis* Fell & I.L. Hunter (1968)

Growth in 5% malt extract: After 7 days at 18°C, cells are spheroidal to ovoidal, (3–5) × (6–8) μ m, single, in pairs or small groups. After 2 weeks there is a sediment and a light ring, but no pellicle.

Growth on 10% malt agar: Cell morphology is similar to that in malt extract. After 2 weeks the streak culture is semi-dull, smooth, white, texture soft, the cross-section is flat and the periphery entire.

Dalmat plate culture on corn meal agar: At 18°C pseudomycelium formation is absent or spotty. If present, its development is rudimentary.

Formation of ascospores: Following the conjugation of two haploid cells of complementary mating types, a large clavate ascus develops, containing two acicular spores. Asci and spores vary in length from about 25 to 40 μ m. Asci do not lyse or discharge the spores at maturity.

Sporeulation occurs on dilute (2%) malt agar at 12°C after 5–10 days.

Fermentation: absent.

Assimilation:

In YNB media + 2 % NaCl at 18°C.

Co-Q: 9 (Y. Yamada, personal communication, 1990).

Mol% G+C: 47.0, CBS 5847, mating type *a* (BD: Mendonça-Hagler et al. 1985).

Origin of the strains studied: CBS 5847, CBS 5848, UCD-FST 68-48, 68-49, 68-50 and 68-51. All strains were isolated from antarctic seawater and obtained from J.W. Fell.

Complementary mating types: CBS 5847 mating

type *a*, and CBS 5848 mating type α , both isolated as haploid cells.

Type strain: CBS 5847 (NRRL Y-7013), designated as the holotype.

Comments: Mendonça-Hagler et al. (1985) investigated the DNA relatedness among aquatic members of the genus *Metschnikowia*. *M. bicuspidata* var. *australis* DNA showed 37–51% relative binding with the DNAs of *M. bicuspidata* var. *bicuspidata* and of its varieties *chathamia* and *californica* (Fell and Hunter 1968, Pitt and Miller 1970a). On this basis, as well as reduced intervarietal fertility (Pitt and Miller 1970b) and unique habitat in antarctic seawater, Mendonça-Hagler et al. (1985) proposed raising the variety *australis* to the rank of species, which we support.

39.3. *Metschnikowia bicuspidata* (Metschnikoff) Kamienski (1899)

This species has three varieties:

Metschnikowia bicuspidata (Metschnikoff) Kamienski var. *bicuspidata* (1969)

Synonyms:

Monospora bicuspidata Metschnikoff (1884)

Monosporella bicuspidata (Metschnikoff) Keilin (1920)

Metschnikowiella bicuspidata (Metschnikoff) Kudryavtsev (1960)

Metschnikowia kamienskii Spencer, Phaff & Gardner (1964)

Metschnikowia wickerhamii Codreanu & Codreanu-Balcescu (1981)

Metschnikowia bicuspidata var. *californica* Pitt & M.W. Miller (1970a)

Metschnikowia bicuspidata var. *chathamia* Fell & Pitt (1969)

Growth in 5% malt extract: After 3 days at 25°C, vegetative cells are mostly ellipsoidal to cylindrical (3–8) × (3–13) μm , in some strains globose, 5–8 μm , or elongate, 23–35 μm , in length. Reproduction is by multilateral budding, cells occur singly or are catenulate. After one month, large refractile globose cells, 7–10 μm , containing a lipid globule, may be present. A ring and abundant sediment are formed, a pellicle is absent.

Growth on 10% malt agar: After one month at 25°C, the growth is cream-colored, the surface is smooth, or in occasional strains rugose, the edge entire or crenulate.

Fig. 113. *M. bicuspidata* var. *bicuspidata*, CBS 5575. Asci formed on V8 agar after 8 days at 25°C. Bar = 10 μm .

Dalmau plate culture on corn meal agar: Rudimentary pseudomycelium is formed, usually profusely.

Formation of ascospores: Asci arise from vegetative cells and are generally clavate, although less regular shapes are also formed, measuring (3–7) × (15–45) μm , sometimes to 60 μm , containing two, often appearing as one, acicular ascospores (0.7–1.1) × (15–50) μm (Fig. 113). Asci have been observed to discharge the spores in some strains through the tip.

Sporulation occurs after 7–20 days on V8 agar or on diluted (1:9) V8 agar at 14–25°C.

Co-Q: 9 (Yamada et al. 1977).

Mol% G + C: 48.0, CBS 5575 (BD: Mendonça-Hagler et al. 1985).

Supplementary description of *M. bicuspidata* var. *californica*: The variety *californica* assimilates α -methyl-D-glucoside well, shows strong growth in the presence of 1 $\mu\text{g}/\text{ml}$ cycloheximide and weak growth with 10 $\mu\text{g}/\text{ml}$. These differences allow it to be separated from the variety *bicuspidata* using standard growth tests.

Mol% G + C: 47.6, CBS 6010 (BD: Mendonça-Hagler et al. 1985).

DNA complementarity between the variety *californica* and the type strain of the variety *bicuspidata* was reported to be 86% (Mendonça-Hagler et al. 1985). The habitat of the two varieties differs. All strains of the variety *californica* came from sea water or kelp off the coast

of southern and central California, while most strains of the variety *bicuspidata* originated in salt lakes, often associated with diseased brine shrimp, and sometimes in fresh water lakes, possibly associated with *Daphnia magna* or with trematode sporocysts.

Supplementary description of *M. bicuspidata* var. *chathamia*:

The variety *chathamia* assimilates α -methyl-D-glucoside well, but does not assimilate D-gluconate and 2-keto-D-gluconate. These differences allow it to be separated from the variety *bicuspidata* using standard growth tests. In addition, some strains grow weakly or latently on ribitol. Growth in the presence of 1 μ g/ml cycloheximide is good, but absent with 10 μ g/ml. Maximum growth temperature is 30°C. DNA complementarity between the variety *chathamii* and the type strain of the variety *bicuspidata* was reported to be 81%.

Mol% G+C: 47.5 (BD: Mendonça-Hagler et al. 1985).

Origin of the strains belonging to the variety *bicuspidata*: Sporocysts of *Diplostomum flexicaudum* (5); brine shrimp (*Artemia salina*) (13); *Castolia odorata* from a lake in Wisconsin (1).

Complementary mating types: CBS 5902 (*a*) and CBS 5903 (*α*).

Type strain: CBS 5575, selected as neotype by L.J. Wickerham, who first isolated it in culture from sporocysts of the parasitic strigeid trematode *Diplostomum flexicaudum* inhabiting the digestive gland of the snail *Stagnicola emarginata angulata* in a fresh water lake in Michigan.

Origin of the strains belonging to the variety *californica*: Sea water or kelp off the coast of California from San Diego to Point Reyes in central California (23).

Type strain: CBS 6010 (UCD-FST 67-100) isolated by Phaff from Pacific ocean water near Point Reyes, California.

Origin of the strains belonging to the variety *chathamia*: Fresh water ponds on Chatham Island, New Zealand (3).

Type strain: CBS 5980 (IMS 23-414, UCD-FST 67-2) isolated by Fell from a fresh water pond near the ocean on Chatham Island.

Comments: Retaining the three varieties of *M. bicuspidata* (Table 30) was based on differences in metabolic profiles, biogeography and habitat. The varieties show interfertility (Pitt and Miller 1970a) and DNA relatedness values ranging from 81 to 86% compared with the variety *bicuspidata* (Mendonça-Hagler et al. 1985). The former variety *australis* (Fell and Hunter 1968) was elevated to the rank of species by Mendonça-Hagler et al. (1985).

Strains of the three varieties comprising the species *M. bicuspidata* are morphologically and physiologically quite similar, and related by their fresh water or marine habitat, ascus shape, number of ascospores and interfertility between mating types. The variety *bicuspidata*

is generally homothallic although heterothallic haploids have been obtained (Wickerham 1964a), apparently by a parasexual mechanism as described by Pitt and Miller (1970b). These haploids are capable of hybridizing with the other heterothallic varieties and producing sparsely sporulating hybrids.

Some strains of the variety *bicuspidata*, i.e., those designated as *M. kamienskii*, in general had slightly lower maximum temperatures for growth (27–28°C) than the strains obtained from sporocysts which generally grew at 30–34°C.

The nine strains of the variety *bicuspidata* which we isolated from diseased *Artemia salina* taken from salt ponds (ca. 10% NaCl) in southern California (Lachance et al. 1976), initially did not grow in the usual assimilation media unless they were supplemented with 2% NaCl.

Asci of these strains have been observed to discharge their spores from the tip of the peduncle, occasionally quite forcefully. The ecological implication and the possibility of active mechanical predation for the variety *bicuspidata* have been discussed by Lachance et al. (1976), who misidentified these strains as *M. bicuspidata* var. *australis*.

39.4. *Metschnikowia gruessii* Giménez-Jurado (1992)

Synonyms:

Anthomyces reukaufii Grüss (1918)

Nectaromyces reukaufii (Grüss) H. Sydow & P. Sydow (1918)

Nectaromyces cruceatus Schoellhorn (1919)

Growth in glucose (2%)–yeast extract (0.5%)–peptone (1%) broth: After 3 days at 25°C, the cells are variable in shape and size, ovoidal, ellipsoidal, sometimes cylindrical and measure (2.5–6.3) × (8.8–27.5) μ m. Cells are usually in pairs or in groups of four giving rise to characteristic “airplane” or trident configurations. After one week, refractile, ovoidal chlamyospores, (5.0–12.5) × (10.0–15.0) μ m, with one or more lipid globules are present. No ring or pellicle is formed.

Growth on glucose (2%)–yeast extract (0.5%)–peptone (1%) agar: After one week at 25°C, most strains form colonies which are cream-colored, smooth, often papillate and glistening. Colony shape is slightly raised and convex with an entire margin. Texture is butyrous.

Dalmu plate cultures on corn meal agar: After 7 days at 25°C, growth under the coverslip consists of short chains of stalagmoid cells with ovoid blastoconidia. Chlamyospores and “airplane” configurations are also present.

Formation of ascospores: Asci may originate from cells and from chlamyospores which elongate at one end to a peduncle. The ellipsoidopedunculate asci measure (6.3–7.5) × (31.3–60.0) μ m and contain 2 acicular to acerose ascospores that are pointed at one end, often appearing bifurcate, and are not released from the ascus at maturity.

Sporulation occurs after one week on dilute (1:14) V8 agar at 17°C.

Co-Q: 9 (79%), Q-8 (9.2%) (Giménez-Jurado 1992).

Mol% G + C: 39.2, CBS 7657 (T_m : Giménez-Jurado 1992).

Origin of the strain studied: Only the type strain was available to us for study and most of the characteristics given are based on the publication by Giménez-Jurado (1992).

Type strain: CBS 7657 (IGC 4382) isolated from the nectaries of *Hebe salicifolia*, Oeiras, Portugal.

Comments: Henriques et al. (1991) developed a ribosomal DNA spacer probe specific for the type strain of *M. reukaufii*. While the probe did not hybridize with other species of *Metschnikowia*, they noted that one strain identified as *M. reukaufii* also did not hybridize with the probe. DNA–DNA hybridization between *M. reukaufii* and the atypical strain revealed only 10% DNA complementarity. In addition, the G+C content of the DNA of the atypical strain was found to be approximately 4 mol% lower than that of the type strain of *M. reukaufii*, virtually precluding conspecificity (Kurtzman and Phaff 1987). Henriques et al. (1991) concluded that the non-reacting strain represented a species different from *M. reukaufii*. A detailed description of this strain as a new species of the genus *Metschnikowia*, *M. gruessii*, was subsequently published by Giménez-Jurado (1992). Besides low DNA reassociation values between the DNAs of *M. gruessii*,

M. reukaufii, and of several additional strains, Giménez-Jurado was able to separate *M. gruessii* phenotypically by the lack of assimilation of trehalose versus strong growth by *M. reukaufii* and the formation of airplane or trident configurations in a 20% honey solution. Additionally, we found in our review that *M. gruessii* does not grow on 2-keto-D-gluconate, whereas *M. reukaufii* shows good growth on this compound.

Giménez-Jurado (1992) also noted that *M. gruessii* and *M. reukaufii* frequently occur side by side in various flower species, but that the latter is far more common. Included in Giménez-Jurado's study was an authentic strain, labeled *Nectaromyces reukaufii* (IGC 3275), that had been studied by Grüss (1918) and various later investigators, who considered it as a synonym of *Candida reukaufii* or an anamorph of *M. reukaufii*. This strain shared 97% of its base sequences with *M. gruessii*, evidencing synonymy with that species. We also have listed *Anthomyces reukaufii* as a synonym of *M. gruessii*, as this was the name originally given by Grüss to the strain that was later renamed *Nectaromyces reukaufii* by H. Sydow and P. Sydow (1918) because *Anthomyces* was a later homonym and thus illegitimate. *Nectaromyces cruciatus* is also assumed to be a synonym of *M. gruessii* because Schoellhorn (1919), who also studied the isolate of Grüss, described it as *Nectaromyces cruciatus*, apparently unaware of the other publications on this yeast cited above.

39.5. *Metschnikowia hawaiiensis* Lachance, Starmer & Phaff (1990)

Growth in 5% malt extract: After 3 days at 25°C, the haploid cells are short ovoidal to ellipsoidal, occur singly, in pairs or as cells with several buds, and measure (2–4) \times (4–6) μ m. A sediment is formed after 2 to 3 weeks.

Growth on 10% malt extract agar: After 2 weeks at 17°C, colonies are large, low convex to umbonate, glabrous, smooth, white, and butyrous. Some cells develop long tubular outgrowths instead of buds.

Dalmat plate cultures on corn meal agar: Branching true hyphae with rare, phase-dark septa are formed after 2 weeks.

Formation of ascospores: As early as 6 hours after mixing of complementary mating types on 1% malt extract agar, conjugation tubes appear on some cells. After 8 hours conjugated pairs and zygotes are present, some with wide, tubular outgrowths. After 1 day, tubular, conical asci, some exceeding 200 μ m in length, may be formed (Fig. 114). Most asci retain signs of the original conjugating pair of parental cells. Two large acicular ascospores (140–180 μ m long) are produced per mature ascus (Fig. 115). The spores are not released from the ascus at maturity.

Fermentation:

Co-Q: Not determined.

Mol% G + C: 46.6–46.7, two strains, CBS 7432 (type) and CBS 7433 (isotype) (BD: Lachance et al. 1990).

Origin of the strains studied: Morning glory flowers (*Ipomoea acuminata*) on the island of Hawaii (5); *Scaptomyza calliginosa* (7) and *Drosophila floricola* (1), both of which breed in morning glory flowers on the island of Hawaii.

Complementary mating types: CBS 7432 and CBS 7433.

Type strain: CBS 7432, isolated from a morning glory flower, island of Hawaii.

39.6. *Metschnikowia krissii* (van Uden & Castelo-Branco) van Uden (1962)

Synonym:

Metschnikowiella krissii van Uden & Castelo-Branco (1961)

Growth in 5% malt extract: After 3 days at 25°C, the cells are spheroidal to ellipsoidal, (4.5–6)×(6–11) µm; elongate cells, (4.5–6)×(11–13) µm, also occur. A thin ring may be formed.

Growth on 10% malt agar: After one month at 25°C, the streak culture is yellowish, semidull, soft, and delicately punctulate to smooth.

Dalmau plate culture on corn meal agar: A rudimentary pseudomycelium is formed.

Formation of ascospores: Asci arise from diploid vegetative cells and are generally clavate, 18–26 µm long, and contain a single, needle-shaped ascospore, which is pointed at one end and nearly as long as the respective ascus.

Asci were observed on V8 agar after 10–14 days at 16°C.

Fermentation: absent.

Co-Q: 9 (Yamada et al. 1977).

Mol% G+C: 45.4, CBS 4823 (BD: Mendonça-Hagler et al. 1985).

Origin of the strains studied: Sea water off the southern California coast (4).

Type strain: CBS 4823, isolated by van Uden and Castelo-Branco (1961) from sea water off La Jolla, California.

39.7. *Metschnikowia lunata* Golubev (1977)**Synonyms:**

Schizoblastosporion kobayashii Soneda & Uchida (1971)

Selenotila intestinalis Krasil'nikov (1927)

Selenozyma intestinalis (Krasil'nikov) Yarrow (von Arx et al. 1977)

Growth in 5% malt extract: After 3 days at 25°C, the cells are lunate, (2–4)×(5–8)µm, or rarely ovoidal, (2.5–5)×(3.5–8)µm, and single or in pairs (Fig. 116). A slight sediment is formed. After one month at 20°C, a sediment and ring are present. Pulcherrima cells, (8–10.5)×(8–12)µm, are present and may have two small, pointed protrusions.

Growth on 10% malt agar: After one month the streak culture is cream-colored, mat, with a smooth surface, pasty, slightly convex with an entire border. Pulcherrimin is not produced.

Dalmau plate culture on corn meal agar: A rudimentary pseudomycelium is formed.

Formation of ascospores: Asci arise from spheroidal chlamydospores, which generally contain a single, prominent lipid globule. The lipid globule is no longer present in the ascus. Asci are ellipsoidopedunculate; the ellipsoidal part measures (7–10)×(7–12)µm, whereas the peduncles

are cylindrical and measure (2–4)×(13–40)µm. Asci contain one to two acicular ascospores (Fig. 117).

Asci are produced on dilute (1:9) V8 agar at 15°C after 10 days.

Asporomyces wuae Mrak & McClung (1940)

Torulopsis dattila (Kluyver) Lodder var. *rohrbachense* von Szilvinyi & Kaulich (1948)

Torulopsis burgeffiana Benda (1962)

Growth in 5% malt extract: After 3 days at 25°C, vegetative cells are globose to ellipsoidal, (2.5–6) × (4–10) μm, usually (2.5–5) × (4–7) μm, single, reproducing by multilateral budding. Chlamydozoospores (*pulcherrima* cells) are not present. After one month at 25°C, *pulcherrima* cells are usually present, highly refractile, globose, (4) × (7–11) μm, or subglobose, containing a single lipid globule, occasionally more than one (Fig. 118); a thin ring and abundant sediment are present, a pellicle is absent.

Growth on 10% malt agar: After one month at 25°C, growth is cream-colored, or if *pulcherrimin* pigment is produced, reddish-brown (sometimes in sectors). The surface is smooth and glistening, in some strains sparsely papillate, edge entire. *Pulcherrimin* pigment usually diffuses into the medium.

Fig. 118. *M. pulcherrima*, CBS 5833. Vegetative and *pulcherrima* cells on malt agar after 6 days. Bar = 10 μm.

Fig. 119. *M. pulcherrima*, CBS 5833. Ascus with distinctly separated ascospores formed on dilute, filtered V8 agar incubated for 2 weeks at 15°C. Bar = 5 μm.

Dalmau plate culture on corn meal agar: Aerobically, pseudomycelium is not produced; anaerobically, rudimentary pseudomycelium is formed, often profusely.

Formation of ascospores: Asci arise from spheroidal chlamydozoospores, with one or more prominent lipid globules (Fig. 118). The lipid globules disappear during ascus development. Asci are sphaeropedunculate, (4–11) × (15–55) μm, usually (6–8) × (20–42) μm, peduncles are cylindrical, (1.0–2.5) × (10–45) μm, usually (1.5–2) × (15–30) μm, containing two, sometimes one, acicular to filiform ascospores, (0.4–1.5) × (9–27) μm (Fig. 119). In some strains, asci were observed to lyse at the peduncle extremity.

Asci are formed on dilute, filtered V8 juice agar, and other dilute media (1:9; 1:29), after incubation for 5–21 days at 12–21°C (Pitt and Miller 1968).

Co-Q: 9 (Yamada and Kondo 1972b).

Mol% G + C: 45.6, CBS 5833 (BD: Mendonça-Hagler et al. 1985).

Origin of the strains studied: Flowers from N.W. Canada (9); flowers and spoiled fruit in California (11); *Drosophila* spp. (4); from exudates of buckeye (*Aesculus*), birch (*Betula*), and willow (*Salix*) spp. in Japan and the U.S. Pacific Northwest (4).

Type strain: CBS 5833, isolated by Mrak and McClung (1940) from grapes.

Comments: As is evident from the number of synonyms of *M. pulcherrima*, a number of yeasts or yeastlike isolates were not recognized initially as members of that species or its anamorph. For example, Castellani (1925) isolated several yeast strains from diseased tissues of human patients which he referred to as *Monilia* sp. or *Cryptococcus* sp. Re (1925) subsequently described these isolates as *Monilia castellanii* or *Cryptococcus castellanii* to provide tentative binomials for the isolates. Castellani (1928) referred to the isolates as *Cryptococcus castellanii* but he and Jacono (1933) changed the name to *Torulopsis castellanii*. Finally, Langeron and Guerra (1941) recognized that these strains were representatives of *Torulopsis pulcherrima*, because they produced a characteristic maroon pigment on media supplemented with ferric ions and produced large lipid-containing chlamydo-spores.

Langeron and Guerra (1941) also reidentified a species named *Cryptococcus interdigitalis* by Pollacci and Nannizzi (1926) as a strain of *Torulopsis pulcherrima*. Lodder (1934) had previously considered *Cryptococcus interdigitalis* as a variety of *T. pulcherrima*.

Anamorph: *Candida reukaufii* (Grüss) Diddens & Lodder

Synonyms:

Candida reukaufii (Grüss) Diddens & Lodder (1942)

Chlamydozyma reukaufii Wickerham (1964a)

Chlamydozyma zygota Wickerham (1964a)

Metschnikowia zygota Fell & I.L. Hunter (1968)

?*Candida rancensis* C. Ramírez & A. González (1984h)

Growth in 5% malt extract: After 3 days at 25°C, vegetative cells are ellipsoidal to cylindroidal, (2–6) × (4–18) µm, usually (2–4) × (6–12) µm, single or catenulate, reproducing by multilateral budding. In some strains longer cells occur, up to 35 µm. Chlamydo-spores are not present. After one month at 25°C, somewhat elongate chlamydo-spores are usually present, (4–10) × (8–30) µm, but usually (8–10) × (10–20) µm. They are highly refractile, and contain several to numerous lipid globules (Fig. 120); a thin ring and abundant sediment are present; a pellicle is absent.

Growth on 10% malt agar: After one month at 25°C, growth is cream-colored, the surface is smooth and glistening, in some strains sparsely papillate, and the edge is entire to crenulate.

Dalmu plate culture on corn meal agar: Aerobically, pseudomycelium is not produced; anaerobically, rudimentary pseudomycelium is profusely formed.

Formation of ascospores: Asci arise from somewhat elongated chlamydo-spores that contain several to numerous lipid globules. Asci are ellipsoidopedunculate to clavate, (5–9) × (20–43) µm, usually (5–8) × (30–37) µm, containing two (rarely one) acicular to acerose ascospores, (0.7–1.1) × (7–30) µm (Fig. 121). Asci do not lyse at maturity.

Asci develop on dilute (1:2 to 1:29), filtered V8 juice agar, and other dilute media after 7–21 days at 12–21°C (Pitt and Miller 1968).

Type strain: CBS 4821, isolated by van Uden and Castelo-Branco (1961) from sea water off La Jolla, California.

Comments on the genus

The 10 species in the genus *Metschnikowia* are characterized by the formation of long needle-shaped or acicular ascospores without appendages. The asci are much larger than the vegetative cells. Six of the species have a terrestrial habitat and are usually found in the corolla of flowers or in decaying fruit or plant tissue; they are transmitted to new niches by insects, such as bees and drosophilids. The other four species (including two varieties) have aquatic habitats (marine, salt lakes or fresh water) and are usually associated with crustacean species and sometimes with fish or kelp. They may be pathogenic to certain crustaceans, e.g., brine shrimp (*Artemia*) and fresh water shrimp (*Daphnia*) (Lachance et al. 1976). Four of the terrestrial species form chlamydo spores that are precursors of asci. The other two terrestrial species and the aquatic species lack chlamydo spores and form asci from diploid vegetative cells or from zygotes of haploid complementary mating types (Table 30).

Characteristics differentiating the species include fermentation of glucose, assimilation of various carbon compounds (Table 30), maximum temperature for growth, growth on media with high osmotic pressure, and ploidy of the vegetative cells. The production of pulcherrimin by *M. pulcherrima* is variable and therefore not always a reliable diagnostic character. Mendonça-Hagler et al. (1993) estimated phylogenetic relationships among type strains

of the eight *Metschnikowia* species known at the time of their study. The extent of divergence of partial sequences of the large and small subunits of rRNA suggested that the aquatic and terrestrial species form two clusters within the genus. Among the terrestrial species, *M. lunata* and *M. hawaiiensis* were well separated from the others, with the latter so divergent that it might even be placed in a new genus. This study did not include the two recently described terrestrial species, *M. agaves* and *M. gruessii*.

Codreanu and Codreanu-Balcescu (1981) reported isolating *Metschnikowia* strains producing monosporic asci from infected *Artemia* and *Daphnia* specimens in Rumania. They proposed that these strains represented the original isolates made by Kamienski (1899) from *Artemia salina* and from *Daphnia magna* by Metschnikoff (1884), and that Wickerham's (1964a) neotype of *M. bicuspidata*, which formed two spores per ascus, should be rejected. Unfortunately, as far as we are aware, no strains isolated by the Rumanian team have been preserved or tested physiologically. Although their electronmicrographs clearly show that the asci contain single acicular spores, it is entirely possible that the number of spores per ascus varies from one to two, as is common in many other yeast genera. The present authors have therefore retained Wickerham's two-spored isolate of *M. bicuspidata* from a strigeid trematode as the neotype of *M. bicuspidata*.

40. *Nadsonia* Sydow

M.W. Miller and H.J. Phaff

Diagnosis of the genus

Cells are lemon-shaped, ovoidal, or elongate. Vegetative reproduction by bud-fission at both poles; this process involves the formation of a bud-like structure on a very wide neck. The bud is separated by the formation of a cross wall, followed by fission. Pseudomycelium is not formed; a few chains of elongate cells may be present.

Two mechanisms of ascospore formation are known. (1) After a heterogamic conjugation between the parent cell and a bud, the contents of the zygote move into another bud formed at the opposite end of the parent cell. This second bud is then delimited by a septum and becomes the ascus. (2) After a heterogamic conjugation between the parent cell and a bud, the bud is normally delimited by a septum and the parent cell becomes the ascus. One or more, rarely two, spherical, brownish, spiny- to warty-walled spores are formed. Spores contain a prominent lipid globule.

Fermentation of glucose is present or absent. Nitrate is not utilized. No growth at 30°C or above. On malt extract a pellicle is usually formed. Diazonium blue B reaction is negative.

Type species

Nadsonia fulvescens (Nadson & Konokotina) Sydow

Species accepted

1. *Nadsonia commutata* Golubev (1973)
2. *Nadsonia fulvescens* (Nadson & Konokotina) Sydow (1912)
 - a. *Nadsonia fulvescens* (Nadson & Konokotina) Sydow var. *fulvescens* (1989)
 - b. *Nadsonia fulvescens* var. *elongata* (Konokotina) Golubev, M.Th. Smith, Poot & Kock (1989)

Key to species

1. a. Glucose fermented; growth in presence of 1 µg/ml cycloheximide positive → 2
 b. Glucose not fermented; absence of growth in presence of 1 µg/ml cycloheximide *N. commutata*: p. 268
- 2(1). a. Maltose assimilated *N. fulvescens* var. *fulvescens*: p. 269
 b. Maltose not assimilated *N. fulvescens* var. *elongata*: p. 269

Systematic discussion of the species

40.1. *Nadsonia commutata* Golubev (1973)

Growth in 5% malt extract: After 3 days at 15°C, cells are ovoidal to apiculate, (4.2–7.7) × (5.6–11.2) µm, single, in pairs or in short chains; budding is bipolar on a broad base (Fig. 123). After one month a ring and sediment are formed, sometimes a pellicle.

Growth on 10% malt agar: Cell shapes and dimensions similar to those observed in malt extract. After one month at 18°C, the streak culture is cream-colored (brownish in sporulating cultures), smooth, semiglossy, texture is pasty and the border is entire to lobate.

Dalmau plate culture on potato agar: Pseudomycelium is not formed.

Formation of ascospores: Asci are formed by mechanism (2), following lysis of the wall separating a parent cell and a polar bud; the nucleus and other contents of the bud pass into the parent cell where karyogamy and meiosis take place. A new septum is produced separating the zygote from the bud. The parent cell, which has become the ascus, normally contains a single or rarely

two spheroidal, spiny to warty, brownish spores with a prominent lipid globule (Fig. 124).

Sporulation occurs on YM or malt agar at 18°C in 7 days.

Fermentation: absent.

Origin of the strains studied: CBS 6640 from field soil, East Falkland Island (South Atlantic ocean) (Golubev 1973); VKM Y-2610 from soil, Carpathian Mts., Eastern Europe.

Type strain: CBS 6640 (VKM Y-1573).

40.2. *Nadsonia fulvescens* (Nadson & Konokotina) Sydow (1912)

This species has two varieties:

Nadsonia fulvescens (Nadson & Konokotina) Sydow var. *fulvescens* (1989)

Synonym:

Guilliermondia fulvescens Nadson & Konokotina (1911)

Nadsonia fulvescens var. *elongata* (Konokotina) Golubev, M.Th. Smith, Poot & Kock (1989)

Synonyms:

Guilliermondia elongata Konokotina (1913)

Nadsonia richteri Kostka (1927)

Saccharomyces sinensis Yue (1977)

Growth in 5% malt extract: After three days at room temperature, the cells are ovoidal to elongate or lemon-shaped, (5–8) \times (8–16) μ m, and occasionally longer, single, in pairs, or in short chains. Budding is bipolar on a broad base (Fig. 125). A septum forms across the constriction connecting bud and parent cell, and the two are separated by fission. A thin, smooth, dry creeping pellicle is present. After one month a thin pellicle and a sediment are present.

Growth on 10% malt agar: After three days at room temperature, the cells are similar to those in malt extract. After one month at 18°C, the streak culture is grayish to cream-colored, nearly smooth, pasty, semidull, raised, border entire or lobulate.

Dalmat plate culture on potato agar: Pseudomycelium absent or rudimentary; in the last case short chains of undifferentiated elongate cells are formed.

Formation of ascospores: Sporulation, although not observed in the variety *fulvescens*, takes place according to the original description as described for the genus under the Diagnosis. When an ascus of the variety *elongata* is mature it normally separates from the two empty cells of a triad by fission (Fig. 126).

Sporulation by the variety *elongata* was observed on 10% malt agar after 4 days at 18°C.

Co-Q: 6 (Yamada et al. 1976a).

Mol% G + C: 41.5, CBS 2596 (BD: H.J. Phaff, unpublished).

Supplementary description of *N. fulvescens* var. *elongata*:

Glucose is the only sugar fermented. Galactose, sucrose, maltose, mannitol, and α -methyl-D-glucoside are not assimilated. The G + C content of the nuclear DNA of CBS 2594 is 41.8 mol%. Morphologically the varieties are similar. Most strains of the variety *elongata* still sporulate, including the type strain that was isolated in 1913. In contrast, none of the strains of the variety *fulvescens* produced ascospores, which was already noted by Stelling-Dekker (1931).

Origin of the strains belonging to the variety *fulvescens*: CBS 2596, from exudate of an oak, Leningrad, Russia; VKM Y-2618 and Y-2619, from the All-Union Institute of Agricultural Microbiology, Russia, source unknown.

Type strain: CBS 2596, received by CBS from Nadson and Konokotina in 1913.

Origin of strains belonging to the variety *elongata*: From exudates of the following trees in Japan: buckeye (*Aesculus* sp.) (1), alder (*Alnus* sp.) (3), birch

(*Betula* sp.) (18), hornbeam (*Carpinus* sp.) (2), dogwood (*Cornus* sp.) (1), *Eurya* sp. (1), beech (*Fagus* sp.) (1), *Prunus* sp. (5), bamboo (*Sinoarundinaria* sp.) (1) (Phaff et al. 1972); from birch exudate, Russia (1); a strain received by CBS in 1927 from Nadson labeled *N. fulvescens* (source unknown) (1); a strain labeled *Nadsonia richteri* (CBS 2593) isolated from hornbeam sap (*Carpinus betulus*) in Czechoslovakia.

Type strain: CBS 2594, isolated by Konokotina in 1913 from birch exudate in the Smolensk area of Russia.

Comments: The two varieties of *N. fulvescens* were originally described as separate species based on a number of differences in physiological properties, some of which were found to be unstable. Golubev et al. (1989) reduced *N. fulvescens* and *N. elongata* to varietal status on the basis of relatively high DNA complementarity (61–71% relative binding). We agree with their interpretation of DNA relatedness values and accept their varietal status as recommended by Golubev et al. (1989).

Comments on the genus

Members of the genus *Nadsonia* were originally isolated from tree exudates in Russia in the early part of the 20th century (Stelling-Dekker 1931). Subsequent ecological studies of yeast habitats revealed that *Nadsonia* species, then known, were found only in tree exudates collected in eastern Europe, Japan, and in some locations of Southeastern USA (Phaff and Starmer 1987). Other areas surveyed extensively for yeast floras from tree exudates and soils indicated that *Nadsonia* species were lacking. Golubev's (1973) discovery of a fundamentally new species of *Nadsonia* in soil from East Falkland Island in the Atlantic Ocean and another isolate of the same species from soil in the Carpathian mountains of eastern Europe (Golubev et al. 1987) revealed an additional soil habitat for members of this genus. Because of the low maximum temperature for growth (22–27°C) of members of *Nadsonia* (Golubev et al. 1989) it is possible that the presence of *Nadsonia* species may have been overlooked in other ecological surveys. The characteristic brown pigment in heavily sporulating cultures of *Nadsonia* has been identified as a melanin compound located in the outer layer of the ascospore wall (Semenova and Golubev 1988). The life cycle of *N. commutata* has been described in detail by Semenova and Golubev (1986).

Note added in proof

Analysis of 5' end large subunit rDNA nucleotide sequences has demonstrated that *Saccharomycodes sinensis* and *Nadsonia fulvescens* var. *elongata* are conspecific, and that *Schizoblastosporion starkeyi-henricii* is an anamorphic member of the *Nadsonia* clade (C.P. Kurtzman and C.J. Robnett, manuscript in preparation).

41. *Pachysolen Boidin & Adzet*

C.P. Kurtzman

Diagnosis of the genus

Asexual reproduction is by multilateral budding on a narrow base. Cells are spheroidal to ellipsoidal and may have one or two small apiculi. Pseudohyphae may be poorly developed or absent. True hyphae are not formed.

Asci are quite unusual and their presence allows immediate recognition of this genus. Generally, a tube grows from a vegetative cell and the end of the tube forms an ascus usually containing four ascospores. The walls of the cell and tube become quite thickened and refractile except for the end bearing the ascospores. The ascospores are hemispheroidal with a narrow ledge at the base.

Glucose is fermented. Nitrate is assimilated. Coenzyme Q-8 is present. Diazonium blue B reaction is negative.

Type species

Pachysolen tannophilus Boidin & Adzet

Species accepted

1. *Pachysolen tannophilus* Boidin & Adzet (1957)

Systematic discussion of the species

41.1. *Pachysolen tannophilus* Boidin & Adzet (1957)

Synonyms:

Hansenula tannophilus (Boidin & Adzet) Campbell (1973)

Pachysolen pelliculatus Boidin & Adzet (1957)

Growth on 5% malt extract agar: After 3 days at 25°C, the cells are spheroidal to ellipsoidal, (1.5–5.0) × (2.0–7.0) μm, and usually have one or two buds. Growth is mucoid to butyrous and tannish-white.

Growth on the surface of assimilation media: Pellicles are formed by some strains.

Dalmau plate culture on morphology agar: After 7 days at 25°C, growth under the coverglass exhibits simple undifferentiated pseudohyphae as well as occasional highly branched strands. True hyphae are not formed. Aerobic growth is tannish-white, glistening, mucoid, low convex with margin entire and with a faint smell of esters.

Formation of ascospores: The ascus forms when a vegetative cell produces a stout tube, generally at one end. Depending upon the culture medium, and perhaps other factors, tubes may be quite short or up to 60 μm in length and are straight or curved. The tip of the tube enlarges to form the ascus, and consequently, the tube may be regarded as an ascophore. Asci contain up to four hemispheroidal ascospores that have a narrow ledge at the base. The ascus wall deliquesces, releasing the spores. Once this happens, it is seen that the ascus formed within what appears to be a V-shaped notch at the end of the ascophore. Ascophore walls appear greatly thickened and become quite refractile. This characteristic of highly refractile ascophores bearing terminal asci makes *Pachysolen* readily identifiable under the light microscope even at moderate magnifications (Fig. 127). Asci may be conjugated or unconjugated. The type strain NRRL Y-2460 forms more unconjugated asci than NRRL

Y-2461, Y-2462, and Y-2463. Single-spore isolates from NRRL Y-2460 gave sporogenous colonies, therefore, the species appears homothallic (Wickerham 1970b).

Ascospores were observed on YM-, Gorodkova-, and malt extract agar, after 1 week at 25°C.

Fermentation:

Mol% G+C: 32.6, CBS 4044 and CBS 4045 (BD: C.P. Kurtzman, unpublished); 43.0, CBS 4044 (T_m : Nakase and Komagata 1968a)

Fig. 127. *P. tannophilus*, CBS 4044. Thick-walled, refractile ascophores bearing terminal asci, after 1 week on YM agar at 25°C. Bar=5 µm.

Origin of the strains studied: NRRL Y-2460 (IRIC 145, CBS 4044, extract of chestnut (*Castanea vesca*), Ludwigshafen, Germany; NRRL Y-2461 (IRIC 146), NRRL Y-2462 (IRIC 152), NRRL Y-6704 (IRIC 164, CBS 4045), the type strain of *P. penicillatus*, from extracts of acacia (*Acacia mollissima*), Ludwigshafen, Germany; NRRL Y-2463 (IRIC 153), shoe leather, Strasbourg, France.

Type strain: CBS 4044 (NRRL Y-2460), designated by Boidin and Adzet (1957) as the type strain.

Comments on the genus

Pachysolen is a rare and unusual yeast. The only reported isolations are those of Boidin and Adzet (1957), who obtained four strains from wood extracts used in tanning

liquors and a fifth strain from shoe leather. Asci of *P. tannophilus* are borne on the tips of refractile tubes which seem to serve as ascophores.

P. tannophilus was originally separated from *P. pelliculatus* because the latter species formed a mat growth on solid media, produced a thin, dry pellicle, had greater development of pseudohyphae, and gave a weaker fermentation of glucose. These differences seem insufficient to differentiate the two species and *P. pelliculatus* is regarded to be a synonym. Wickerham (1970b) showed that a mat form could be selected from *P. tannophilus* by allowing an amoeba to feed on the cultures. The amoeba preferentially ingested mucoid colonies and allowed proliferation of the mat form.

In recent years, *P. tannophilus* has received considerable attention because of its ability to ferment D-xylose, the major pentose of hemicellulosic plant residues (Schneider et al. 1981, Slininger et al. 1982, Kurtzman et al. 1982). Until this discovery, yeasts were not known to produce ethanol from pentoses. Soon after the preceding work, *Pichia stipitis* (Toivola et al. 1984) and *Candida shehatae* (du Preez and van der Walt 1983) were also demonstrated to ferment D-xylose, thus providing three species capable of converting pentoses from biomass to fuel alcohol. Slininger et al. (1987) reviewed the biochemistry and genetics of D-xylose fermentation by *P. tannophilus*. Kurtzman (1990b) estimated phylogenetic relatedness among the three species from extent of rRNA divergence and showed *Pichia stipitis* and *Candida shehatae* to be separate but closely related species whereas *P. tannophilus* was much more distantly related.

42. *Pichia* E.C. Hansen emend. Kurtzman

C.P. Kurtzman

Diagnosis of the genus

Asexual reproduction is by multilateral budding on a narrow base. Some species may also form arthroconidia. Cells are spheroidal, ellipsoidal, or elongate and occasionally may be tapered, but they are not ogival in shape. Pseudohyphae and true hyphae may be produced by some species.

Asci produce one to four (infrequently more) ascospores that may be hat-shaped (galeate), hemispheroidal, or spheroidal with a ledge. Generally asci are deliquescent, but occasionally they are persistent. Asci are unconjugated, or if conjugated, they may show conjugation between bud and parent or between independent cells. Hyphal or pseudohyphal cells may serve as asci, but they do not become swollen or spindle-like. Asci are not borne on ascophores. Species are homothallic or heterothallic.

Sugars may be fermented. Nitrate may be assimilated. Diazonium blue B reaction is negative.

Type species

Pichia membranifaciens E.C. Hansen

Species accepted

^a Abbreviations: Ferment., fermentation; G, glucose; Su, sucrose.

Assimilation: Ga, galactose; L-Sor, L-sorbose; Su, sucrose; Ce, cellobiose; Mz, melezitose; St, soluble starch; D-Xy, D-xylose; L-Ar, L-arabinose; D-Ar, D-arabinose; L-Rh, L-rhamnose; D-Gm, D-glucosamine; D-Gcl, D-glucitol; Sa, salicin; D-Glt, D-gluconate; Cit, citrate; 2-Keto, 2-keto-D-gluconate; NO₃, nitrate.

Other: Vfr, growth in vitamin-free medium; Osm, growth in osmotic medium (10% sodium chloride + 5% glucose); 37°, growth at 37°C; Gel, gelatin liquefaction; TrH, presence of true hyphae.

^b Symbols: +, strong positive; x, weak or strong; w, weak; v, variable; l, latent; -, negative.

Systematic discussion of the species

42.1. *Pichia acaciae* van der Walt (1966b)

Synonym:

Yamadazyma acaciae (van der Walt) Billon-Grand (1989)

Growth on 5% malt extract agar: After 3 days at 25°C, the cells are spheroidal to elongate, (1.5–5.5) × (2.5–11) µm, and occur singly, in pairs or in small clusters. Growth is butyrous and tannish-white in color.

Growth on the surface of assimilation media: Pellicles are formed.

Dalmu plate culture on morphology agar: After 7 days at 25°C, growth under the coverglass shows moderately well-developed pseudohyphae but no true hyphae. Aerobic growth is butyrous, dull, grayish-white, and has a somewhat wrinkled surface and a lobed margin.

Formation of ascospores: Asci show conjugation between a cell and its bud, or rarely, conjugation between independent cells. Two to four hat-shaped ascospores are produced in each ascus, and they are released soon after formation (Fig. 128).

Ascospores were observed on YM and 5% malt extract agars after 5–8 days at 15°C.

Fermentation:

Glucose	+	Lactose	–
Galactose	w/–	Raffinose	–
Sucrose	–	Trehalose	+
Maltose	+		

Assimilation:

Glucose	+	<i>N</i> -Acetyl-D-glucosamine	+
Galactose	+	Methanol	–
L-Sorbose	v	Ethanol	+
Sucrose	–	Glycerol	+
Maltose	+	Erythritol	+
Cellobiose	+	Ribitol	+
Trehalose	+	Galactitol	–
Lactose	v	D-Mannitol	+
Melibiose	–	D-Glucitol	+
Raffinose	–	α-Methyl-D-glucoside	+
Melezitose	–	Salicin	+/w
Inulin	–	D-Gluconate	v
Soluble starch	–	DL-Lactate	–
D-Xylose	+/w	Succinate	+
L-Arabinose	+	Citrate	+
D-Arabinose	–	Inositol	–
D-Ribose	+	Hexadecane	+
L-Rhamnose	–	Nitrate	–
D-Glucosamine	–	Vitamin-free	–

Additional assimilation tests and other growth characteristics:

2-Keto-D-gluconate	–	Starch formation	–
5-Keto-D-gluconate	–	Gelatin liquefaction	w/–
Saccharate	–	Growth at 37°C	+
10% NaCl/5% glucose	+		

Co-Q: 9, CBS 5656 (Billon-Grand 1989).

Mol% G + C: 46.0 (J.B. Fiol, cited by Billon-Grand 1981).

Fig. 128. *P. acaciae*, CBS 5656. Ascospore culture after 2 weeks, 15°C, on 5% malt extract agar. Bar = 5 µm.

Origin of the strains studied: Frass of Buprestidae beetle larvae infesting acacia (*Acacia nilotica* var. *kraussiana*), South Africa (1); tunnels of the beetle *Sinoxylon ruficorne* in *Combretum apiculatum*, South Africa (1).

Type strain: CBS 5656 (NRRL Y-7117), from frass of Buprestidae larvae.

Comments:

Some differences in carbon assimilation for *P. acaciae* were noted among van der Walt's (1966b) original description, Kreger-van Rij's (1970c) study and the present treatment. Consequently, growth on soluble starch and ribitol might be variable rather than positive as given in this study. Additionally, the type strain gave a late, weak reaction on D-xylose rather than a negative reaction as previously reported. *P. acaciae* is phenotypically quite similar to *P. media*, and the two differ only because *P. media* is nonfermentative.

42.2. *Pichia alni* (Phaff, M.W. Miller & Miranda) Kurtzman (1984a)

Synonym:

Hansenula alni Phaff, M.W. Miller & Miranda (1979)

Growth on 5% malt extract agar: After 3 days at 25°C, the cells are ovoidal and measure (2.3–4.8) × (2.9–5.7) µm. They occur singly, in pairs, or in small clusters. Growth is butyrous, glistening, and cream-colored to white.

Growth on the surface of assimilation media: Thin, climbing pellicles are formed.

Dalmu plate culture on morphology agar: After 7 days at 25°C, growth under the coverglass is sparse and pseudohyphae are poorly developed. True hyphae are not produced. Aerobic growth is tannish-white, smooth to faintly striated, glistening and with a slightly depressed center. Colony margins are entire to broadly lobed. A faint acidic odor is present.

Formation of ascospores: This species is heterothallic and has been isolated from nature only in the haploid state. Ascospores develop in diploid cells resulting from

Fig. 129. *P. alni*, CBS 6986×CBS 6987. Ascosporegenous culture after 10 days, 25°C, on 5% malt extract agar. Bar = 5 μ m.

conjugation between complementary mating types. Infrequently, the zygote itself will serve as the ascus. There are two to four hat-shaped ascospores per ascus, and asci are deliquescent (Fig. 129).

Ascospores were observed on 5% malt extract agar after 5–7 days at 25°C.

Fermentation: absent.

Co-Q: 7, CBS 6986 (Y. Yamada and H.J. Phaff, personal communication).

Mol% G + C: 41.8–42.0, CBS 6986 and 2 additional strains (BD: Phaff et al. 1979).

Origin of the strains studied: Flux from alder (*Alnus rubra* Bongard), British Columbia, Canada (2); flux from *A. rubra*, Washington, U.S.A. (1).

Complementary mating types: NRRL Y-11625 (CBS 6986, type strain) and NRRL Y-11626 (CBS 6987).

Type strain: CBS 6986 (UCD-FST 68-928A, NRRL Y-11625), isolated by Phaff et al. (1979) from flux of *A. rubra*, British Columbia, Canada.

Comments: Phaff et al. (1979) reported limited conjugation between the mating types of *P. alni* and *P. canadensis* (*Hansenula wingei*), but ascospores were not formed. In an accompanying study, Fuson et al. (1979) showed the two species to exhibit only 6% nDNA base sequence complementarity, thus confirming them as separate taxa. All isolates of *P. alni* have been from deciduous trees, whereas *P. canadensis* occurs exclusively on coniferous trees. Nonetheless, it appears that the two species have recently evolved from a common ancestor.

Minor differences in carbon assimilation were noted between the original description and the present study. Phaff et al. (1979) reported weak growth on soluble starch and no growth on ribitol. In the present study, none of the strains grew on soluble starch, and one of the strains (NRRL Y-11626) gave a strong but latent reaction on ribitol.

42.3. *Pichia americana* (Wickerham) Kurtzman (1984a)

Synonyms:

Hansenula bimundalis Wickerham & Santa Maria var. *americana* Wickerham (1965b)

Hansenula americana (Wickerham) Kurtzman (1984b)

Candida bimundalis Wickerham & Santa Maria var. *americana* Wickerham (1965b)

Growth on 5% malt extract agar: After 3 days at 25°C, the cells are spheroidal to ellipsoidal, (1.8–4.0)×(1.9–4.2) μ m, and single or in pairs. Growth is butyrous and light cream colored.

Growth on the surface of assimilation media: Only occasional strains form pellicles.

Dalmat plate culture on morphology agar: After 7 days at 25°C, growth under the coverglass shows abundant and moderately well differentiated pseudohyphae as well as true hyphae. Aerobic growth is white to tannish-white, butyrous, and glistening or dull. Hyphae or pseudohyphae may be found along the edges of colonies. An ester-like odor is produced.

Formation of ascospores: This species is heterothallic and only haploid strains have been isolated from nature. Following conjugation between complementary mating types, zygotes usually serve as asci, although occasional diploid cells bud from the zygote and become asci. The ascospores are hat-shaped and there are usually four per ascus. Asci are deliquescent.

Ascospores were observed on 5% malt extract agar after 5–20 days at 25°C, following pairing of complementary mating types.

Co-Q: 7, CBS 5644 (Yamada et al. 1973a).

Mol% G+C: 42.9, 43.6, 44.0, CBS 5644 (T_m : Nakase and Komagata 1971b; BD: Fuson et al. 1979; BD: Kurtzman 1984b); 43.2, NRRL YB-2444 (BD: Kurtzman 1984b).

Origin of the strains studied: Frass from a Jeffrey pine (*Pinus jeffreyi* Grev. & Balf.), California, U.S.A. (3); frass from a ponderosa pine (*Pinus ponderosa* Laws.), New Mexico, U.S.A. (2).

Complementary mating types: NRRL Y-2156 (CBS 5644) and NRRL Y-2157 (CBS 5645).

Type strain: CBS 5644 (NRRL Y-2156), one of the strains from frass from Jeffrey pine, California, U.S.A.

Comments: In 1965, Wickerham (1965b) described the species *Hansenula bimundalis* and the variety *americana*. Strains of *H. bimundalis* var. *bimundalis* are associated with coniferous trees of Europe and Asia, whereas strains of *H. bimundalis* var. *americana* are found with coniferous trees of southwestern United States. The variety *bimundalis* assimilates D-arabinose and grows at 37°C, but the variety *americana* does not. Wickerham also noted that hyphae of the variety *bimundalis* are about twice as long as hyphae of the variety *americana*. In mating studies, zygotes formed from intervarietal crosses, but ascospores were never produced.

Fuson et al. (1979) examined the nDNA of certain tree-inhabiting species of *Hansenula* (= *Pichia*) and noted that the G+C content of *H. bimundalis* var. *americana* was 2.5% higher than that of *H. bimundalis* var. *bimundalis*. On the basis of previous experience, this was highly suggestive that the varieties represented distinct species. Kurtzman (1984b) demonstrated by nDNA reassociation studies that the two varieties showed only 21% base sequence complementarity. This relatively low nDNA relatedness coupled with the infertility of intervarietal

crosses provided evidence for elevation of *P. bimundalis* var. *americana* to species status.

42.4. *Pichia amethionina* Starmer, Phaff, Miranda & M.W. Miller (1978b)

This species has two varieties:

Pichia amethionina* Starmer, Phaff, Miranda & M.W. Miller var. *amethionina* (1978b)**Pichia amethionina* var. *pachycereana* Starmer, Phaff, Miranda & M.W. Miller (1978b)**

Growth on 5% malt extract agar: After 3 days at 25°C, the cells are ovoidal to elongate, (1.2–4.0) × (3.0–9.0) μ m, and occur singly, in pairs, in short branched chains and in stellate clusters. Growth is butyrous and tannish-white in color.

Growth on the surface of assimilation media: Pellicles are not formed.

Dalmat plate culture on morphology agar: After 7 days at 25°C, growth under the coverglass shows no true hyphae and only a few rudimentary pseudohyphae. Aerobic growth is white in color, smooth, glistening, and butyrous with an irregular and finely serrate margin.

Formation of ascospores: This species is heterothallic and asci are either unconjugated if formed by diploid cells or conjugated when produced by the pairing of complementary mating types. Each ascus contains one to four hat-shaped ascospores which are readily released at maturity.

Ascospores were observed on 5% malt extract agar after 3–4 days at 25°C.

Fermentation: absent.

Assimilation:

Glucose	+	N-Acetyl-D-glucosamine	-
Galactose	-	Methanol	-
L-Sorbose	-	Ethanol	+
Sucrose	-	Glycerol	+
Maltose	-	Erythritol	-

Additional assimilation tests and other growth characteristics:

2-Keto-D-gluconate	v	Starch formation	-
5-Keto-D-gluconate	-	Gelatin liquefaction	-
Saccharate	-	Growth at 37°C	+
10% NaCl/5% glucose	-		

Co-Q: 7, CBS 6940 (Billon-Grand 1985).

Mol% G+C: 33.0–33.1, CBS 6940 and 5 additional strains of the

variety *amethionina*; 32.8–33.5, CBS 6943 and 3 additional strains of the variety *pachycereana* (BD: Starmer et al. 1978b).

Supplementary description of *P. amethionina* var. *pachycereana*: The variety *pachycereana* assimilates D-mannitol, but does not assimilate D-xylose, thereby providing a means to separate it from the variety *amethionina*.

Origin of the strains belonging to the variety *amethionina*: From cina cactus (*Rathbunia alamosensis*) (1) and agria cactus (*Macherocereus gummosus*) (2), Mexico.

Complementary mating types: NRRL Y-10979 (CBS 6942) and NRRL Y-10980 (CBS 6941), derived from the type strain by Starmer et al. (1978b).

Type strain: CBS 6940 (NRRL Y-10978).

Origin of the strains belonging to the variety *pachycereana*: From cardon cactus (*Pachycereus pringlei*) (2) and agria cactus (*Macherocereus gummosus*) (1), Mexico.

Complementary mating types: NRRL Y-10982 (CBS 6945) and NRRL Y-10983 (CBS 6944), derived from the type strain by Starmer et al. (1978b).

Type strain: CBS 6943 (NRRL Y-10981).

Comments: Starmer et al. (1978b, 1979) observed no mating between *P. amethionina* and *P. delftensis*, *P. heedii* or *P. opuntiae* despite their phenotypic similarity, and it appears that these species are biologically distinct. *P. amethionina* and *P. caribaea* seem unique among the yeasts because all strains require an exogenous source of methionine or cysteine (Starmer et al. 1978b, Phaff et al. 1992). Shen and Lachance (1993) have compiled the published data on extent of nDNA complementarity among closely related cactus yeasts.

42.5. *Pichia amylophila* Kurtzman, Smiley, Johnson, Wickerham & Fuson (1980a)

Growth on 5% malt extract agar: After 3 days at 25°C, the cells are single, or rarely, clustered, and spheroidal, ellipsoidal, or elongate, (2.0–5.5) × (3.0–14.0) μm. Growth is butyrous and tannish-white in color.

Growth on the surface of assimilation media: Pellicles are not formed but rings develop occasionally.

Dalmau plate culture on morphology agar: After 7 days at 25°C, growth under the coverglass shows abundant and highly branched pseudohyphae as well as occasional true hyphae. The true hyphae show no evidence of a dolipore septum when viewed under the light microscope. Aerobic growth is cream colored, dull, and moist with a serrate margin and a slightly raised center. A faint, ester-like odor is produced.

Formation of ascospores: Diploid cells convert to asci and usually form two hat-shaped ascospores. Asci are generally free but may form on pseudohyphae where they are sessile or attached by short sterigmata. At maturity, the asci become deliquescent. Single-spore isolations showed

this species to be heterothallic although most of the ascospores from the parent strain are diploid. Asci from pairing of the mating types predominantly form three or four ascospores.

Ascospores were observed on 5% malt extract and YM agars after 2–4 days at 25°C.

Fermentation:

5-Keto-D-gluconate	–	Gelatin liquefaction	–
Saccharate	–	Growth at 37°C	+
10% NaCl/5% glucose	–		

Co-Q: 7, CBS 7020 (Billon-Grand 1985).

Mol% G+C: 45.4, CBS 7020 (BD: Kurtzman et al. 1980a).

Origin of the strain studied: Frass from loblolly pine (*Pinus taeda* L.) Mississippi, U.S.A.

Complementary mating types: NRRL YB-1287-82-2 (CBS 7021) and NRRL YB-1287-82-3 (CBS 7022), derived as single-ascospore isolates from the type strain.

Type strain: CBS 7020 (NRRL YB-1287).

Comments: *P. amylophila* is phenotypically quite like *P. mississippiensis* and differs from the latter only in its ability to assimilate soluble starch. Complementary mating types from the two species conjugate but the resulting ascospores are infertile. In a comparison of nDNA relatedness, the two taxa showed only 25% base sequence complementarity (Kurtzman et al. 1980a), but this is still higher than the 0–15% commonly found between more distantly related species. Thus, the data show that these two species have recently evolved from a common ancestor. *P. amylophila* and *P. mississippiensis* are similar to *P. rhodanensis*, *P. wickerhamii* and *P. veronae*, which are also heterothallic, but Kurtzman et al. (1980a) found that they gave no mating reactions

with these latter three taxa nor did they show significant nDNA relatedness with them.

42.6. *Pichia angophorae* M.W. Miller & Barker (1968)

Growth on 5% malt extract agar: After 3 days at 25°C, the cells are spheroidal to ellipsoidal, (2.0–6.0) × (3.0–7.0) µm, and occur singly, in pairs or in short chains. Growth is butyrous and light tan in color.

Growth on the surface of assimilation media: Thin pellicles are formed.

Dalmou plate culture on morphology agar: After 7 days at 25°C, growth under the coverglass shows well-developed pseudohyphae bearing blastoconidia. True hyphae are not formed. Aerobic growth is light tan in color, moderately glistening, butyrous, and with entire margins.

Formation of ascospores: Miller and Barker (1968) reported ascus development in their original isolates to be preceded by iso- or heterogamic conjugations, or rarely by no conjugation. Two to four hat-shaped ascospores are formed in each ascus. Asci are deliquescent. Single-spore isolates yielded both sporogenous and asporogenous cultures and the species was described as both homo- and heterothallic (Miller and Barker 1968). The occurrence of haploid as well as diploid spores could account for these observations. The type strain, NRRL Y-7118 (CBS 5823), is now asporogenous, but conjugates and sporulates when paired with mating type NRRL Y-7843.

Ascospores were observed on 5% malt extract agar after 1–3 days at 25°C, following pairing of complementary mating types.

5-Keto-D-gluconate	–	Gelatin liquefaction	–
Saccharate	–	Growth at 37°C	–
10% NaCl/5% glucose	–		

Co-Q: Not determined.

Mol% G + C: 33.0 (J.B. Fiol, cited by Billon-Grand 1981).

Origin of the strains studied: Gum exudate of a red gum tree (*Angophora costata*), Australia (1); mating types derived from the type strain, Kreger-van Rij.

Complementary mating types: NRRL Y-7843 (CBS 5823) and NRRL Y-7844 (CBS 5830), derived from the type strain.

Type strain: CBS 5823 (NRRL Y-7118), from *Angophora costata*.

Comments: *P. angophorae* is phenotypically similar to *P. spartinae* but differs from the latter by its growth on D-xylose and lack of growth on hexadecane, L-sorbose and at 37°C. No response was noted in mixtures of mating types from the two species (Kurtzman and Ahearn 1976).

42.7. *Pichia angusta* (Teunisson, Hall & Wickerham) Kurtzman (1984a)

Synonyms:

Hansenula angusta Wickerham (1951) nom. nud.

Hansenula angusta Teunisson, Hall & Wickerham (1960)

Hansenula polymorpha Falcão de Morais & Dália Maia (1959)

Opataea polymorpha (Falcão de Morais & Dália Maia) Y. Yamada, Maeda & Mikata (1994c)

Torulopsis methanothermo Urakami (1975) nom. nud.

Growth on 5% malt extract agar: After 3 days at 25°C, the cells are spheroidal to elongate, (1.5–4.6) × (1.9–5.3) µm, and single, in pairs, or in small clusters. Growth is butyrous and tannish-white in color.

Growth on the surface of assimilation media: Very thin pellicles are occasionally produced.

Dalmou plate culture on morphology agar: After 7 days at 25°C, neither hyphae nor pseudohyphae are detected under the coverglass. Aerobic growth is white to slightly tannish-white, smooth to finely striated, glistening, and butyrous. Colony margins are entire or finely lobed.

Formation of ascospores: Asci are unconjugated, or exhibit conjugation between parent and bud, or less frequently between independent cells. One to four hemispheroidal or narrow brimmed hat-shaped ascospores are formed per ascus. The asci are deliquescent. Single-spore isolates from four-spored asci from the type strain gave sporogenous colonies, and the species is presumed homothallic (Kurtzman, unpublished).

Ascospores were observed on 5% malt extract, YM, and McClary's acetate agars after 4–7 days at 25°C.

Saccharate	-	Growth at 37°C	+
10% NaCl/5% glucose	+		

Co-Q: 7, CBS 7073 and 3 additional strains (Yamada et al. 1973a).

Mol% G + C: 47.8–48.3, CBS 7073 and 3 additional strains (T_m : Nakase and Komagata 1971b); 48.0, CBS 4732 (BD: Kurtzman, unpublished).

Origin of the strains studied: Soil (1); concentrated orange juice (1); *Drosophila* spp. (5); intestinal tract of swine (1); 'alpechin' (1); insect frass from various deciduous trees and nuts (19).

Type strain: CBS 7073 (NRRL Y-2214), isolated from the fruit fly *Drosophila pseudoobscura* in California, U.S.A. (Shehata et al. 1955), and selected by Teunisson et al. (1960) as the type strain of *Hansenula angusta*.

Comments: With the transfer of *Hansenula* species with hat-shaped ascospores to *Pichia* (Kurtzman 1984a), several nomenclatural difficulties arose. One of these concerned *Hansenula polymorpha* because of prior usage of the combination *Pichia polymorpha*. Because of the unavailability of the name *polymorpha*, *Pichia angusta* was selected for the new combination because *H. angusta* is an obligate synonym of *H. polymorpha*.

Phaff (1985) reported *P. angusta* to be common in rotting opuntia cacti. The cactus isolates show G + C contents about 1 mol% higher than non-cactus strains but reduced (ca. 65–70%) nDNA complementarity with these strains. The cactus isolates differ phenotypically by slow, weak growth on methanol but grow at elevated temperatures (45°–46°C).

42.8. *Pichia anomala* (E.C. Hansen) Kurtzman (1984a)

Hansenula anomala (E.C. Hansen) H. & P. Sydow var. *longa* Dekker (Stelling-Dekker 1931)

Hansenula anomala (E.C. Hansen) H. & P. Sydow var. *robusta* Dekker (Stelling-Dekker 1931)

Hansenula nivea Castelli (1933)

Hansenula panis Castelli (1933)

Saccharomyces aceris-sachari Fabian & Hall (1933)

Hansenula anomala (E.C. Hansen) H. & P. Sydow var. *heteromorpha* Bedford (1942) nom. nud.

Hansenula miso (and forms α , β , β var. 1) Mogi (1942) nom. nud.

Hansenula octospora Mogi (1942) nom. nud.

Hansenula miso var. *octosporus* S. Goto & Yokotsuka (1962b) nom. nud.

Candida pelliculosa Redaelli var. *cylindrica* Diddens & Lodder (1942)

Candida beverwijkii Novák & Vitéz (1964)

Hansenula ukrainica Kvasnikov, Nagornaya & Shchelokova (1979b)

Growth on 5% malt extract agar: After 3 days at 25°C, the cells are spheroidal to elongate, (1.9–4.1) × (2.1–6.1) μ m, and occur singly, in pairs, or in small clusters. Growth is butyrous and faintly tan in color.

Growth on the surface of assimilation media:

Pellicles are produced by some strains and when present vary from thin and smooth to thick and folded.

Dalmat plate culture on morphology agar: After 7 days at 25°C, growth under the coverglass may show abundant, branched pseudohyphae, although some strains form no pseudohyphae. None of the isolates form true hyphae. Aerobic growth is white to tannish-white and generally butyrous. Some strains are smooth and glistening while others are dull and somewhat chalky. Colony margins range from entire to lobed and occasionally show

a fringe of pseudohyphae. The cultures usually produce a faintly pleasant odor.

Formation of ascospores: *P. anomala* is heterothallic, but the sporogenous diploid form is usually isolated from nature. Diploid cells directly convert to asci and form one to four hat-shaped ascospores (Fig. 130). Asci are deliquescent.

Ascospores were observed on 5% malt extract agar, V8 agar, and sterilized carrot slices after 3–10 days at 25°C.

Fig. 130. *P. anomala*, CBS 5759. Ascospore culture after 3 days, 25°C, on 5% malt extract agar. Bar = 5 µm.

5-Keto-D-gluconate	–	Gelatin liquefaction	–
Saccharate	–	Growth at 37°C	v
10% NaCl/5% glucose	v		

Co-Q: 7, CBS 5759, and 5 additional strains (Yamada et al. 1973a).

Mol% G+C: 35.9–36.6, CBS 5759, AJ 4160, AJ 4167 (T_m : Nakase

and Komagata 1971b); 36.8, CBS 605 (T_m : Stenderup and Bak 1968); 35.8–37.4, CBS 5759 and 5 additional strains (BD: Kurtzman 1984b).

Origin of the strains studied: Contaminants from industrial or pilot plant fermentations (12); ragi, Java (10); soil (9); gums of trees, principally *Prunus* (9); stored grain (6); ensilage (4); lakes or streams (3); warm-blooded animals (3); tree exudates (2); frass (2); fermenting mushrooms (2); sewage (2); fruit (1); from various collections and investigators (58).

Complementary mating types: NRRL Y-366-8 (CBS 1984) and NRRL Y-2153-4 (CBS 1982).

Type strain: CBS 5759 (NRRL Y-366), received from Fabian, U.S.A., as *Willia anomala* Saito.

Comments: Wickerham (1970a) separated *Hansenula anomala* var. *schneegii* from *H. anomala* var. *anomala* because the former is less capable of fermenting sucrose than the latter, and it does not grow in osmotic medium. Additionally, the variety *schneegii* does not assimilate raffinose. Perhaps even more striking, the variety *schneegii* produces cylindrical and often markedly elongated thread-like cells while the variety *anomala* does not. However, sexual reactions tend to obscure the other differences between the varieties. Reactions between strains of the variety *schneegii* are weak, but mixtures that contain one strain of each variety are stronger.

Kurtzman (1984b) compared *H. anomala* var. *anomala* and *H. anomala* var. *schneegii* from extent of nDNA reannealing. The two varieties showed 94% base sequence complementarity. Consequently, in view of the great similarity of these strains at the molecular level, the varietal designations have not been maintained. In other nDNA comparisons, *Hansenula ukrainica* was shown to be a synonym of *P. anomala* (Kurtzman 1992b).

42.9. *Pichia antillensis* Starmer, Phaff, Tredick, Miranda & Aberdeen (1984)

Growth on 5% malt extract agar: After 3 days at 25°C, the cells are spheroidal, or ellipsoidal to short elongate, (1.5–4.1) × (2.1–7.1) µm, and occur singly, in pairs, or infrequently, in small clusters. Growth is butyrous and light tannish-white in color.

Growth on the surface of assimilation media: Pellicles are not formed.

Dalmat plate culture on morphology agar: After 7 days at 25°C, growth under the coverglass is devoid of hyphae or pseudohyphae, but small outgrowths of undifferentiated cells may form. Aerobic growth is white, glistening, and butyrous with a depressed center and an irregularly lobed margin. A faint musky, acidic odor is present.

Formation of ascospores: This species is heterothallic and is often isolated from nature in the asporogenous haploid state, although diploids are occasionally found. Asci form from naturally occurring diploid cells or those arising following conjugation of complementary mating

types. Asci generally contain four hat-shaped ascospores that are released soon after formation.

Ascospores were observed on YM agar after 5 days at 25°C.

Fermentation: absent.

Assimilation:

Glucose	+	<i>N</i> -Acetyl-D-glucosamine	–
Galactose	–	Methanol	–
L-Sorbose	–	Ethanol	+
Sucrose	–	Glycerol	+
Maltose	–	Erythritol	–
Cellobiose	–	Ribitol	–
Trehalose	–	Galactitol	–
Lactose	–	D-Mannitol	s
Melibiose	–	D-Glucitol	–
Raffinose	–	α-Methyl-D-glucoside	–
Melezitose	–	Salicin	v
Inulin	–	D-Gluconate	–
Soluble starch	–	DL-Lactate	+
D-Xylose	–	Succinate	+
L-Arabinose	–	Citrate	+
D-Arabinose	–	Inositol	–
D-Ribose	–	Hexadecane	–
L-Rhamnose	+	Nitrate	–
D-Glucosamine	–	Vitamin-free	–

Additional assimilation tests and other growth characteristics:

2-Keto-D-gluconate	–	Starch formation	–
5-Keto-D-gluconate	–	Gelatin liquefaction	–
Saccharate	–	Growth at 37°C	–
10% NaCl/5% glucose	–		

Co-Q: Not determined.

Mol% G+C: 33.4–33.7, CBS 7111 and 5 additional strains (BD: Starmer et al. 1984).

Origin of the strains studied: Necrotic tissue of the columnar cactus *Cephalocereus royenii* from the Virgin Islands: Prickly Pear Island, Virgin Gorda (CBS 7111, CBS 7113); Beef Island, Tortola (CBS 7112).

Complementary mating types: CBS 7112 (NRRL Y-12882) and CBS 7113 (NRRL Y-12883), isolated by Starmer et al. (1984).

Type strain: CBS 7111 (NRRL Y-12881).

Comments: Starmer et al. (1984) noted that *P. antillensis* shares many physiological and ecological similarities with *P. heedii*, *P. amethionina*, *P. opuntiae* and *P. thermotolerans*, all of which are heterothallic. Comparisons of nDNA complementarity showed *P. antillensis* to have, respectively, about 50% and 28% relatedness with *P. opuntiae* and *P. thermotolerans*, but because no conjugation was detected between mating types of the taxa, they are considered separate biological species. At present, *P. opuntiae* is known only from Australia, *P. thermotolerans* from Mexico, and *P. antillensis* from the West Indies. Results of the present comparison are in good agreement with the original description except that one strain (CBS 7113) showed a delayed growth reaction on salicin rather than being unable to assimilate this compound.

42.10. *Pichia barkeri* Phaff, Starmer, Tredick-Kline & Aberdeen (1987a)

Growth on 5% malt extract agar: After 3 days at 25°C, the cells are spheroidal, ellipsoidal to elongate, (2.0–6.0)×(2.5–10.0) μm, and occur singly, in pairs and in small clusters. Growth is butyrous, dull-glistening and tannish-white.

Growth on the surface of assimilation media: Moderate, climbing pellicles are formed.

Dalmat plate culture on morphology agar: After 7 days at 25°C, growth under the coverglass shows abundant well-branched pseudohyphae with blastoconidia, but no true hyphae. Aerobic growth is a faint yellow-tan in color, butyrous with a dull, roughened surface, and irregularly lobed margins. A faint acidic odor is present.

Formation of ascospores: Ascosporeulation begins with the development of a protuberance on a vegetative cell. The terminal end of the protuberance swells and seems to serve as a conjugating cell. Up to four hat-shaped ascospores form in one of the cells, usually the parent cell. Asci become deliquescent soon after spore formation. On the basis of this life cycle, Phaff et al. (1987a) proposed that *P. barkeri* appears to be homothallic.

Ascospores were observed on McClary's acetate agar after 5–10 days at 25°C.

Fermentation:

Glucose	+	Lactose	–
Galactose	–	Raffinose	–
Sucrose	–	Trehalose	–
Maltose	–		

Assimilation:

Glucose	+	<i>N</i> -Acetyl-D-glucosamine	s
Galactose	–	Methanol	–
L-Sorbose	–	Ethanol	+
Sucrose	–	Glycerol	+
Maltose	–	Erythritol	–
Cellobiose	–	Ribitol	–
Trehalose	–	Galactitol	–
Lactose	–	D-Mannitol	–
Melibiose	–	D-Glucitol	–
Raffinose	–	α-Methyl-D-glucoside	–
Melezitose	–	Salicin	–
Inulin	–	D-Gluconate	–
Soluble starch	–	DL-Lactate	+
D-Xylose	v	Succinate	+
L-Arabinose	–	Citrate	–
D-Arabinose	–	Inositol	–
D-Ribose	–	Hexadecane	–
L-Rhamnose	–	Nitrate	–
D-Glucosamine	+	Vitamin-free	–

Additional assimilation tests and other growth characteristics:

2-Keto-D-gluconate	–	Starch formation	–
5-Keto-D-gluconate	–	Gelatin liquefaction	–
Saccharate	–	Growth at 37°C	+
10% NaCl/5% glucose	+		

Co-Q: 7 (Y. Yamada and H.J. Phaff, personal communication).

Mol% G+C: 35.7–36.6, CBS 7256 and 21 additional strains (BD: Phaff et al. 1987a).

Origin of the strains studied: Rotting cladodes of

prickly pear cactus (*Opuntia stricta*) from Discovery Bay, Jamaica (CBS 7256), and Cayman Brac, Caribbean Sea (CBS 7257).

Type strain: CBS 7256 (NRRL Y-17350).

Comments: The work of Phaff et al. (1987a) shows the habitat of *P. barkeri* to be restricted to rotting cladodes of *Opuntia stricta*. Further, *P. barkeri* has been isolated only from *O. stricta* growing on several islands of the Caribbean Sea and from a small area in New South Wales, Australia. *P. barkeri* is phenotypically quite similar to *P. kluyveri* var. *kluyveri* although the two can be separated because *P. barkeri* is characterized by the production of lipase. Additionally, *P. kluyveri* var. *kluyveri* shows killer activity against *Candida glabrata* whereas *P. barkeri* does not (Phaff et al. 1987a). The two taxa show about 20% nDNA complementarity, suggesting that their divergence as separate species has been relatively recent (Phaff et al. 1987a): the G+C content of *P. barkeri* is 6 mol% higher than that of *P. kluyveri*. In contrast to the original description, citrate assimilation was not detected in the present study.

42.11. *Pichia besseyi* Kurtzman & Wickerham (1972)

Synonym:

Yamadazyma besseyi (Kurtzman & Wickerham) Billon-Grand (1989)

Growth on 5% malt extract agar: After 3 days at 25°C, the cells are spheroidal to ellipsoidal, (4.3–7.0) × (4.3–8.2) μm, and occur singly or occasionally in pairs. Growth is butyrous and tannish-white in color.

Growth on the surface of assimilation media: Thin pellicles are formed.

Dalmau plate culture on morphology agar: After 7 days at 25°C, growth under the coverglass shows neither pseudohyphae nor true hyphae, but “tree-like” outgrowths of elongated cells are detected on corn meal agar after 2 weeks. Aerobic growth is dull-glistening and butyrous with an entire margin. The colony color is initially white to cream but becomes pink to brown as ascospores are formed.

Formation of ascospores: Occasionally, asci are formed following conjugation between independent cells, but the majority are unconjugated. Asci usually contain four spores and become deliquescent upon maturity. The shape of ascospores is generally hemispheroidal; for most spores, the underside appears concave and the lower periphery is somewhat thickened, but some spores seem to have a flattened, saturn-like appearance (Fig. 131). Single-spore isolates from four-spored asci are sporogenous and the species is presumed to be homothallic.

Ascospores were observed on 5% malt extract, morphology and YM agars after 1 week at 25°C.

Fig. 131. *P. besseyi*, CBS 6343. Ascospore culture after 3 days, 25°C, on 5% malt extract agar. Bar = 5 μm.

Fermentation:

Glucose	+	Lactose	–
Galactose	–	Raffinose	–
Sucrose	–	Trehalose	–
Maltose	–		

Assimilation:

Glucose	+	<i>N</i> -Acetyl-D-glucosamine	–
Galactose	–	Methanol	–
L-Sorbose	–	Ethanol	+
Sucrose	–	Glycerol	–
Maltose	–	Erythritol	–
Cellulobiose	–	Ribitol	–
Trehalose	–	Galactitol	–
Lactose	–	D-Mannitol	+
Melibiose	–	D-Glucitol	+
Raffinose	–	α-Methyl-D-glucoside	–
Melezitose	–	Salicin	–
Inulin	–	D-Gluconate	–
Soluble starch	–	DL-Lactate	+
D-Xylose	–	Succinate	+
L-Arabinose	–	Citrate	–
D-Arabinose	–	Inositol	–
D-Ribose	–	Hexadecane	–
L-Rhamnose	–	Nitrate	–
D-Glucosamine	–	Vitamin-free	–

Additional assimilation tests and other growth characteristics:

2-Keto-D-gluconate	–	Starch formation	–
5-Keto-D-gluconate	–	Gelatin liquefaction	+
Saccharate	–	Growth at 37°C	–
10% NaCl/5% glucose	–		

Co-Q: 7, CBS 6343 [Yamada, pers. comm.; the determination of Co-Q 9 by Billon-Grand (1985) appears incorrect].

Mol% G+C: 35.1, 35.2, CBS 6343 (T_m : Billon-Grand 1981; BD: Kurtzman, unpublished).

Origin of the strain studied: Shallow water in a marsh near Bonaventure, Gaspé Peninsula, Quebec, Canada (1).

Type strain: CBS 6343 (NRRL YB-4711).

Comments: *P. besseyi* assimilates only a limited number of carbon compounds making it phenotypically similar to *P. membranifaciens*. However, it assimilates mannitol and glucitol, compounds on which *P. membranifaciens* is incapable of growth. Likewise, *P. besseyi* assimilates lactic acid, but not ribitol and may be distinguished

from *P. delftensis* by these characters. rRNA comparisons place *P. besseyi* in the *Saturnispora* clade (Kurtzman and Robnett, manuscript in preparation).

42.12. *Pichia bimundalis* (Wickerham & Santa María) Kurtzman (1984a)

Synonyms:

Hansenula bimundalis Wickerham & Santa María (Wickerham 1965b)

Candida bimundalis Wickerham & Santa María var. *bimundalis* (Wickerham 1965b)

Growth on 5% malt extract agar: After 3 days at 25°C, the cells are spheroidal to ellipsoidal, (1.8–4.3) × (2.0–5.2) μm, and single or in pairs. Growth is butyrous and light cream colored.

Growth on the surface of assimilation media: Usually pellicles are not formed, but occasional strains give waxy climbing pellicles.

Dalmou plate culture on morphology agar: After 7 days at 25°C, growth under the coverglass consists of abundant and moderately well differentiated pseudohyphae. True hyphae are also present. Aerobic growth is white to tannish-white, butyrous, and glistening or mat rugose. Colonies may be fringed with hyphae or pseudohyphae. An ester-like odor is produced.

Formation of ascospores: This species is heterothallic and only haploid strains have been isolated from nature. Following conjugation between complementary mating types, zygotes may serve as asci or diploid cells arising from the zygotes become asci. The ascospores are hat-shaped with prominent brims and there are usually four per ascus. Asci are deliquescent.

Ascospores were observed on 5% malt extract agar after 3–10 days at 25°C, following pairing of complementary mating types.

Fermentation:

Glucose	s	Lactose	–
Galactose	–	Raffinose	–
Sucrose	–	Trehalose	–

2-Keto-D-gluconate	w/–	Starch formation	–
5-Keto-D-gluconate	–	Gelatin liquefaction	–
Saccharate	–	Growth at 37°C	+
10% NaCl/5% glucose	–		

Co-Q: 7, CBS 5642 (Yamada et al. 1973a).

Mol% G + C: 40.1, 41.1, CBS 5642 (T_m : Nakase and Komagata 1971b; BD: Fuson et al. 1979); 41.5, 42.1, NRRL YB-2805, CBS 5642 (BD: Kurtzman 1984b).

Origin of the strains studied: Larvae of the beetle *Ergates faber* and larvae of three other beetle genera living principally in stumps of Scotch pine (*Pinus sylvestris* Linn.), Spain (8); frass of a fir tree (*Abies firma* Sieb. & Zucc.), Japan (1).

Complementary mating types: NRRL Y-5343 (CBS 5642) and NRRL Y-5354 (CBS 5643).

Type strain: CBS 5642 (NRRL Y-5343), isolated from a larva of *Ergates faber* (Wickerham 1965b).

Comments: The close relationship between *P. bimundalis* and *P. americana* is discussed in the treatment of the latter species.

42.13. *Pichia bispora* (Wickerham) Kurtzman (1984a)

Synonyms:

Endomyces bisporus Beck (1922)

Endomyces bispora (Beck) Dekker (Stelling-Dekker 1931)

Hansenula beckii Wickerham (1951)

Growth on 5% malt extract agar: After 3 days at 25°C, the cells are ovoidal to elongate and measure (1.7–5.8) × (2.8–11.3) μm. They occur singly, in pairs, or in small clusters. Growth is light tan in color, and, depending upon the isolate, is either butyrous or mycelial.

Growth on the surface of assimilation media: Pellicles or rings are not formed.

Dalmou plate culture on morphology agar: After 7 days at 25°C, growth under the coverglass shows abundant and well-branched pseudohyphae as well as true hyphae. Aerobic growth is light tan in color and may be butyrous or mycelial. Colony margins are entire or finely lobed. A faint ester-like odor is present.

Formation of ascospores: Beck (1922) reported the asci to be free cells in which two hat-shaped spores were formed. Subsequent investigators found Beck's strain (CBS 1890) to be asporogenous (Kreger-van Rij 1970c), but her original description leaves no doubt about the presence of ascospores. An additional strain (CBS 6468, NRRL Y-11610) of *P. bispora* became available, and this culture formed two to four hat-shaped spores per ascus. Asci are single, unconjugated cells which become deliquescent upon maturation of the ascospores (Fig. 132). Colonies of single-spore isolates from four-spored asci proved sporogenous and the species is presumed to be homothallic (Kurtzman, unpublished).

Fig. 132. *P. bispora*, CBS 6468. Ascosporeogenous culture after 3 days, 25°C, on YM agar. Bar = 5 μm.

Ascospores were observed on YM agar after 3–5 days at 25°C.

Fermentation:

Glucose	w/–	Lactose	–
Galactose	–	Raffinose	–
Sucrose	–	Trehalose	–
Maltose	–		

Assimilation:

Glucose	+	<i>N</i> -Acetyl-D-glucosamine	–
Galactose	–	Methanol	–
L-Sorbose	–	Ethanol	+
Sucrose	+	Glycerol	+
Maltose	+	Erythritol	–
Cellobiose	+	Ribitol	v
Trehalose	s	Galactitol	–
Lactose	–	D-Mannitol	v
Melibiose	–	D-Glucitol	+/w
Raffinose	–	α-Methyl-D-glucoside	+/w
Melezitose	+	Salicin	+/w
Inulin	–	D-Gluconate	s
Soluble starch	–	DL-Lactate	v
D-Xylose	+	Succinate	+
L-Arabinose	w/–	Citrate	+
D-Arabinose	–	Inositol	–
D-Ribose	v	Hexadecane	–

D-Glucosamine	–	Vitamin-free	–

Additional assimilation tests and other growth characteristics:

2-Keto-D-gluconate	–	Starch formation	–
5-Keto-D-gluconate	–	Gelatin liquefaction	–
Saccharate	–	Growth at 37°C	–
10% NaCl/5% glucose	–		

Co-Q: 7, CBS 1890 (Yamada et al. 1973a).

Mol% G + C: 36.6, 37.1, CBS 1890 (T_m : Nakase and Komagata 1971b; BD: Fuson et al. 1979).

Origin of the strains studied: Frass from tunnels in the bark of a spruce (*Abies* sp.), Beck, Austria (1); human scalp, Laaksonen, Finland (1).

Type strain: CBS 1890 (NRRL Y-1482), frass from spruce bark.

Comments: In their study of septa in ascomycetous yeasts by electron microscopy, Kreger-van Rij and Veenhuis (1973) showed *P. bispora* (*Endomycopsis bispora*)

to have hyphal septa with a closure line typical of other mycelial *Pichia* species. In view of this, *P. bispora* has been retained in *Pichia*.

Strain CBS 6468 (NRRL Y-11610) was found to differ from the type strain by giving a weak and late fermentation of glucose and by the inability to assimilate ribitol, mannitol, and lactic acid. In a comparison of their nDNAs, the two strains exhibited 97% base sequence complementarity and represent the same species (Kurtzman, unpublished).

Separation of *P. bispora*, *P. canadensis*, *P. americana* and *P. alni* using standard tests is problematical; however, DNA reassociation studies clearly show the species to be genetically isolated (Fuson et al. 1979) despite their many phenotypic similarities. The strong growth shown by *P. canadensis* at 37°C serves to separate it from the other three species, which fail to grow at this temperature. *P. americana* and *P. bispora* form true hyphae whereas *P. alni* does not. Glucose fermentation by *P. americana* is weak or strong and occurs early (1–10 days), in contrast to *P. bispora* which either does not ferment glucose or gives a late (greater than 10 days) and weak fermentation of this sugar.

42.14. *Pichia bovis* van Uden & do Carmo-Sousa (1957)

Synonym:

Zymopichia bovis (van Uden & do Carmo-Sousa) Novák & Zsolt (1961).

Growth on 5% malt extract agar: After 3 days at 25°C, the cells are spheroidal to ovoidal, (1.9–5.1) × (2.1–9.2) μm, and occur singly or in pairs. Growth is butyrous and tannish-white in color.

Growth on the surface of assimilation media: Dry climbing pellicles are formed.

Dalmat plate culture on morphology agar: After 7 days at 25°C, growth of pseudohyphae under the coverglass may be quite rudimentary or moderately well developed. True hyphae are not formed. Aerobic growth is tannish-white, smooth, faintly glistening, butyrous, and with an entire margin. A faint ester-like odor is present.

Formation of ascospores: Asci are unconjugated and generally contain no more than two spores. The ascospores are hat-shaped and liberated from the asci soon after formation.

Ascospores were observed on 5% malt extract agar after 2–3 days at 25°C.

Fermentation:

Glucose	+	Lactose	–
Galactose	–	Raffinose	–

Mol% G + C: 39.8, 42.3, CBS 2616 (T_m : Nakase and Komagata 1970b; BD: Kurtzman, unpublished).

Origin of the strains studied: Cecum of a cow, van Uden (1); from Santa María (1).

Type strain: CBS 2616 (NRRL YB-4184), from the cecum of a cow.

Comments: *Pichia bovis* is phenotypically quite similar to *P. onychis*, but differs from the latter by the inability to ferment and to assimilate raffinose.

42.15. *Pichia burtonii* Boidin, Pignal, Lehodey, Vey & Abadie (1964)

Anamorph: *Candida variabilis* (Lindner) Berkhout

Synonyms:

Endomycopsis burtonii (Boidin, Pignal, Lehodey, Vey & Abadie) Kreger-van Rij (1970b)

Hyphopichia burtonii (Boidin, Pignal, Lehodey, Vey & Abadie) von Arx & van der Walt (1976)

Monilia variabilis Lindner (1898b)

Oospora variabilis (Lindner) Lindau (1907)

Candida variabilis (Lindner) Berkhout (1923)

Trichosporon variabile (Lindner) Delitsch (Lembke 1943)

Dematium chodati Nechitsch (1904)

Cladosporium chodati (Nechitsch) Saccardo (1906)

Candida chodati (Nechitsch) Berkhout (1923)

Endomycopsis chodati Wickerham & Burton (1952) nom. nud.

?*Sporotrichum carougeai* Langeron (1922)

Sporotrichum anglicum Castellani (1937b)

Trichosporon behrendii Lodder & Kreger-van Rij (1952)

Fermentotrichon behrendii (Lodder & Kreger-van Rij) Novák & Zsolt (1961)

Candida armeniaca-cornusmas Sarukhanyan (1957)

Candida fibrae Nakase (1971a)

Cladosporium fermentans S. Goto, Yamakawa & Yokotsuka (1975a)

Growth on 5% malt extract agar: After 3 days at

25°C, the cells are ovoidal to elongate, (2.3–5.7) × (6.0–9.0) μ m, and occur singly, in pairs and in small clumps. Pseudohyphae and true hyphae may be present. Growth is tannish-yellow in color and may be butyrous to somewhat mycelial.

Growth on the surface of assimilation media:

Depending upon the strain, pellicles may be thin and incomplete or quite thick.

Dalmau plate culture on morphology agar:

After 7 days at 25°C, growth under the coverglass shows abundant pseudohyphae as well as true hyphae. Blastoconidia may be borne on denticles. Denticles occur on blastoconidia as well as on hyphae and pseudohyphae. Arthroconidia are also produced. Aerobic growth is white to tannish-white in color, dull and sometimes powdery, and usually fringed by a broad mycelial band. A faint ester-like odor is present.

Formation of ascospores:

This species is heterothallic. Asci may form directly from diploid cells or result from the pairing of complementary mating types. Each ascus contains one to four hat-shaped ascospores which are readily released at maturity (Fig. 133).

Ascospores were observed on 5% malt extract- and YM agars after 3–5 days at 25°C.

Co-Q: 8, CBS 2352, AJ 4275 (Yamada et al. 1976b).

Mol% G + C: 35.6, AJ 4832 (T_m : Nakase and Komagata 1971g); 37.3, CBS 2352 (BD: Kurtzman, unpublished).

Fig. 133. *P. burtonii*, CBS 2352×CBS 2353. Ascosporeogenous culture after 3 days, 25°C, on 5% malt extract agar. Bar=5 µm.

Origin of the strains studied: Pollen carried by wild bees in Brazil (1); silage (1); stored rice (6); wheat (2); wheat flour (3); chicken feed (7); fig tree (1); wound on palm tree (1); ragi (1); sputum (1); skin (1); other substrates (6).

Complementary mating types: NRRL Y-1933 (CBS 2352) and NRRL Y-1938 (CBS 2353).

Type strain: CBS 2352 (NRRL Y-1933), from pollen.

Comments: The presence of budding cells and arthroconidia as well as sometimes profuse amounts of true hyphae has prompted the assignment of *P. burtonii* to various genera. In 1952, Wickerham and Burton discovered the ascospore stage of this species and showed it to be heterothallic. They described it as *Endomycopsis chodati* but a Latin diagnosis was not provided. Boidin et al. (1964) validly described the species as *P. burtonii* and in 1970 Kreger-van Rij (1970b) transferred it to *Endomycopsis*. In 1971, van der Walt and Scott (1971b) showed *Endomycopsis* to be an obligate synonym of *Saccharomycopsis* Schiönning and transferred many of the *Endomycopsis* species to *Saccharomycopsis*, but not *P. burtonii*. Later, von Arx and van der Walt (1976) transferred *P. burtonii* to their newly created genus *Hyphopichia*. Cardinal features of this new genus included heterothallism, presence of septate hyphae, asci formed from conjugating yeast cells and denticulate conidiogenous cells. These workers excluded *P. burtonii* from *Pichia* because it formed expanding septate hyphae and conidia borne on denticles and from *Saccharomycopsis* because it produced asci comprised of pairs of conjugating cells.

In the present treatment, *Hyphopichia* is not accepted because the phenotypic characters used for its definition do not distinguish it from several other genera. Features such as heterothallism, presence of septate hyphae and formation of asci from conjugating cells are widespread. Further, although the denticulate conidiogenous cells of *P. burtonii* are quite pronounced, they are not unique to any one taxon and may be found in *Stephanosascus ciferrii*,

Cephalosascus albidus, *Yarrowia lipolytica*, *P. rhodanensis*, *P. wickerhamii* and the euascomycete *Aureobasidium pullulans*.

42.16. *Pichia cactophila* Starmer, Phaff, Miranda & M.W. Miller (1978a)

Growth on 5% malt extract agar: After 3 days at 25°C, the cells are ovoidal to elongate, (1.2–5.0)×(2.0–8.1) µm, and occur singly, in pairs and in short chains. Growth is butyrous and cream-colored.

Growth on the surface of assimilation media: Thin climbing pellicles are formed.

Dalmau plate culture on morphology agar: After 7 days at 25°C, growth under the coverglass shows only rudimentary pseudohyphae and no true hyphae. Aerobic growth is slightly glistening, smooth, butyrous, tannish-white in color, and with irregular and finely serrate margins. A faint acidic odor is present.

Formation of ascospores: This species has been isolated from nature in the diploid form and cells convert directly to asci, producing two hat-shaped ascospores that are liberated at maturity. Colonies derived from single ascospores are ascosporeogenous, but because tetrads are not formed, it is not certain whether the species is homothallic or heterothallic.

Ascospore formation was observed on YM and 5% malt extract agars after 3–7 days at 25°C.

Fermentation:

Glucose	w/–	Lactose	–
Galactose	–	Raffinose	–
Sucrose	–	Trehalose	–
Maltose	–

Additional assimilation tests and other growth characteristics:

2-Keto-D-gluconate	–	Starch formation	–
5-Keto-D-gluconate	–	Gelatin liquefaction	–
Saccharate	–	Growth at 37°C	+
10% NaCl/5% glucose	–		

Co-Q: 7, CBS 6926 (Billon-Grand 1985).

Mol% G+C: 36.0–36.5, CBS 6926 and 2 additional strains (BD: Holzschu et al. 1983).

Origin of the strains studied: Cacti (*Stenocereus* spp., *Lemaireocereus pruinosus*) from Mexico (3).

Type strain: CBS 6926 (UCD-FST 76-243A, NRRL Y-10963) from organ pipe cactus (*Stenocereus thurberi*), Baja California, Mexico.

Comments: Results from the present study are in good agreement with the data of Starmer et al. (1978a), except that D-xylose assimilation was found to be late and either weak or strong rather than negative. None of the strains examined fermented glucose, but Starmer et al. (1978a) reported a few isolates of *P. cactophila* to give a slow and weak fermentation of this sugar, consequently, glucose fermentation is listed as either weak or absent.

P. cactophila has been isolated from a wide variety of cacti (Starmer et al. 1978a, 1990), and this lack of cactus habitat specificity contrasts with the more stringent niche requirements of most other cactophilic *Pichia* spp. *P. cactophila* and *P. pseudocactophila* show about 35% nDNA relatedness. For further discussion of these two species, see the Comments sections under *P. pseudocactophila*.

42.17. *Pichia canadensis* (Wickerham) Kurtzman (1984a)

Anamorph: *Candida melinii* Diddens & Lodder

Synonyms:

Hansenula canadensis Wickerham (1951)

Azymohansenula canadensis (Wickerham) Novák & Zsolt (1961)

Candida melinii Diddens & Lodder (1942)

Hansenula wingei Wickerham (1956)

Endomycopsis wingei (Wickerham) Novák & Zsolt (1961)

Growth on 5% malt extract agar: After 3 days at 25°C, the cells are spheroidal to elongate, (1.1–4.6) × (2.8–8.0) μm, and single or in pairs. Growth is butyrous and tannish-white.

Growth on the surface of assimilation media: Pellicles are absent or barely visible.

Dalmau plate culture on morphology agar: After 7 days at 25°C, growth under the coverglass shows abundant and highly branched pseudohyphae. True hyphae are also present. Aerobic growth is light tan in color, glistening, and butyrous. Margins of colonies are entire to lobed and may be fringed with pseudohyphae. An ester-like odor is present.

Formation of ascospores: Asci of the type strain are unconjugated single cells that contain two or rarely three hat-shaped ascospores. Asci deliquesce to liberate the spores. Single-spore isolates from two-spored asci gave

sporogenous colonies. The low frequency of three-spored asci has prevented their analysis for mating types, and it is not certain whether the type strain is homothallic as originally described (Wickerham 1951).

Strains of *Hansenula wingei*, now considered conspecific with *P. canadensis*, may be haploid or diploid when isolated from nature. Asci usually contain four hat-shaped spores and become deliquescent upon maturity. Strains described as *H. wingei* are heterothallic and it is the first fungus in which sexual agglutination was shown (Wickerham 1956).

Ascospores were observed on YM and 5% malt extract agars after 5–10 days at 25°C.

Fermentation: absent.

Assimilation:

Glucose	+	<i>N</i> -Acetyl-D-glucosamine	–
Galactose	–	Methanol	–

Additional assimilation tests and other growth characteristics:

2-Keto-D-gluconate	–	Starch formation	–
5-Keto-D-gluconate	–	Gelatin liquefaction	–
Saccharate	–	Growth at 37°C	+
10% NaCl/5% glucose	–		

Co-Q: 7, CBS 1991 (Yamada et al. 1973a).

Mol% G+C: 40.9, CBS 661 (T_m : Stenderup and Bak 1968); 39.0–40.0, CBS 1992, CBS 2431 (T_m : Nakase and Komagata 1971b); 39.7–40.8, CBS 1992 and 6 additional strains (BD: Fuson et al. 1979).

Origin of the strains studied: Frass from a red pine (*Pinus resinosa* Ait.), Ontario, Canada (1); frass from an eastern white pine (*Pinus strobus* L.), New Hampshire (1); dead conifer, Wyoming (1); from fungi cultured from a live bark beetle obtained from an Engelmann spruce (*Picea engelmannii* Parry), Colorado (2); Engelmann spruce, Wyoming (3); frass from a dead coniferous tree, Quebec, Canada (1).

Complementary mating types: NRRL Y-2340-5 (CBS 2432) and NRRL Y-2340-21 (CBS 2433), derived as single-ascospore isolates from the type strain of the synonym *Hansenula wingei*.

Type strain: CBS 1992 (NRRL Y-1888), isolated by Wickerham from frass of a red pine.

Comments: Wickerham (1956, 1970a) noted the phenotypic similarity of *P. (H.) canadensis* and *P. (H.) wingei* but

distinguished between the two, observing that *P. canadensis* produced no true hyphae and appeared homothallic while *H. wingei* formed true hyphae and was heterothallic. Indeed, *H. wingei* was quite remarkable in that mixtures of opposite mating types showed strong sexual agglutination (Wickerham 1956). Subsequently, this process was studied in detail by various investigators (Brock 1965, Conti and Brock 1965, Crandall and Brock 1968, Herman et al. 1966, Hunt and Carpenter 1963, Taylor and Orton 1968).

Fuson and coworkers (1979) compared the nDNA relatedness of several *Pichia* (*Hansenula*) species and showed *H. canadensis* and *H. wingei* to share 78% of their nuclear DNA base sequences. On the basis of previously established guidelines (Price et al. 1978), these workers suggested the two taxa to be conspecific. Kurtzman (unpublished), using somewhat different techniques, found the two species to have 76% nDNA complementarity, thus confirming this unexpected relatedness. Because *H. canadensis* was described 5 years earlier than *H. wingei*, the former species epithet has priority of usage.

Extensive single-spore isolations failed to detect heterothallism in *P. canadensis* and, therefore, precluded demonstration of conspecificity with *H. wingei* through mating studies (Kurtzman, unpublished). However, all single-spore isolates were obtained from two-spored asci, and it is entirely possible that these spores were diploid. By comparison, because of the predominance of diploid spores, heterothallism in *Pichia amylophila* nearly escaped detection (Kurtzman et al. 1980a). Regardless of whether *P. canadensis* is homothallic or heterothallic, considering the mating system as a key character for taxonomic separation seems unsound. It has been shown that the mutation of a single locus in *Saccharomyces cerevisiae* (Hicks and Herskowitz 1976) and in *Schizosaccharomyces pombe* (Leupold 1950) will change the mating behavior from heterothallic to homothallic.

During studies of nDNA relatedness among strains of *P. canadensis* (Kurtzman, unpublished), two isolates were included that were phenotypically similar to the others except that they did not utilize nitrate. Both isolates were obtained from the frass of conifers. When reassociated with NRRL Y-1888, NRRL YB-1915 showed 91% complementarity and NRRL YB-1931 gave 95%. These comparisons have provided additional evidence that nitrate utilization is not a species- or genus-specific character and account for the variable nitrate reaction given for *P. canadensis*.

42.18. *Pichia capsulata* (Wickerham) Kurtzman (1984a)

Anamorph: *Candida molischiana* (Zikes) S.A. Meyer & Yarrow, on the basis of phenotypic similarity (see Comments).

Synonyms:

Hansenula capsulata Wickerham (1951)

Kuraishia capsulata (Wickerham) Y. Yamada, Maeda & Mikata (1994c)

Torula molischiana Zikes (1911)

Torulopsis molischiana (Zikes) Lodder (1934)

Cryptococcus molischianus (Zikes) Skinner (1947b)

Candida molischiana (Zikes) S.A. Meyer & Yarrow (Yarrow and Meyer 1978)

Torulopsis methanophiles Urakami (1975)

Growth on 5% malt extract agar: After 3 days at 25°C, the cells are spheroidal to ellipsoidal, (1.2–5.0) × (2.4–5.8) μm, and single, in pairs, or occasionally in small clusters. Growth is butyrous and tannish-white in color.

Growth on the surface of assimilation media: Infrequently, thin pellicles may be produced and mucoid rings are occasionally formed.

Dalmat plate culture on morphology agar: After 7 days at 25°C, growth under the coverglass is devoid of pseudohyphae or true hyphae. Aerobic growth is white to tannish-white, glistening, and mucoid. Cultures usually produce a faint pleasant odor.

Formation of ascospores: There are one or two hat-shaped ascospores per ascus (Fig. 134). Conjugation usually precedes sporulation and may be between a cell and its bud or infrequently between independent cells. In the latter case, conjugants commonly are a cell and the bud of another cell. Asci are deliquescent and spores are liberated soon after formation. Single-spore isolates produce sporogenous cultures, but because no more than two spores are formed per ascus, the evidence that this species is homothallic is not conclusive. However, the presence of parent–bud conjugation is suggestive of homothallism.

Ascospores were observed on YM and 5% malt extract agars after 5–10 days at 25°C.

Co-Q: 8, CBS 1993, AJ 4173 (Yamada et al. 1973a).

Mol% G+C: 46.8, 47.1, CBS 1993, CBS 5807 (T_m : Nakase and Komagata 1971b); 46.9, CBS 1993 (BD: Kurtzman, unpublished).

Origin of the strains studied: Frass from mainly coniferous trees (53); soil on humus (3); lichen (1); cattle dung (1).

Fig. 134. *P. capsulata*, CBS 1993. Ascospore culture after 3 days, 25°C, on 5% malt extract agar. Bar = 5 µm.

Type strain: CBS 1993 (NRRL Y-1842), isolated by Wickerham from frass of a coniferous tree on the shore of Wabatonigushi Lake, near Franz, Ontario, Canada.

Comments: *P. capsulata* produces copious amounts of extracellular polysaccharides. The structures of the mannans and phosphomannans synthesized by this species have been studied in detail by Slodki et al. (1972), Gorin (1973) and Seymour et al. (1976).

Ascospore formation has not been observed for *Candida molischiana*, and the proposed conspecificity with *P. capsulata* is based on similar appearance in culture and the same assimilation profile. However, Lee and Komagata (1983) noted that the two taxa had somewhat different electrophoretic patterns for their cellular enzymes and raised the possibility that they may not represent an anamorph–teleomorph pair.

42.19. *Pichia caribaea* Phaff, Starmer, Lachance, Aberdeen & Tredick-Kline (1992)

Synonym:

Pichia amethionina Starmer, Phaff, Miranda & M.W. Miller var. *fermentans* Starmer & Phaff (1983) nom. nud.

Growth on 5% malt extract agar: After 3 days at 25°C, the cells are ovoidal to cylindrical, (1.8–4.0) × (3.0–10.2) µm, and single, in pairs or in short chains. Growth is butyrous and tannish-white.

Growth on the surface of assimilation media: Pellicles are absent but a film may form.

Dalmau plate culture on morphology agar: After 7 days at 25°C, growth under the coverglass shows some “tree-like” outgrowths comprised of short cells, but well-branched pseudohyphae and true hyphae are lacking. Aerobic growth is butyrous, tannish-white, and glistening with an irregular surface and a finely lobed margin. Colonies are convex in profile. A faint acidic, ester-like odor is present.

Formation of ascospores: This species is heterothallic. Natural isolates may be either haploid or diploid. Diploids, such as the type strain, undergo ascospore formation without prior conjugation and form three to four hat-shaped ascospores that are freed through ascus deliquescence. Paired complementary mating types may show strong sexual agglutination prior to conjugation and ascospore formation.

Ascospore formation occurs on McClary’s acetate agar, or less frequently on YM and 5% malt extract agars, after 3–5 days at 25°C.

Fermentation:

Glucose	+	Lactose	–

5-Keto-D-gluconate	–	Gelatin liquefaction	–
Saccharate	–	Growth at 37°C	v
10% NaCl/5% glucose	–		

Co-Q: Not determined.

Mol% G+C: 34.0–34.4, CBS 7692, and 3 additional strains (BD: Phaff et al. 1992).

Origin of the strains studied: CBS 7692 (UCD-FST 81-62, NRRL Y-17468) from rotting prickly pear cactus (*Opuntia stricta*), Exuma chain, Bahamas; CBS 7695 (UCD-FST 82-570C, NRRL Y-17469) from rotting columnar cactus (*Cephalocereus royerii*), Island of Montserrat, West Indies; CBS 7696 (UCD-FST 83-711.2, NRRL Y-17472) from prickly pear cactus, Conception Island, Bahamas.

Complementary mating types: CBS 7693 [UCD-FST 81-280, NRRL Y-17470 (*h*⁻)] and CBS 7694 [UCD-FST 81-279, NRRL Y-17471 (*h*⁺)], single-spore isolates from UCD-FST 81-36, from the Exhumas chain, Bahamas (Phaff et al. 1992).

Type strain: CBS 7692.

Comments: Phaff et al. (1992) reported ca. 40% nDNA relatedness between *P. caribaea* and each of the two varieties of *P. amethionina*. Interspecific matings gave zygotes, but asci were aberrant and produced malformed ascospores. These data showed the two taxa to be reproductively isolated sibling species. The host range of *P. caribaea* and its geographical distribution throughout the Caribbean was well documented by Phaff et al. (1992).

Results from the present study are in agreement with Phaff et al. (1992) except that NRRL Y-17469 latently assimilated D-xylose in contrast to the reported inability to grow on this pentose, and the strain also failed to grow at 37°C. Phaff et al. (1992) reported that, as for *P. amethionina*, *P. caribaea* is a naturally occurring auxotroph that requires an organic form of sulfur, such as L-methionine or L-cysteine.

42.20. *Pichia castillae* Santa María & García Aser (1970)

Synonym:

Yamadazyma castillae (Santa María & García Aser) Billon-Grand (1989)

Growth on 5% malt extract agar: After 3 days at 25°C, the cells are ovoidal to ellipsoidal, (1.4–3.5) × (2.0–7.0) μm, and occur singly, in pairs and in clusters. Growth is butyrous and tannish-white in color.

Growth on the surface of assimilation media: Thin, slightly climbing pellicles are present.

Dalmau plate culture on morphology agar: After 7 days at 25°C, growth under the coverglass shows only sparse and poorly differentiated pseudohyphae. True hyphae are not present. Aerobic growth is tannish-white in color, somewhat butyrous, and with a smooth, dull to faintly glistening surface. The margin is lobate. A faint acidic odor is present.

Formation of ascospores: The asci, which show isogamic or heterogamic conjugation, produce two to four hat-shaped ascospores. Spores are released rapidly following their formation. Santa María and García Aser (1970) reported this species to be homothallic.

Ascospores were observed on YM and 5% malt extract agars after 10 days at 25°C.

Fermentation: absent.

Assimilation:

Co-Q: 9, CBS 6053 (Billon-Grand 1985).

Mol% G + C: 39.5, CBS 6053 (*T_m*: Billon-Grand 1981).

Origin of the strain studied: Frass of insects infesting the tree *Gymnocladus canadensis* (1).

Type strain: CBS 6053 (NRRL Y-7501).

42.21. *Pichia chambardii* (C. Ramírez & Boidin) Phaff (1956)

Synonyms:

Saccharomyces chambardi C. Ramírez & Boidin (1954) (also in Ramírez & Boidin 1955)

Petasospora chambardi (C. Ramírez & Boidin) Boidin & Abadie (1954)

Growth on 5% malt extract agar: After 3 days at 25°C, the cells are ovoidal, (1.8–4.1) × (2.6–6.8) μm, and occur singly or in pairs. Growth is butyrous and grayish-white in color.

Growth on the surface of assimilation media: Thin pellicles are formed.

Dalmau plate culture on morphology agar: After 7 days at 25°C, growth under the coverglass shows only infrequent undifferentiated pseudohyphal strands. True hyphae are not formed. Aerobic growth is white in color, butyrous, smooth, dull-glistening, and with an occasionally lobed margin. A faint acidic odor is present.

Formation of ascospores: Asci are unconjugated and form one to four (usually two) hat-shaped ascospores. The spores are liberated at maturity. It is not known whether the species is homothallic or heterothallic.

Ascospores were observed on 5% malt extract agar after 3 days at 25°C.

Fermentation: absent.

Type strain: CBS 1900 (NRRL Y-2378).

42.22. *Pichia ciferrii* (Lodder) Kurtzman (1984a)**Synonyms:**

Hansenula ciferrii Lodder (1932)

Hansenula anomala (Hansen) H. & P. Sydow var. *ciferrii* Lodder & Kreger-van Rij (1952)

Endomycopsis ciferrii (Lodder) Novák & Zsolt (1961)

Growth on 5% malt extract agar: After 3 days at 25°C, the cells are spheroidal to ellipsoidal, (3.3–5.0) × (3.9–9.5) μ m, and single, in pairs, or in small clusters. Growth is butyrous and white in color.

Growth on the surface of assimilation media: Pellicles are thin, smooth, and waxy.

Dalmau plate culture on morphology agar: After 7 days at 25°C, growth under the coverglass shows abundant and highly branched pseudohyphae. Mycelial variants derived from the type strain, such as NRRL Y-1322, form abundant true hyphae. Aerobic growth is white, faintly glistening to dull, and butyrous. Colony margins are usually lobed and may be fringed with pseudohyphae. A faint ester-like odor is present.

Formation of ascospores: Diploid cells convert to asci and form one to four hat-shaped ascospores. Asci are deliquescent. This species is heterothallic, and Wickerham and Burton (1954b) obtained mating types by heat-treating the sporogenous diploid type culture.

Ascospores were observed on 5% malt extract agar and sterilized carrot slices after 4–10 days at 25°C.

Co-Q: 7, CBS 111 (Yamada et al. 1973a).

Mol% G + C: 32.2, CBS 111 (T_m : Nakase and Komagata 1971b).

Origin of the strain studied: Pod from the Tonka-bean tree (*Dipteryx odorata*), Dominican Republic (1).

Complementary mating types: NRRL Y-1031-11 (CBS 1990) and NRRL Y-1031-27 (CBS 1991).

Type strain: CBS 111 (NRRL Y-1031), isolated by Ciferri from Tonka-bean.

Comments: On standard tests, *P. ciferrii* differs from *P. anomala* only in the ability to assimilate rhamnose. Wickerham (1970a) considered the species distinct, however, because they showed no mating response following mixture of their mating types, and *P. ciferrii* produces crystals of tetraacetylphytosphingosine (Wickerham and Stodola 1960, Stodola and Wickerham 1960, Wickerham and Burton 1962), but *P. anomala* has never been observed to produce this compound. Additionally, Nakase and Komagata (1971b) reported *P. ciferrii* to have a G + C content nearly 4% lower than that of *P. anomala* which suggests an almost complete lack of nDNA base sequence complementarity.

42.23. *Pichia delftensis* Beech (1965)

Growth on 5% malt extract agar: After 3 days at 25°C, the cells are ovoidal, (2.5–5.3) × (2.7–8.9) μ m, and occur singly or in pairs. Growth is butyrous and tannish-white in color.

Growth on the surface of assimilation media: Pellicles are formed.

Dalmou plate culture on morphology agar: After 7 days at 25°C, growth under the coverglass shows only an occasional undifferentiated pseudohyphal outgrowth. True hyphae are not formed. Aerobic growth is white in color, dull to slightly glistening, butyrous and with a finely lobed margin.

Formation of ascospores: Asci may be unconjugated, or show conjugation between independent cells. One to four hat-shaped ascospores are formed per ascus, and the ascus slowly deliquesce. It is not known whether the species is homothallic or heterothallic.

Ascospores were observed on YM and 5% malt extract agars after 3–10 days at 25°C.

Fermentation:

Glucose	w/–	Lactose	–
Galactose	–	Raffinose	–

Co-Q: 7, CBS 2614 (Billon-Grand 1985).

Mol% G+C: 33.2, CBS 2614 (BD: Kurtzman, unpublished).

Origin of the strain studied: Naturally fermented apple juice, England (1).

Type strain: CBS 2614 (NRRL Y-7119).

Comments: As noted earlier, *P. delftensis* resembles *P. amethionina* and many other species isolated from cacti.

42.24. *Pichia deserticola* Phaff, Starmer, Tredick & Miranda (1985)

Anamorph: *Candida deserticola* Phaff, Starmer, Tredick & Miranda

Synonym:

Candida deserticola Phaff, Starmer, Tredick & Miranda (1985)

Growth on 5% malt extract agar: After 3 days at

25°C, the cells are ellipsoidal to elongate, (2.2–4.5) × (2.7–7.6) μm, and single, in pairs and in small clusters. Growth is tannish-white, semi-glistening and butyrous.

Growth on the surface of assimilation media: Thin pellicles often form.

Dalmou plate culture on morphology agar: After 7 days at 25°C, growth under the coverglass shows pseudo-hyphae that range from poorly differentiated to moderately branched. True hyphae are not produced. Aerobic growth is tannish-white, semi-glistening, butyrous, and convex in profile with a depressed center. Colony margins are smooth to finely scalloped. A faint acidic odor is present.

Formation of ascospores: Asci are often unconjugated but some appear to have undergone conjugation with a bud. Ascospores are hat-shaped and two are formed per deliquescent ascus (Fig. 135). Single-spore isolates form ascosporegenous colonies.

Fig. 135. *P. deserticola*, CBS 7119. Ascosporegenous culture after 10 days, 25°C, on McClary's acetate agar. Bar = 5 μm.

Ascospores were observed on McClary's acetate agar after 2–10 days at 25°C.

Fermentation: absent.

Assimilation:

Glucose	+	<i>N</i> -Acetyl-D-glucosamine	–
Galactose	–	Methanol	–
L-Sorbose	–	Ethanol	+

D-Arabinose	–	Inositol	–
D-Ribose	–	Hexadecane	–
L-Rhamnose	–	Nitrate	–
D-Glucosamine	–	Vitamin-free	–

Additional assimilation tests and other growth characteristics:

2-Keto-D-gluconate	–	Starch formation	–
5-Keto-D-gluconate	–	Gelatin liquefaction	–
Saccharate	–	Growth at 37°C	+
10% NaCl/5% glucose	–		

Co-Q: Not determined.

Mol% G + C: 27.4–28.4, CBS 7119 and 7 additional strains (BD: Phaff et al. 1985).

Origin of the strains studied: *P. deserticola*: CBS 7119 (UCD-FST 83-467.3, NRRL Y-12918), from prickly pear cactus (*Opuntia phaeacantha*), Santa Catalina Mountains, Arizona, U.S.A.; CBS 7120 (UCD-FST 81-403B, NRRL Y-12919), from *O. phaeacantha*, Tucson Mountains, Arizona. *Candida deserticola*: CBS 7121 (UCD-FST 76-355A, NRRL Y-12920), type strain, from columnar cactus (*Stenocereus gummosus*), Mulegé, Baja California, Mexico; CBS 7122 (UCD-FST 82-451A, NRRL Y-12921), from columnar cactus (*Stenocereus hystrix*), Gonnaïves, Haiti.

Type strain: CBS 7119.

Comments: Results from the present study are in good agreement with the original description. Phaff et al. (1985) showed nearly 100% nDNA relatedness between *P. deserticola* and the nonascosporogenous strains designated as *Candida deserticola*. The former taxon occurs in species of prickly pear cacti whereas the latter is almost exclusive to columnar cacti. *P. deserticola* and its anamorph are noteworthy because they assimilate so few carbon compounds, although their strong growth on ethyl acetate provides one means to separate them from *P. antillensis*. It should be pointed out that *P. deserticola* has the lowest nDNA base composition of any known yeast.

42.25. *Pichia dryadoides* (D.B. Scott & van der Walt) Kurtzman (1984a)

Synonym:

Hansenula dryadoides D.B. Scott & van der Walt (1971a)

Growth on 5% malt extract agar: After 3 days at 25°C, the cells are spheroidal or ellipsoidal, (2.5–5.3) × (2.6–7.7) μm, and single, in pairs, and in small clusters. Growth is butyrous and tannish-white in color.

Growth on the surface of assimilation media: Pellicles are not formed but occasional incomplete rings may be observed.

Dalmau plate culture on morphology agar: After 7 days at 25°C, growth under the coverglass shows only rudimentary pseudohyphae. True hyphae are not produced. Aerobic growth is tannish-white, glistening, and butyrous. Margins vary from entire to lobed. A faintly acidic odor is present.

Formation of ascospores: Diploid cells convert directly to asci and each ascus contains two, or less frequently one, hat-shaped ascospores with prominent brims. Asci

are persistent. Scott and van der Walt (1971a) reported that heat treatment of sporogenous cultures gave colonies which sporulated, thus suggesting this species to be homothallic. However, ascospores from two-spored asci may be diploid.

Ascospores were observed on 5% malt extract and YM agars after 3–10 days at 25°C.

Fermentation: absent.

Assimilation:

Glucose	+	<i>N</i> -Acetyl-D-glucosamine	–
Galactose	–	Methanol	–
L-Sorbose	–	Ethanol	+
Sucrose	–	Glycerol	+
Maltose	–	Erythritol	–
Cellobiose	+	Ribitol	–
Trehalose	–	Galactitol	–
Lactose	–	D-Mannitol	+
Melibiose	–	D-Glucitol	+
Raffinose	–	α-Methyl-D-glucoside	–
Melezitose	–	Salicin	–
Inulin	–	D-Gluconate	+
Soluble starch	–	Di.-Lactate	+
D-Xylose	v	Succinate	+
L-Arabinose	–	Citrate	+
D-Arabinose	–	Inositol	–
D-Ribose	–	Hexadecane	–
L-Rhamnose	–	Nitrate	+
D-Glucosamine	–	Vitamin-free	+

Additional assimilation tests and other growth characteristics:

2-Keto-D-gluconate	–	Starch formation	–
5-Keto-D-gluconate	–	Gelatin liquefaction	–
Saccharate	–	Growth at 37°C	v
10% NaCl/5% glucose	–		

Co-Q: Not determined.

Mol% G + C: 31.8, 31.0, CBS 6154 (HPLC: Miller and Bahareen 1979; BD: Phaff et al. 1983).

Origin of the strains studied: From tunnels of the pin hole borer *Platypus externedentatus* Fairm. infesting various figs (*Ficus* spp.), Natal, South Africa (2).

Type strain: CBS 6154 (NRRL Y-10990), isolated from *Ficus sycomorus* L.

Comments: Minor differences in growth reactions were noted between the original description and the present study. Scott and van der Walt (1971a) reported growth on D-xylose, salicin, in osmotic medium and at 37°C. Of the two strains examined in the present study, neither grew on salicin nor in osmotic medium, and one failed to grow on D-xylose as well as at 37°C. Scott and van der Walt (1971a) noted that *Candida berthetii* is rather similar to *P. dryadoides*, but the 5% difference in G + C that Poncet (1973a) detected between the two taxa would preclude conspecificity.

42.26. *Pichia euphorbiae* van der Walt & Opperman (1983)

Anamorph: *Candida euphorbiae* van der Walt & Opperman

Synonym:

Candida euphorbiae van der Walt & Opperman (1983)

Growth on 5% malt extract agar: After 3 days at

25°C, the cells are occasionally spheroidal, but usually ellipsoidal to cylindroidal, (1.1–6.0)×(2.2–12.1) µm, and single, in pairs, and in small clusters. Growth is butyrous, slightly glistening and tannish-white.

Growth on the surface of assimilation media: Pellicles were not observed, but rings and islets of surface growth occur.

Dalmau plate culture on morphology agar: After 7 days at 25°C, growth under the coverglass is comprised of well-branched pseudohyphae with blastoconidia; true hyphae are present as well. Aerobic growth is white to tannish-white, moderately glistening and butyrous. Colony margins are scalloped with hyphal outgrowths. A faintly acidic odor is present.

Formation of ascospores: This species is heterothallic and has been isolated from nature only as haploid mating types. Cultures of paired complementary mating types form asci with one to four hat-shaped ascospores. Asci are deliquescent.

Ascospores were observed on 5% malt extract agar after 10–15 days at 15°C.

Fermentation:

Glucose	+	Lactose	–
Galactose	–	Raffinose	–
Sucrose	ws	Trehalose	–
Maltose	–		

Assimilation:

Glucose	+	<i>N</i> -Acetyl-D-glucosamine	–
Galactose	–	Methanol	–
L-Sorbose	–	Ethanol	+
Sucrose	+	Glycerol	+
Maltose	+	Erythritol	–

Soluble starch	–	DL-Lactate	+
D-Xylose	+	Succinate	+
L-Arabinose	+	Citrate	+
D-Arabinose	–	Inositol	–
D-Ribose	–	Hexadecane	–
L-Rhamnose	+	Nitrate	–
D-Glucosamine	–	Vitamin-free	–

Additional assimilation tests and other growth characteristics:

2-Keto-D-gluconate	–	Starch formation	–
5-Keto-D-gluconate	–	Gelatin liquefaction	–
Saccharate	–	Growth at 37°	v
10% NaCl/5% glucose	–		

Co-Q: Not determined.

Mol% G + C: Not determined.

Origin of the strains studied: Insect infested spurge (*Euphorbia ingens* E. Mey.), Groblersdal area, South Africa (2).

Complementary mating types: CBS 7082 (NRRL Y-17233) and CBS 7083 (NRRL Y-17757).

Type strain: CBS 8033 (NRRL Y-17232), a diploid constructed by the mating of CBS 7082 and CBS 7083.

Comments: Van der Walt and Opperman (1983) noted *P. euphorbiae* to be phenotypically similar to *P. rhodanensis*, *P. wickerhamii*, *P. amylophila*, *P. mississippiensis*, *P. veronae* and *P. meyeriae*, which are also heterothallic. Pairings with these species gave a mating reaction only with *P. meyeriae*. The reaction was limited to formation of infrequent zygotes that failed to produce ascospores, suggesting the two taxa to be closely related but reproductively isolated species.

42.27. *Pichia euphorbiiphila* (van der Walt)

Kurtzman (1984a)

Anamorph: *Candida euphorbiiphila* van der Walt

Synonyms:

Hansenula euphorbiiphila (as *H. euphorbiaphila*) van der Walt (1982b)

Candida euphorbiiphila (as *C. euphorbiaphila*) van der Walt (1982b)

Growth on 5% malt extract agar: After 3 days at 25°C, the cells are short ellipsoidal to cylindroidal, (2.0–4.6)×(2.3–8.5) µm, and occasionally tapered. Growth is butyrous, glistening and white to tannish-white.

Growth on the surface of assimilation media:

Pellicles are not formed but rings are occasionally seen.

Dalmau plate culture on morphology agar: After 7 days at 25°C, growth under the coverglass shows abundant, well-branched pseudohyphae with blastoconidia. True hyphae are not formed. Aerobic growth is white to tannish-white, glistening, butyrous, convex in profile with a slight central depression, and with margins that are smooth to finely scalloped. There is a faint odor of esters.

Fig. 136. *P. euphorbiiphila*, CBS 8033. Ascosporegenous culture after 3 days, 25°C, on McClary's acetate agar. Bar = 5 µm.

Formation of ascospores: This species is heterothallic but has been isolated from nature only in the diploid state. Asci from diploid strains are unconjugated and produce two to four hat-shaped ascospores (Fig. 136). Asci become deliquescent at maturity. Van der Walt (1982b) isolated

haploid mating types from the sporulated type strain through heat treatment.

Ascospores were observed on McClary's acetate agar, and to a lesser extent on 5% malt extract agar, after 2–5 days at 25°C.

Fermentation:

Glucose	+	Lactose	–
Galactose	–	Raffinose	–
Sucrose	–	Trehalose	–

5-Keto-D-gluconate	–	Gelatin liquefaction	–
Saccharate	–	Growth at 37°	+
10% NaCl/5% glucose	w/–		

Co-Q: Not determined.

Mol% G + C: 47.3, CBS 8083 (BD: Kurtzman, unpublished).

Origin of the strains studied: CBS 8083 (NRRL Y-12742), from insect infested decaying tissue of spurge (*Euphorbia ingens*), Transvaal, South Africa; CBS 7912 (NRRL Y-12743) and CBS 7913 (Y-12744), which were derived from heat-treatment of the type strain.

Complementary mating types: CBS 7912 (*a*) and CBS 7913 (α), derived from CBS 8083.

Type strain: CBS 8083.

Comments: Van der Walt (1982b) noted the phenotypic similarity of *P. euphorbiiphila* with *P. americana* and *P. bimundalis*, but mating types of *P. euphorbiiphila* showed no response to those of the latter two species.

42.28. *Pichia fabianii* (Wickerham) Kurtzman (1984a)

Anamorph: *Candida fabianii* K. Kodama, Kyono, Iida & Onoyama
Synonyms:

Hansenula fabianii Wickerham (1965a)

Candida fabianii K. Kodama, Kyono, Iida & Onoyama (1964a)

Growth on 5% malt extract agar: After 3 days at 25°C, the cells are spheroidal to ellipsoidal, (1.0–4.2) × (2.0–6.5) μ m, and single, in pairs, or in small clusters. Growth is butyrous and tannish-white in color.

Growth on the surface of assimilation media: Thin pellicles and rings are produced.

Dalmat plate culture on morphology agar: After 7 days at 25°C, growth under the coverglass shows occasional pseudohyphae. True hyphae are not produced. Aerobic growth is tannish-white, glistening, and butyrous. Margins are entire or lobed; pseudohyphae are not formed around the periphery of aerobic colonies. An ester-like odor is produced.

Formation of ascospores: This species is heterothallic and only asporogenous haploid isolates have been obtained from nature. Following the mixture of complementary mating types, zygotes may directly convert to asci or they may bud diploid cells which can become asci. The asci contain one to four hat-shaped ascospores and become deliquescent upon maturity.

Ascospores were observed on 5% malt extract agar after 5–10 days at 25°C.

Co-Q: 7, CBS 5640 and 3 additional strains (Yamada et al. 1973a).

Mol% G + C: 44.4–45.6, CBS 5640 and 5 additional strains (T_m : Nakase and Komagata 1971b); 46.7, CBS 5640 (BD: Kurtzman, unpublished).

Origin of the strains studied: A contaminant of a fermentor inoculated with *Aerobacter aerogenes* for production of butylene glycol, U.S.A. (1); alcohol fermentation plant, Cheju Island, Korea (3); rice koji, Japan (4).

Complementary mating types: NRRL Y-1871 (CBS 5640) and NRRL Y-1873 (CBS 5641).

Type strain: CBS 5640 (NRRL Y-1871), isolated from a fermentor used for butylene glycol production.

Comments: Of the heterothallic species of *Pichia*, *P. fabianii* is most like *P. subpelliculosa*. The two are dissimilar only in their assimilation of erythritol, which is negative for *P. fabianii*. Nakase and Komagata (1971b) reported the G+C contents of the two species to differ by nearly 11% and this would preclude their conspecificity.

42.29. *Pichia farinosa* (Lindner) E.C. Hansen (1904)

Synonyms:

- Saccharomyces farinosus* Lindner (1894)
Zygosaccharomyces farinosus (Lindner) Papadakis (1922)
Zygopichia farinosa (Lindner) Klöcker (1924)
Yamadazyma farinosa (Lindner) Billon-Grand (1989)

Pichia farinosa (Lindner) E.C. Hansen var. *japonica* Ohara & Nonomura (1954b) nom. nud.
Pichia minuscula Soneda (1959)
Debaryomyces halotolerans Sasaki & Yoshida (1966) nom. nud.
Candida cacaoi H.R. Buckley & van Uden (1968)
Pichia petrophilum Mu (Mu et al. 1979)
Pichia sorbitophila Rodrigues de Miranda, Appel & Seyfarth (1980)

Growth on 5% malt extract agar: After 3 days at 25°C, the cells are ovoidal to elongate, (1.5–5.0) × (3.0–18.0) µm, and occur singly, in pairs and in short chains. Growth is white to occasionally faintly yellowish-white in color.

Growth on the surface of assimilation media: Heavy, dry climbing pellicles develop.

Dalmau plate culture on morphology agar: After 7 days at 25°C, growth under the coverglass shows pseudohyphae which, depending upon the strain, may be poorly differentiated to moderately branched. True hyphae are not formed. Aerobic growth is white, smooth to rugose, powdery, and generally has lobed margins. A faint ester-like odor is produced by some strains.

Formation of ascospores: Asci show parent cell–bud conjugation and produce one to four spheroidal to subspheroidal ascospores (Fig. 137). Asci are generally persistent, although free spores are occasionally observed. Single-spore isolates from four-spored asci from the type strain and one additional strain were sporogenous, indicating the species to be homothallic (Kurtzman, unpublished). Kawakami et al. (1961) and Kreger-van Rij (1970c) reported the spores to have

Fig. 137. *P. farinosa*, NRRL Y-2060. Ascosporengous culture after 3 days, 25°C, on V8 agar. Bar = 5 µm.

a thin, subequatorial ledge visible under the electron microscope.

Ascospores were observed on V8, RG and YM agars after 3–5 days at 25°C.

Co-Q: 9, CBS 185 and 5 additional strains (Yamada et al. 1973a).

Mol% G+C: 38.8–39.8, AJ 4134, AJ 4136, AJ 4138 (T_m : Nakase and Komagata 1970b); 42.7, CBS 185 (BD: Kurtzman, unpublished).

Origin of the strains studied: ‘Jopenbier’ (1); fermenting cacao, Trinidad (1); miso (2); stored rice (4); wheat flour (1); other substrates (2); *Debaryomyces*

halotolerans (2); *P. sorbitophila* (CBS 7064, NRRL Y-12695); *P. petrophilum* (CBS 7911, NRRL Y-11953).

Type strain: CBS 185 (NRRL Y-7553) from 'Jopen-bier'.

Comments: The extent of nDNA relatedness between the type strain of *P. farinosa* and the type strains of *Debaryomyces halotolerans*, *P. sorbitophila* and *P. petrophilum* was 100%, 70% and 72%, respectively (Kurtzman, unpublished). These results indicate the latter three taxa to be conspecific with *P. farinosa*.

42.30. *Pichia fermentans* Lodder (1932)

Anamorph: *Candida lambica* (Lindner & Genoud) van Uden & H.R. Buckley, on the basis of phenotypic similarity.

Synonyms:

Zymopichia fermentans (Lodder) Novák & Zsolt (1961)

Saccharomyces pastorianus-arborescens van Laer (1902)

Mycoderma lambica Lindner & Genoud (1913)

Candida lambica (Lindner & Genoud) van Uden & H.R. Buckley (1970)

Torula monosa Kluuyver (1914)

Mycotorula monosa (Kluuyver) Harrison (1928)

Candida monosa (Kluuyver) Diddens & Lodder (1942)

Saccharomyces dombrowskii Sacchetti (1933)

Pichia dombrowskii Sacchetti, nom. nud.? (Lodder & Kreger-van Rij 1952)

Saccharomyces scandinavicus Dietrichson (1954)

Candida fimetaria Soneda (1959)

Candida krusei (Castellani) Berkhout var. *transitoria* Saëz (1965)

Growth on 5% malt extract agar: After 3 days at 25°C, the cells are ovoidal to ellipsoidal, (1.9–6.5) × (4.0–14.4) μm, and occur singly, in pairs and in short chains. Growth is tannish-yellow in color.

Growth on the surface of assimilation media: Thin to thick climbing pellicles are formed.

Dalmau plate culture on morphology agar: After 7 days at 25°C, growth under the coverglass shows abundant and moderately branched pseudohyphae. True hyphae are not present. Aerobic growth is white and dull with the surface wrinkled by convoluted growth. Margins are lobate. A weak ester-like odor is produced by some strains.

Formation of ascospores: Asci may be unconjugated or show conjugation between independent cells or between a parent cell and a bud. Two to four ascospores are formed per ascus, and asci become deliquescent. Spores are hat-shaped but the ledge is not always easily detected under the light microscope. Single-spore isolates from four-spored asci are ascosporegenous, indicating the species to be homothallic.

Ascospores were observed on YM, 5% malt extract, and V8 agars after 10–20 days at 25°C.

Fermentation:

Glucose	+	Lactose	–
Galactose	–	Raffinose	–
Sucrose	–	Trehalose	–
Maltose	–		

Assimilation:

Glucose	+	<i>N</i> -Acetyl-D-glucosamine	+
Galactose	–	Methanol	–
L-Sorbose	–	Ethanol	+
Sucrose	–	Glycerol	+
Maltose	–	Erythritol	–

D-Glucosamine	+	Vitamin-free	–

Additional assimilation tests and other growth characteristics:

2-Keto-D-gluconate	–	Starch formation	–
5-Keto-D-gluconate	–	Gelatin liquefaction	–
Saccharate	–	Growth at 37°	+
10% NaCl/5% glucose	v		

Co-Q: 7, CBS 246 (Yamada et al. 1973a).

Mol% G+C: 42.2, AJ 4458, AJ 4891 (T_m : Nakase and Komagata 1970b); 43.1, CBS 187 (BD: Fuson et al. 1980).

Origin of the strains studied: Buttermilk (1); stracchino cheese (1); sputum (1); spoiled orange juice (1); kefir (1); cecum of cow (1); *Cyanochen cyanopterus* (1); *Cygnus olor* (1).

Type strain: CBS 187 (NRRL Y-1619) from buttermilk.

Comments: There is considerable phenotypic similarity between *P. fermentans* and *P. kluuyveri* var. *kluuyveri*. However, the two may be separated on the basis of the strong assimilation of citrate and D-xylose shown by *P. fermentans* (De Camargo and Phaff 1957). These species also differ by about 14% in G+C contents.

42.31. *Pichia finlandica* Kurtzman (1984a)

Synonyms:

Hansenula wickerhamii Capriotti (1961c)

Ogataea wickerhamii (Capriotti) Y. Yamada, Matsuda, Maeda & Mikata (1995a)

Growth on 5% malt extract agar: After 3 days at 25°C, the cells are spheroidal or ellipsoidal, (1.4–3.3) × (1.4–3.5) μm, and single or in pairs. Growth is butyrous and tannish-white in color.

Growth on the surface of assimilation media: Pellicles are not produced.

Dalmau plate culture on morphology agar: After 7 days at 25°C, neither hyphae nor pseudohyphae are detected under the coverglass. Aerobic growth is tannish-white, smooth, glistening, and butyrous. Colony margins are entire to finely lobed.

Formation of ascospores: Asci generally form after conjugation between independent cells, but occasionally

they are unconjugated or a parent cell may conjugate with a bud. The asci usually produce three or four rather small hat-shaped ascospores that are soon released by deliquescence. Single-spore isolates give ascosporegenous colonies and the species appears to be homothallic (Kurtzman, unpublished).

Ascospores were observed on 5% malt extract agar after 2–3 days at 25°C.

Fermentation: absent.

Assimilation:

Glucose	+	<i>N</i> -Acetyl-D-glucosamine	–
Galactose	–	Methanol	+
L-Sorbose	+	Ethanol	+
Sucrose	–	Glycerol	+
Maltose	–	Erythritol	+
Cellobiose	–	Ribitol	+

L-Arabinose	v	Citrate	–
D-Arabinose	+	Inositol	–
D-Ribose	+	Hexadecane	–
L-Rhamnose	+	Nitrate	+
D-Glucosamine	–	Vitamin-free	–

Additional assimilation tests and other growth characteristics:

2-Keto-D-gluconate	–	Starch formation	–
5-Keto-D-gluconate	–	Gelatin liquefaction	w/–
Saccharate	–	Growth at 37°C	–
10% NaCl/5% glucose	–		

Co-Q: 7, CBS 4307 (Yamada et al. 1973a).

Mol% G + C: 45.4, CBS 4307 (T_m : Nakase and Komagata 1971b).

Origin of the strains studied: Soil from a swamp in which spruce and broad-leaved trees were growing, Hyytiala Province of Tavastia Australis, Finland (2).

Type strain: CBS 4307 (NRRL YB-4943), Capriotti's strain 241-A which he had designated as the type of *Hansenula wickerhamii*.

Comments: With the transfer of species of *Hansenula* with hat-shaped ascospores to *Pichia* (Kurtzman 1984a), the name *Hansenula wickerhamii* was replaced owing to earlier usage of the validly described binomial *Pichia wickerhamii* (van der Walt) Kreger-van Rij. The species epithet *finlandica* was chosen to denote the country from which the species was isolated.

42.32. *Pichia fluxuum* (Phaff & Knapp) Kreger-van Rij (1964b)

Synonyms:

Debaryomyces fluxuum (as *D. fluxorum*) Phaff & Knapp (1956)

Growth on 5% malt extract agar: After 3 days at 25°C, the cells are ovoidal to elongate, (2.0–6.1) × (3.5–10.5) μ m, and occur singly or in pairs. Growth is yellowish-white in color.

Growth on the surface of assimilation media: Dry climbing pellicles are present.

Dalmat plate culture on morphology agar: After 7 days at 25°C, growth under the coverglass shows occasional, sparingly branched pseudohyphae but no true hyphae. Aerobic growth is tannish-white, dull, smooth to partly wrinkled, and with an entire to broadly lobed margin.

Formation of ascospores: Asci are unconjugated and form one or two, rarely three or four, spheroidal, roughened spores (Fig. 138). In addition to the roughening, electron microscopy reveals the spores to have a thin subequatorial ring (Kawakami and Nehira 1958, Kreger-van Rij 1964b, Kurtzman and Smiley 1974). Asci are persistent. It is unknown whether the species is homothallic or heterothallic.

Fig. 138. *P. fluxuum*, CBS 2287. Ascosporegenous culture after 8 days, 15°C, on 5% malt extract agar. Bar = 5 μ m.

Ascospores were observed on YM, 5% malt extract and V8 agars after 3–10 days at 15 or 25°C.

Fermentation: absent.

Assimilation:

Glucose	+	<i>N</i> -Acetyl-D-glucosamine	–
Galactose	–	Methanol	–
L-Sorbose	–	Ethanol	+
Sucrose	–	Glycerol	v
Maltose	–	Erythritol	–

D-Arabinose	–	Inositol	–
D-Ribose	–	Hexadecane	–
L-Rhamnose	–	Nitrate	–
D-Glucosamine	–	Vitamin-free	–

Additional assimilation tests and other growth characteristics:

2-Keto-D-gluconate	–	Starch formation	–
5-Keto-D-gluconate	–	Gelatin liquefaction	–
Saccharate	–	Growth at 37°C	–
10% NaCl/5% glucose	–		

Co-Q: 7, CBS 2287 (Yamada et al. 1973a).

Mol% G+C: 32.2, 33.8, CBS 2287 (T_m : Nakase and Komagata 1970b; BD: Price et al. 1978).

Origin of the strains studied: Slime flux of oak (*Quercus kelloggii*) (2); slime flux of fir (*Abies concolor*) (2); sauerkraut (3).

Type strain: CBS 2287 (NRRL YB-4273), from *Quercus kelloggii*.

42.33. *Pichia galeiformis* Endo & S. Goto (Goto et al. 1987b)

Growth on 5% malt extract agar: After 3 days at 25°C, the cells are ovoidal to cylindrical, (2.6–3.7) × (3.6–7.5) μm, and single, in pairs and small clusters. Growth is tannish-white, dull and butyrous.

Growth on the surface of assimilation media: Moderately heavy climbing pellicles are produced.

Dalmat plate culture on morphology agar: After 7 days at 25°C, growth under the coverglass shows well-branched pseudohyphae with blastoconidia, but true hyphae are not formed. Aerobic growth is tannish-white, dull and butyrous. Colonies are convex with finely scalloped margins. A faint musky odor is present.

Formation of ascospores: Vegetative cells are directly transformed into unconjugated asci which produce 1–4 hat-shaped ascospores. Asci deliquesce on maturity. It is not known whether this species is homothallic or heterothallic.

Ascospores were formed on McClary's acetate agar after 5 days at 25°C.

Fermentation: absent.

Assimilation:

Glucose	+	<i>N</i> -Acetyl-D-glucosamine	+
Galactose	–	Methanol	–
L-Sorbose	–	Ethanol	+
Sucrose	–	Glycerol	+
Maltose	–	Erythritol	–
Cellobiose	–	Ribitol	–
Trehalose	–	Galactitol	–
Lactose	–	D-Mannitol	–
Melibiose	–	D-Glucitol	–

D-Xylose	–	Succinate	+
L-Arabinose	–	Citrate	–
D-Arabinose	–	Inositol	–
D-Ribose	–	Hexadecane	–
L-Rhamnose	–	Nitrate	–
D-Glucosamine	–	Vitamin-free	+

Additional assimilation tests and other growth characteristics:

2-Keto-D-gluconate	–	Starch formation	–
5-Keto-D-gluconate	–	Gelatin liquefaction	–
Saccharate	–	Growth at 37°C	+
10% NaCl/5% glucose	+		

Co-Q: 7, CBS 7324 (Goto et al. 1987b).

Mol% G+C: 35.6, CBS 7324 (T_m : Goto et al. 1987b).

Origin of the strains studied: CBS 7324 (NRRL Y-17349), from feces, Japan; CBS 763 (NRRL Y-17348), originally from Guilliermond.

Type strain: CBS 7324.

Comments: Assimilation reactions determined in the present study differ considerably from those listed in the original description of this species. Goto et al. (1987b) reported assimilation of sucrose, maltose, cellobiose, raffinose, melezitose and soluble starch (weak), but absence of growth on glycerol, lactate and succinate. Comparisons of large subunit rRNA partial sequences suggest *P. galeiformis* to be a sibling species of *P. membranifaciens* (Kurtzman and Robnett, manuscript in preparation). Separation of these two species is discussed in the Comments section of *P. membranifaciens*.

Note in proof: Rodrigues et al. (1996) reported high nDNA relatedness between *P. galeiformis* and *P. mandshurica* Saito, resulting in the former species becoming a synonym of the latter.

42.34. *Pichia glucozyma* (Wickerham) Kurtzman (1984a)**Synonyms:**

Hansenula glucozyma Wickerham (1969b)

Ogataea glucozyma (Wickerham) Y. Yamada, Maeda & Mikata (1994c)

Growth on 5% malt extract agar: After 3 days at 25°C, the cells are spheroidal or ellipsoidal, (2.5–7.1) × (2.5–7.6) μm, and single, in pairs, or in small clusters. Growth is generally mucoid and tannish-white in color.

Growth on the surface of assimilation media: Pellicles are not produced.

Dalmat plate culture on morphology agar: After 7 days at 25°C, growth under the coverglass shows no evidence of hyphae or pseudohyphae. Aerobic growth is pink from the presence of ascospores, smooth, moderately glistening, and butyrous. Colony margins are entire or lobed. A faint sweet odor may be present.

Formation of ascospores: Conjugation usually, but not always, precedes ascus formation. Generally, conjugation is between a parent cell and a bud, but may also occur between independent cells. Asci are deliquescent and produce from one to four hat-shaped ascospores. Single-spore isolates from four-spored asci form sporogenous cultures; consequently, the species is regarded to be homothallic (Kurtzman, unpublished).

Ascospores were observed on YM and 5% malt extract agars after 2–15 days at 25°C.

Co-Q: 7, CBS 5766 (Yamada et al. 1973a).

Mol% G+C: 45.1, CBS 5766 (T_m : Nakase and Komagata 1971b).

Origin of the strain studied: The only known strain of *P. glucozyma* was isolated from frass from an Engelmann spruce (*Picea engelmannii* Parry) growing in the Medicine Bow Mountains, Wyoming, U.S.A.

Type strain: CBS 5766 (NRRL YB-2185).

Comments: *P. glucozyma* is a particularly interesting species because of its similarity to *P. pini*. In standard tests, the species differ only in that *P. glucozyma* has the ability to assimilate nitrate. Kreger-van Rij (1964b) reported that although none of the strains of *P. pini* that she studied could assimilate nitrate, some could assimilate nitrite. Despite their great phenotypic likeness, Kurtzman (unpublished) found the type cultures of *P. glucozyma* and *P. pini* to share only 3% common nDNA base sequences.

42.35. *Pichia guilliermondii* Wickerham (1966)

Candida amidevorans Balloni, Florenzano, Mazza & Polsinelli (1987)

Growth on 5% malt extract agar: After 3 days at 25°C, the cells are ovoidal to elongate, (1.5–4.8) × (2.0–15.0) μm, and occur singly, in pairs, or in short chains. Growth is smooth to wrinkled and tannish-white in color.

Growth on the surface of assimilation media: Generally pellicles are not formed, but rings may be present.

Dalmat plate culture on morphology agar: After 7 days at 25°C, growth under the coverglass shows abundant, well-branched pseudohyphae bearing whorls of blastoconidia. True hyphae are not present. Aerobic growth is tannish-white, sometimes butyrous, smooth and glistening or dull and rugose. Margins are usually lobate.

Formation of ascospores: This species is heterothallic and only haploid forms have been isolated. Following the pairing of complementary mating types, the resulting asci produce one to four hat-shaped ascospores. The spores are liberated soon after formation.

Ascospores were observed on 5% malt extract agar at 25°C, 5–15 days after pairing of complementary mating types.

Co-Q: 9, CBS 2082 (Yamada et al. 1973a).

Mol% G+C: 44.4, 44.6 CBS 2021, CBS 2082 (T_m : Nakase and Komagata 1970b); 44.4, CBS 2030 (BD: Fuson et al. 1980).

Origin of the strains studied: Frass of American elm (*Ulmus americana*), U.S.A. (1); alcohol strain, Argentina (1); frass, Balsam fir (*Abies balsamea*), U.S.A. (1); frass, spruce (*Picea excelsa*), Germany (1); sputum (1); blood (1); atmosphere (1); unknown substrates received from Castellani (2), Langeron (1), Mackinnon (1).

Complementary mating types: NRRL Y-2075 (CBS 2030) and NRRL Y-2076 (CBS 2031).

Type strain: CBS 2030 (NRRL Y-2075), from *Ulmus americana*.

Comments: Wickerham and Burton (1954b) discovered ascosporeulation in strains of *Candida guilliermondii* var. *guilliermondii* and tentatively named the sexual state *Endomycopopsis guilliermondii*. Wickerham (1966) later validated the ascosporeic state as *Pichia guilliermondii*. Only a small minority of natural isolates of *C. guilliermondii* are sexually reactive (Wickerham and Burton 1954b), and the type strain was not among them. Kurtzman (1992b) showed 98% nDNA complementarity between type strains of *C. guilliermondii* and *P. guilliermondii*, thus confirming the expected anamorph–teleomorph connection.

42.36. *Pichia hampshiresensis* Kurtzman (1987a)

Growth on 5% malt extract agar: After 3 days at 25°C, the cells are single or in pairs, spheroidal to ellipsoidal, (2.5–5.0)×(2.7–6.9)µm, and occasionally

tapered. Pseudohyphae are common and moderately branched. True hyphae are not formed.

Growth on the surface of assimilation media: Pellicles are not formed, but a thin ring of surface growth may be present.

Dalmau plate culture on morphology agar: After 7 days at 25°C, growth under the coverglass shows only sparse formation of pseudohyphae and no true hyphae. Aerobic growth is tannish-white, slightly glistening and butyrous. A faint ester-like odor is present.

Formation of ascospores: Asci (3.0–5.0)×(5.0–6.5)µm form from vegetative cells following conjugation between a parent cell and its bud. Generally, the asci arise from budded yeast cells, but occasionally pseudohyphal cells also serve as asci. Asci are deliquescent. Ascospores are hat-shaped, (1.0–1.4)×(1.5–2.3)µm, with one to four per ascus. Single-spore isolates from four-spored asci form ascosporegenous colonies demonstrating the species to be homothallic.

Ascospores are abundant on 5% malt extract and YM agars after 3–5 days at 25°C.

Co-Q: Not determined.

Mol% G+C: 39.3, CBS 7208 (BD: Kurtzman 1987a).

Origin of the strain studied: NRRL YB-4128 is the only known strain of this species and was isolated in 1956, by L.J. Wickerham from the frass of a dead, cut oak (*Quercus* sp.) at Camp Sargent, New Hampshire, U.S.A.

Type strain: CBS 7208 (NRRL YB-4128).

42.37. *Pichia haplophila* Shifrine & Phaff (1956)**Synonym:***Yamadazyma haplophila* (Shifrine & Phaff) Billon-Grand (1989)

Growth on 5% malt extract agar: After 3 days at 25°C, the cells are ovoidal, (1.5–4.2)×(2.5–8.0) μm, and occur singly, in pairs or in small clusters. Growth is butyrous and tannish-white in color.

Growth on the surface of assimilation media: Dry, climbing pellicles are present.

Dalmu plate culture on morphology agar: After 7 days at 25°C, growth under the coverglass shows occasional rudimentary pseudohyphae. True hyphae are not formed. Aerobic growth is butyrous with a dull, tannish-white almost powdery surface. The margin is finely lobed. A faint acidic odor may be present.

Formation of ascospores: Asci show conjugation between a cell and its bud or infrequently between independent cells. Two to four hat-shaped ascospores are formed by each ascus, and they are readily liberated. The predominance of conjugations between cells and their buds in ascosporegenous cultures suggests this species to be homothallic.

Ascospores were observed on 5% malt extract agar after 3–5 days at 25°C.

Fermentation: absent.

Assimilation:

Saccharate	–	Growth at 37°C	+
10% NaCl/5% glucose	–		

Co-Q: 7, CBS 6930 (Billon-Grand 1985).

Mol% G + C: 32.3–32.7, CBS 6930 and 5 additional strains (BD: Phaff et al. 1978b).

Origin of the strains studied: From senita cactus (*Lophocereus schottii*), Baja California Sur, Mexico (1); saguaro cactus (*Carnegiea gigantea*), Arizona, U.S.A. (1).

Complementary mating types: NRRL Y-10968

(CBS 6931) and NRRL Y-10969 (CBS 6932), both derived from the sporogenous diploid type culture.

Type strain: CBS 6930 (NRRL Y-10967).

Comments: Phaff et al. (1978b) reported *P. heedii* to be isolated only from two species of cacti belonging to the subtribe Pachycereinae, senita (*Lophocereus schottii*) and saguaro (*Carnegiea gigantea*), and their associated *Drosophila* species, *D. pachea* and *D. nigrospiracula*, respectively. It was later found (Starmer et al. 1980, Holzschu and Phaff 1982) that the strains from senita utilize citrate whereas those isolated from saguaro do not. The two metabolic types have greater than 95% nDNA complementarity, and mating between the two types produces four-spored asci that segregate 2:2 with respect to citrate utilization, indicating control by a single genetic locus. *P. heedii* may be separated from *P. amethionina*, *P. cactophila*, *P. pseudocactophila* and *P. opuntiae* by its strong assimilation of D-xylose. Starmer et al. (1979) observed no mating among *P. heedii*, *P. amethionina* and *P. opuntiae*. *P. heedii* may be separated from *P. membranifaciens* on the basis of its failure to assimilate N-acetyl-D-glucosamine, its smaller cell size, comparatively slower release of ascospores and higher maximum growth temperature. The 10% difference in G+C contents between these two phenotypically similar species would preclude conspecificity.

42.39. *Pichia heimii* Pignal (1970)

Growth on 5% malt extract agar: After 3 days at 25°C, the cells are ovoidal, (2.0–4.2) × (3.0–6.0) μm, and occur singly and in pairs. Growth is tannish-white and smooth to somewhat convoluted.

Growth on the surface of assimilation media: Moderately thick pellicles are formed.

Dalmou plate culture on morphology agar: After 7 days at 25°C, growth under the coverglass shows abundant, moderately branched pseudohyphae with large clusters of blastoconidia. True hyphae are not formed. Infrequently, a pseudohyphal cell will be found which contains up to six endospores. Aerobic growth is tannish-white, glistening, smooth to slightly convoluted, and with a sparingly lobed margin. A faint acidic odor is present.

Formation of ascospores: Spores were not observed in the present study. Pignal (1970) reported the asci to arise from conjugation between independent cells or, less frequently, from conjugation between a cell and its bud. One to four hat-shaped ascospores were formed in each ascus, and they were liberated soon after formation.

Fermentation:

Glucose	+	Lactose	–
Galactose	+	Raffinose	–

L-Rhamnose	+	Nitrate	–
D-Glucosamine	+	Vitamin-free	+

Additional assimilation tests and other growth characteristics:

2-Keto-D-gluconate	+	Starch formation	–
5-Keto-D-gluconate	–	Gelatin liquefaction	–
Saccharate	–	Growth at 37°C	–
10% NaCl/5% glucose	+		

Co-Q: Not determined.

Mol% G+C: 39.7, CBS 6139 (T_m : J.B. Fiol, cited by Billon-Grand 1981).

Origin of the strain studied: Decaying, insect-invaded wood, Equatorial Africa.

Type strain: CBS 6139 (NRRL Y-7502).

Comments: The results of the present study are in agreement with the original description except that Pignal (1970) reported a weak fermentation of raffinose and weak growth on L-sorbose, which were not detected.

42.40. *Pichia henricii* (Wickerham) Kurtzman (1984a)

Synonyms:

Hansenula henricii Wickerham (1969b)

Ogataea henricii (Wickerham) Y. Yamada, Maeda & Mikata (1994c)

Growth on 5% malt extract agar: After 3 days at 25°C, the cells are spheroidal or ellipsoidal, (3.1–5.4) × (3.4–7.5) μm, and occur singly, in pairs, and in small clusters. Growth is butyrous and tannish-white in color. Growth from some single-ascospore isolates can be mucoid.

Growth on the surface of assimilation media: Neither pellicles nor rings are produced.

Dalmou plate culture on morphology agar: After 7 days at 25°C, growth under the coverglass shows neither pseudohyphae nor true hyphae. Occasional short chains of cells are observed. Aerobic growth is tannish-white, smooth, faintly glistening, and butyrous. Colony margins are entire.

Formation of ascospores: Asci may be unconjugated or arise from conjugation between independent cells or a parent cell and its bud. Ascospores are hat-shaped and

the asci are deliquescent. Usually only two spores are formed per ascus on YM- or 5% malt extract agar, but on morphology agar, three- or four-spored asci are common. The species apparently is homothallic because single-spore isolates from four-spored asci give ascosporegenous colonies (Kurtzman, unpublished).

Ascospores were observed on YM, 5% malt extract, and yeast morphology agars after 10–20 days at 25°C.

Fermentation: absent.

Co-Q: 7, CBS 5765 and 2 additional strains (Yamada et al. 1973a).

Mol% G+C: 49.8–50.2, CBS 5765, AJ 5164, AJ 5165 (T_m : Nakase and Komagata 1971b); 49.6, CBS 5765 (BD: Fuson et al. 1979).

Origin of the strains studied: Bird (?) feces collected in the Medicine Bow Mountains, Wyoming, U.S.A. (1); frass from a lodgepole pine (*Pinus contorta* Douglas) collected near Markleeville, California, U.S.A. (1); soil, Medicine Bow Mountains, Wyoming (1).

Type strain: CBS 5765 (NRRL YB-2194), from bird (?) feces, Medicine Bow Mountains, Wyoming.

42.41. *Pichia holstii* (Wickerham) Kurtzman (1984a)

Anamorph: *Candida silvicola* Shifrine & Phaff

Synonyms:

Hansenula holstii Wickerham (1960)

Nakazawaea holstii (Wickerham) Y. Yamada, Maeda & Mikata (1994c)

Candida silvicola Shifrine & Phaff (1956)

Growth on 5% malt extract agar: After 3 days at 25°C, the cells are ellipsoidal to elongate, (1.7–4.0) × (2.1–6.9) μ m, and single, in pairs, or in small clusters. Growth is mucoid to butyrous and white in color.

Growth on the surface of assimilation media: Infrequently, thin pellicles or rings may be formed.

Dalmau plate culture on morphology agar: After 7 days at 25°C, growth under the coverglass shows abundant and well-branched pseudohyphae as well as true hyphae. Aerobic growth is white to tannish-white, dull to glistening, and mucoid to butyrous. Colony margins are entire or lobed and generally bordered by pseudohyphae and true hyphae. Freshly isolated strains sometimes have cells that produce tapered outgrowths at one or both ends. The outgrowths may attain a length of several times that of the main portion of the cell. A faint ester-like odor is produced.

Formation of ascospores: *P. holstii* is heterothallic, and only asporogenous haploid strains have been isolated from nature. Asci are formed following conjugation of complementary mating types, and they contain two to four hat-shaped ascospores. The asci are deliquescent. Many natural isolates lack mating competence or show a very weak reaction (Wickerham 1960, Kurtzman et al. 1973a). Following mixture of complementary mating types, 2 or 3 weeks may pass before conjugants are observed. Few isolates from frass of *Pinus* show mating competence, but a much higher percentage of isolates from gums of *Prunus* spp. are sexually reactive. Herman (1971a) reported increased mating frequency and increased sporulation in shaken cultures employing a minimal medium developed to enhance extracellular polymer production (Slodki et al. 1972).

Ascospores were observed at 25°C on 5% malt extract agar and in shaken cultures of polymer production medium, sometimes after only 5–10 days.

Co-Q: 8, CBS 4140, CBS 4069 (Yamada et al. 1973a).

Mol% G+C: 36.8, 37.1, CBS 4140 (T_m : Nakase and Komagata 1971b; BD: Kurtzman, unpublished).

Origin of the strains studied: Several genera of coniferous and broadleaf trees from throughout the U.S. and Canada as well as from lichens, soil, lakes, and streams (154); cadaver (1).

Complementary mating types: NRRL Y-2154 (CBS 4141) and NRRL Y-2155 (CBS 4140).

Type strain: CBS 4140 (NRRL Y-2155), isolated by Wickerham (1960) from frass of an apparent yellow spruce (*Picea rubens?*) from the Gaspé Peninsula, Canada.

Comments: As with *P. capsulata*, *P. holstii* produces large quantities of extracellular polysaccharides. Slodki and coworkers (Slodki et al. 1972, Seymour et al. 1976) have shown the mannans and phosphomannans of these two species to be different.

42.42. *Pichia inositovora* Golubev & Blagodatskaya (Golubev et al. 1981)

Synonym:

Yamadazyma inositovora (Golubev & Blagodatskaya) Billon-Grand (1989)

Growth on 5% malt extract agar: After 3 days at 25°C, the cells are short ovoidal to elongate, (2.1–4.5) × (2.5–7.6) μm, and single or infrequently in pairs. Colonies are butyrous, glistening and tannish-white.

Growth on the surface of assimilation media: Thin climbing pellicles are formed.

Dalmau plate culture on morphology agar: After 7 days at 25°C, growth under the coverglass shows neither pseudohyphae nor true hyphae. Aerobic growth is tannish-white, glistening, butyrous, and low convex in profile with a depressed center. Colony margins are entire to infrequently lobed. A faint musky-acidic odor is produced.

Formation of ascospores: Asci are unconjugated and form one to four hat-shaped ascospores that are released at maturity (Fig. 139). It is not known whether the species is homothallic or heterothallic. Golubev et al. (1981) observed from transmission electron microscopy that bulb-like structures sometimes form on the brims of ascospores.

Fig. 139. *P. inositovora*, CBS 8006. Ascospore culture after 3 weeks, 15°C, on YM agar. Bar = 5 μm.

Ascospores were observed on YM and 5% malt extract agars after 2–3 weeks at 15°C.

Fermentation: absent.

Co-Q: 9, CBS 8006 (Billon-Grand 1985).

Mol% G+C: 49.9, CBS 8006 (BD: Kurtzman, unpublished).

Origin of the strain studied: The only known strain of this species was isolated from highmoor peat in the Moscow region, Russia.

Type strain: CBS 8006 (IBPhM Y-888, NRRL Y-12698).

Comments: Results from the present study are in agreement with the original description. The only exception was lactate assimilation, which was absent in the present examination but reported to be positive but slow by Golubev et al. (1981). *P. inositovora* is one of only a few

ascomycetous yeasts that assimilate *i*-inositol as a carbon source.

42.43. *Pichia jadinii* (A. & R. Sartory, Weill & J. Meyer) Kurtzman (1984a)

Anamorph: *Candida utilis* (Henneberg) Lodder & Kreger-van Rij
Synonyms:

Saccharomyces jadinii A. & R. Sartory, Weill & J. Meyer (1932)

Hansenula jadinii (A. & R. Sartory, Weill & J. Meyer) Wickerham (1951)

Torula utilis Henneberg (1926)

Torulopsis utilis (Henneberg) Lodder (1934)

Cryptococcus utilis (Henneberg) Anderson & Skinner (1947)

Candida utilis (Henneberg) Lodder & Kreger-van Rij (1952)

?*Torula mineralis* Hayduck & Haehn ex F.C. Harrison (1928)

Candida guilliermondii (Castellani) Langeron & Guerra var. *nitratophila* Diddens & Lodder (1942)

Torulopsis utilis (Henneberg) Lodder var. *major* Thaysen & Morris (1943)

Growth on 5% malt extract agar: After 3 days at 25°C, the cells are ellipsoidal to elongate, (2.5–8.0) × (4.1–11.2) μm, and occur singly or in pairs. Growth is butyrous and tannish-white in color.

Growth on the surface of assimilation media: Thin pellicles may form infrequently on some media.

Dalmau plate culture on morphology agar: After 7 days at 25°C, growth under the coverglass shows occasional pseudohyphae and these may be highly branched. True hyphae are not produced. Aerobic growth is white to tannish-white, smooth, glistening, and butyrous. Colony margins are entire or infrequently lobed. A faint ester-like odor may be produced.

Formation of ascospores: *P. jadinii* forms one to four hat-shaped ascospores in unconjugated deliquescent asci (Fig. 140). Kurtzman et al. (1979) showed that single-spore isolates from the type strain either sporulated no better than the parent or not at all. Because the parent culture sometimes failed to sporulate and because mixtures of asporogenous single-spore isolates did not sporulate, it was concluded that *P. jadinii* is homothallic.

Fig. 140. *P. jadinii*, CBS 1600. Ascosporeogenous culture after 2 weeks, 25°C, on a carrot wedge. Bar = 5 μm.

Ascospores were observed on 5% malt extract agar and on sterilized carrot slices after 10–30 days at 25°C.

Fermentation:

Saccharate	–	Growth at 37°C	+
10% NaCl/5% glucose	–		

Co-Q: 7, CBS 1600 (Yamada et al. 1973a).

Mol% G + C: 43.2, CBS 1600 (T_m : Nakase and Komagata 1971b); 45.1–45.8, CBS 1600, 5609, 621 (BD: Kurtzman et al. 1979).

Origin of the strains studied: Pus from a human abscess (1), the udder of a cow with mastitis (1), industrial fermentations (4).

Type strain: CBS 1600 (NRRL Y-1542), isolated by Sartory et al. (1932) from the pus of a human abscess.

Comments: *Candida utilis* had been proposed as the asexual state of *P. jadinii* because of phenotypic similarities (Wickerham 1970a). DNA reassociation studies demonstrated that *C. utilis* and *P. jadinii* share 85% common base sequences (Kurtzman et al. 1979). These data, confirmed by Manachini (1979), show *C. utilis* to be the anamorphic form of *P. jadinii*. By contrast, *P. petersonii* showed only 9% DNA relatedness with *C. utilis* and *P. jadinii* and, therefore, must be considered a separate species.

The possibilities of growing *C. utilis* (Torula yeast) as a foodstuff on a commercial scale were first recognized by German workers in Berlin at the Institut für Gärungsgewerbe during World War I (Lindner 1922, as cited by Pyke 1958). Because *C. utilis* is capable of utilizing pentoses, pulping-waste liquors from the paper industry have been used for about four decades as an economical substrate for culturing this yeast. The general acceptance of *C. utilis* by the food and feed industries

as a safe and nutritious form of single-cell protein has made it an important species for cultivation on other types of biological wastes. Because of its importance to the food industry, the habitats of *P. jadinii* and *C. utilis* deserve further comment. One of the two known strains of *P. jadinii* was isolated from abscesses of a young woman and the second strain was obtained from a localized infection in a cow. *C. utilis* has been isolated from flowers and as a contaminant in industrial fermentations, but also from human and animal sources. In view of this, strains of *C. utilis* that have a long history of safety need to be used when *Torula* yeast is produced. Three strains of *C. utilis* used commercially since at least the mid-1940's are NRRL Y-900 (CBS 5609), NRRL Y-1082 (CBS 1517), and NRRL Y-1084 (CBS 841).

42.44. *Pichia japonica* Kurtzman (1987a)

Growth on 5% malt extract agar: After 3 days at 25°C, the cells are spheroidal to ellipsoidal, (2.2–5.0) × (2.8–8.5) μm, and single or in pairs. Branched pseudohyphae are present, but true hyphae are not formed.

Growth on the surface of assimilation media: Pellicles are not formed, but a thin ring of surface growth may be present.

Dalmau plate culture on morphology agar: After 7 days at 25°C, growth under the coverglass shows moderately branched pseudohyphae with straight or curved cells. True hyphae are not present. Aerobic growth is grayish-white, glistening, butyrous to slightly mucoid and fringed with pseudohyphae. A faint ester-like odor is present.

Formation of ascospores: Asci (3.0–4.0) × (4.5–7.0) μm form from vegetative cells following conjugation between a parent cell and its bud. Asci arise from budded yeast cells or occasionally from pseudohyphal cells. The asci are deliquescent. Ascospores are hat-shaped and one to four occur in each ascus (Fig. 141). Single-spore isolates from four-spored asci give ascosporegenous colonies indicating the species to be homothallic.

Fig. 141. *P. japonica*, CBS 7209. Ascosporegenous culture after 3 days, 25°C, on 5% malt extract agar. Bar = 5 μm.

Ascosporeulation is abundant on 5% malt extract agar and only slightly less so on YM agar, after 7–10 days at 25°C.

Fermentation:

Glucose	+/w	Lactose	–
Galactose	–	Raffinose	–

Co-Q: Not determined.

Mol% G+C: 46.4–46.7, CBS 7209, 7210, 7211, 7212 (BD: Kurtzman 1987a).

Origin of the strains studied: All four known strains of this species [NRRL YB-2750 (CBS 7209), YB-2751 (CBS 7210), YB-2752 (CBS 7211) and YB-2753 (CBS 7212)] were isolated in 1951 by L.J. Wickerham from a frass sample from fir (*Abies firma*) sent by the Ministry of Agriculture and Forestry, Tokyo, Japan.

Type strain: CBS 7209 (NRRL YB-2750)

Comments: Comparisons of nDNA complementarity between *P. japonica*, *P. hampshirensis* and other phenotypically similar species of *Pichia* and *Candida* showed *P. japonica* to be a genetically distinct species (Kurtzman 1987a).

42.45. *Pichia kluyveri* Bedford ex Kudryavtsev (1960)

This species has three varieties:

***Pichia kluyveri* Bedford ex Kudryavtsev (1960) var. *kluyveri* (1987)**

Synonyms:

Pichia kluyveri Bedford (1942) nom. nud.

Hansenula kluyveri (Bedford) Kudryavtsev (1960)

Pichia belgica (Lindner) Dekker var. *microspora* Negroni & Fischer (1941) nom. nud.

Pichia kluyveri* var. *cephalocereana* Phaff, Starmer & Tredick-Kline (1987b)**Pichia kluyveri* var. *eremophila* Phaff, Starmer & Tredick-Kline (1987b)**Anamorph: *Candida eremophila* Phaff, Starmer & Tredick-Kline**Synonym:***Candida eremophila* Phaff, Starmer & Tredick-Kline (1987b)

Growth on 5% malt extract agar: After 3 days at 25°C, the cells are ovoidal to elongate, (2.0–5.5) × (4.0–11.0) μm, and occur singly, in pairs, or in short chains. Growth is yellowish-tan, dull and with fine wrinkles.

Growth on the surface of assimilation media: Dry, climbing pellicles are formed.

Dalmay plate culture on morphology agar: After 7 days at 25°C, growth under the coverglass shows moderately well-branched pseudohyphae, but they produce few blastoconidia. True hyphae are not formed. Aerobic growth is tannish-white, dull, sometimes almost powdery, and with fine striations radiating from center to colony edge. Margins are entire to finely serrate.

Formation of ascospores: Two to four hat-shaped spores are produced in each ascus, and they are released very soon after formation (Fig. 142). Phaff et al. (1987b) reported that most strains are heterothallic but some, including the two-spored strains, appear homothallic.

Fig. 142. *P. kluyveri* var. *kluyveri*, CBS 1525. Ascosporeogenous culture after 3 days, 25°C, on YM agar. Bar = 5 μm.

Ascospores were observed on McClary's acetate, YM and 1% malt extract agars, usually after 5–15 days at 25°C.

Fermentation:

Glucose	+	Lactose	–
Galactose	–	Raffinose	–
Sucrose	–	Trehalose	–
Maltose	–		

Assimilation:

Co-Q: 7, AJ 4139, AJ 4145 (Yamada et al. 1973a).

Mol% G + C: 28.3–28.5, AJ 4145, AJ 4426, var. *kluyveri* (T_m : Nakase and Komagata 1970b); 29.4–31.4, CBS 188 and 7 additional strains, var. *kluyveri* (BD: Phaff et al. 1987b); 29.9–30.5, CBS 7273 and 3 additional strains, var. *cephalocereana* (BD: Phaff et al. 1987b); 29.8–30.8, CBS 7272 and 3 additional strains, var. *eremophila* (BD: Phaff et al. 1987b); 29.4–30.4, CBS 7271 and 3 additional strains, *Candida eremophila* (BD: Phaff et al. 1987b).

Supplementary description of *P. kluyveri* varieties:

Variety *kluyveri*: glucose fermentation is strong; citrate assimilation is weak or absent; killer activity against *Candida glabrata*; rare in cacti, common in rotting fruit of other plants (Phaff et al. 1987b, Starmer et al. 1992).

Variety *cephalocereana*: glucose fermentation is slow and usually late; citrate is assimilated; no killer activity against *C. glabrata*; from columnar cacti on the Caribbean island of Montserrat (Phaff et al. 1987b).

Variety *eremophila*: glucose fermentation is weak or absent; citrate is assimilated; killer activity against *C. glabrata*; nearly exclusive to *Opuntia* cactus rots in southern Arizona and Texas (Phaff et al. 1987b).

Origin of the strains belonging to the variety

***kluyveri*:** Olives, Bedford (1); *P. belgica* var. *microspora* (CBS 1358), P. Negroni; tropical products (1); fermenting cacao (2); *Drosophila* sp. from tomato (2); prickly pear cactus (*Opuntia stricta*) (2).

Complementary mating types: CBS 7907 [SU (Syracuse University) 84-670.2B, NRRL Y-17734 (h^+)] and CBS 7908 [SU 84-670.2C, NRRL Y-17752 (h^-)].

Type strain: CBS 188 (NRRL Y-11519), from olives.

Origin of the strains belonging to the variety

***cephalocereana*:** Rots of columnar cactus (*Cephalocereus royenii*), island of Montserrat (2).

Complementary mating types: CBS 7909 [SU 82-555B.17, NRRL Y-17718 (*h*⁺)] and CBS 7910 [SU 82-556D.30, NRRL Y-17738 (*h*⁻)].

Type strain: CBS 7273 (SU 82-555B, NRRL Y-17225).

Origin of the strains belonging to the variety *eremophila*: Rots of prickly pear cacti: *Opuntia phaeacantha*, southern Arizona, USA (1); *Opuntia* sp., Baja California, Mexico (1). Rotting organ pipe cactus (*Stenocereus thurberi*), Baja California, Mexico (1); type strain of *Candida eremophila* (CBS 7271, UCD-FST 76-202B, NRRL Y-17226).

Complementary mating types: CBS 7906 [SU 83-466.1AC, NRRL Y-17753 (*h*⁺)] and CBS 7905 [SU 86-541.5A, NRRL Y-17751 (*h*⁻)].

Type strain: CBS 7272 (SU 83-466.1, NRRL Y-17224), from *Opuntia phaeacantha*.

Comments: Following an extensive survey of the yeast flora of rotting cacti, Phaff et al. (1987b) demonstrated three genetically divergent populations among isolates of *P. kluyveri*. Nuclear DNA relatedness within populations was high, but intergroup nDNA relatedness ranged from 66–72%. A majority of the strains that produced four-spored asci from each of the populations was demonstrated to be heterothallic through single-ascospore isolations. Fertility of progeny from intergroup crosses appeared somewhat diminished. Because of reduced nDNA relatedness and reduced fertility between the groups, Phaff et al. (1987b) proposed that the groups represented taxonomic varieties. A fourth group of strains that was isolated from *Stenocereus* rots had high nDNA relatedness with the variety *eremophila* but failed to show any mating response. This group was described as *Candida eremophila*. Separation of *P. kluyveri* var. *eremophila* from *P. galeiformis* and *P. membranifaciens* is discussed in the Comments section of the latter species.

42.46. *Pichia kodamae* van der Walt & Yarrow (van der Walt et al. 1982)

Synonym:

Ogataea kodamae (van der Walt & Yarrow) Mikata & Y. Yamada (1995)

Growth on 5% malt extract agar: After 3 days at 25°C, the cells are spheroidal, ellipsoidal or infrequently elongate, (1.5–5.6) × (1.5–6.3) μm, and single, in pairs or in small clusters. Growth is mucoid, glistening and tannish-white.

Growth on the surface of assimilation media: Pellicles are not formed.

Dalmau plate culture on morphology agar: After 7 days at 25°C, growth under the coverglass is devoid of either pseudohyphae or hyphae. Aerobic growth is tannish-white, mucoid, glistening, convex in profile and with an entire margin. A musky, acidic odor is present.

Formation of ascospores: Asci may be unconjugated or show parent cell–bud conjugation. The asci produce one to four hat-shaped ascospores and become deliquescent at

maturity. Van der Walt et al. (1982) reported the species to be homothallic.

Ascosporeulation was observed on YM and 5% malt extract agars after 5–7 days at 25°C.

Fermentation:

Glucose	s	Lactose	–
Galactose	–	Raffinose	–
Sucrose	–	Trehalose	–
Maltose	–		

Assimilation:

Glucose	+	<i>N</i> -Acetyl-D-glucosamine	–
Galactose	–	Methanol	ws
L-Sorbose	v	Ethanol	ws
Sucrose	–	Glycerol	+
Maltose	–	Erythritol	+
Cellobiose	+	Ribitol	+
Trehalose	–	Galactitol	–
Lactose	–	D-Mannitol	+

D-Glucosamine	–	Vitamin-free	–

Additional assimilation tests and other growth characteristics:

2-Keto-D-gluconate	–	Starch formation	–
5-Keto-D-gluconate	–	Gelatin liquefaction	–
Saccharate	–	Growth at 37°C	w
10% NaCl/5% glucose	–		

Co-Q: 7, CBS 7081 (Billon-Grand 1985).

Mol% G + C: Not determined.

Origin of the strain studied: CBS 7081 (NRRL Y-17234), from insect infestations of spurge (*Euphorbia ingens*), Groblersdal district, South Africa.

Type strain: CBS 7081.

Comments: Methanol assimilation by *P. kodamae* appears somewhat variable. In the original description, van der Walt et al. (1982) reported methanol not to be assimilated, whereas Barnett et al. (1990) reported a delayed assimilation of this compound. In the present study, growth on methanol was weak and slow.

Van der Walt et al. (1982) noted *P. kodamae* to be phenotypically similar to *P. methanolica* and *P. pini*. Their attempts to induce mating between auxotrophic mutants of *P. kodamae* and the other two species failed, which suggested *P. kodamae* to be a separate species.

42.47. *Pichia lynferdii* (van der Walt & E. Johannsen) Kurtzman (1984a)

Synonyms:

Hansenula lynferdii van der Walt & E. Johannsen (1975b)

Candida lynferdii van der Walt & E. Johannsen (1975b)

Growth on 5% malt extract agar: After 3 days

at 25°C, the cells are spheroidal to ellipsoidal, (2.1–5.8)×(2.7–7.5)µm, and single or in pairs. Growth is butyrous and tannish-white in color.

Growth on the surface of assimilation media: Thin creeping pellicles are formed.

Dalmu plate culture on morphology agar: After 7 days at 25°C, growth under the coverglass shows occasional moderately well-developed pseudohyphae. True hyphae are not formed. Aerobic growth is tannish-white, slightly glistening, and butyrous. Colony margins are entire to finely lobed. A faint acidic odor is produced.

Formation of ascospores: Asci are unconjugated and arise directly from vegetative cells. There are one to four hat-shaped ascospores per ascus, and asci are deliquescent. Van der Walt and Johannsen (1975b) reported that heat-treatment of sporogenous cultures gave only sporogenous colonies suggesting the species to be homothallic.

Ascospores were observed on YM, 5% malt extract and V8 agars after 5–7 days at 25°C.

Fermentation:

Glucose	+	Lactose	–
Galactose	–	Raffinose	w
Sucrose	+	Trehalose	–
Maltose	–		

Assimilation:

Glucose	+	N-Acetyl-D-glucosamine	–
Galactose	+	Methanol	–
L-Sorbose	–	Ethanol	+
Sucrose	+	Glycerol	+
Maltose	+	Erythritol	+
Cellobiose	+	Ribitol	+
Trehalose	+	Galactitol	–
Lactose	–	D-Mannitol	+
Melibiose	–	D-Glucitol	+
Raffinose	+	α-Methyl-D-glucoside	+
Melezitose	+	Salicin	+
Inulin	+	D-Gluconate	+
Soluble starch	–	DL-Lactate	+
D-Xylose	–	Succinate	+
L-Arabinose	–	Citrate	+
D-Arabinose	–	Inositol	–
D-Ribose	+	Hexadecane	–
L-Rhamnose	–	Nitrate	+
D-Glucosamine	–	Vitamin-free	+

Additional assimilation tests and other growth characteristics:

2-Keto-D-gluconate	–	Starch formation	–
5-Keto-D-gluconate	–	Gelatin liquefaction	–
Saccharate	–	Growth at 37°C	–
10% NaCl/5% glucose	+		

Co-Q: Not determined.

Mol% G+C: 39.3, CBS 6695 (HPLC: Miller and Bahareen 1979).

Origin of the strain studied: The only known strain of this species was recovered from uncultivated grassland soil collected near Pretoria, South Africa.

Type strain: CBS 6695 (NRRL Y-7723), isolated from soil in South Africa and received from van der Walt.

Comments: *Pichia lynferdii* shares many characteristics

with *P. jadinii* and *P. petersonii* including a tolerance to embalming fluid (van der Walt and Johannsen 1975b). The three species can be separated by their assimilation reactions on L-rhamnose, galactose, and erythritol. Van der Walt and Johannsen (1975b) reported *P. lynferdii* to give slow, weak growth on L-arabinose, but in the present study, no growth was detected on this compound.

42.48. *Pichia media* Boidin, Pignal, Lehodey, Vey & Abadie (1964)

Synonym:

Yamadazyma media (Boidin, Pignal, Lehodey, Vey & Abadie) Billon-Grand (1989)

Growth on 5% malt extract agar: After 3 days at 25°C, the cells are ovoidal, (1.9–3.5)×(3.0–5.5)µm, and occur singly or in pairs. Growth is yellowish-white, smooth, dull-glistening, and butyrous.

Growth on the surface of assimilation media: Pellicles are formed.

Dalmu plate culture on morphology agar: After 7 days at 25°C, growth under the coverglass shows neither pseudohyphae nor true hyphae. Aerobic growth is light tannish-white, smooth, or with minute striations, dull-glistening, butyrous, and with a smooth to finely lobed margin.

Formation of ascospores: Conjugation between parent cell and bud or occasionally between independent cells precedes ascus formation. Asci contain one to four hat-shaped ascospores which are liberated soon after formation. Based on manner of conjugation, it is expected that this species is homothallic.

Ascospores were observed on 5% malt extract agar after 5–10 days at 25°C.

Fermentation: absent.

Assimilation:

Glucose	+	N-Acetyl-D-glucosamine	+
Galactose	+	Methanol	–

Additional assimilation tests and other growth characteristics:

2-Keto-D-gluconate	–	Starch formation	–
5-Keto-D-gluconate	–	Gelatin liquefaction	–
Saccharate	–	Growth at 37°C	–
10% NaCl/5% glucose	+		

Co-Q: 9, CBS 5521 (Billon-Grand 1985).

Mol% G+C: 36.1, CBS 5521 (T_m : J.B. Fiol, cited by Billon-Grand 1981).

Origin of the strains studied: Xylophagous insect larvae, France (2).

Type strain: CBS 5521 (NRRL Y-7122).

Comments: Kreger-van Rij (1970c) noted some inconsistencies in assimilation between her tests and those of the original description. In turn, some differences with her results were found in the present study. This may reflect differences in the purity of the carbon compounds used or more likely variability within *P. media* itself. In contrast to the 1970 study, assimilation of soluble starch was negative or weak, L-arabinose was positive rather than variable, D-ribose was positive but sometimes slow, D-arabinose was positive rather than variable, and galactitol was variable rather than negative.

42.49. *Pichia membranifaciens*¹ (E.C. Hansen) E.C. Hansen (1904)

Anamorph: *Candida valida* (Leberle) van Uden & H.R. Buckley, on the basis of phenotypic similarity.

Synonyms:

Saccharomyces membranifaciens (as *S. membranaefaciens*) E.C. Hansen (1888a)

?*Saccharomyces pyriformis* Ward (1892)

Saccharomyces anomalus E.C. Hansen var. *belgicus* Lindner (1895)

Pichia scaptomyzae C. Ramirez & González (1984e)

Pichia miyazi Mikata & Banno (1985) nom. nud.

Growth on 5% malt extract agar: After 3 days at 25°C, the cells are ovoidal to elongate, (1.8–4.5) × (2.5–17.0) μm, and occur singly, in pairs, in chains, or in clusters. Growth is yellowish-tan, dull and smooth or wrinkled.

Growth on the surface of assimilation media: Dry, climbing pellicles are formed.

Dalmat plate culture on morphology agar: After 7 days at 25°C, growth under the coverglass generally shows moderately branched pseudohyphae, although some strains may form none. True hyphae are not produced. Aerobic growth is tannish-white, dull, smooth to wrinkled and with an irregular lobed margin. A faint acidic odor may be present.

Formation of ascospores: Asci may be unconjugated or show conjugation between independent cells or between a parent cell and a bud. One to four ascospores are usually formed per ascus, but Santa Maria (1960, 1966) has observed as many as seven. Ascospores may be spheroidal or hemispheroidal and with or without a ledge (Figs. 143,

¹ The original spelling of the species epithet *membranaefaciens* has been treated as an orthographic error.

144). Ascospores with ledges may appear nearly hat-shaped or nearly saturn-shaped. When viewed in the scanning electron microscope, it is not uncommon to find a single strain producing the whole range of spore shapes. Spores are generally liberated from the ascus. Single-spore isolates from four-spored asci show some cultures to be homothallic, but Slooff (1964) and Kreger-van Rij (1970c) clearly demonstrated other strains to be heterothallic. Of further interest was Kreger-van Rij's (1970c) observation of enhanced sporulation in certain self-sporulating strains following their conjugation with one or the other of the mating types.

Ascospores were observed on YM, 5% malt extract, and V8 agars after 2–15 days at 25°C.

Fig. 143. *P. membranifaciens*, CBS 1329. Ascosporeogenous culture after 12 days, 25°C, on YM agar. Bar = 5 µm.

Fig. 144. *P. membranifaciens*, CBS 1329. Scanning electron micrograph showing placement of ledges on ascospores to be saturn-like, hat-like, or incomplete. Bar = 0.5 µm.

Co-Q: 7, AJ 4110, AJ 4113, AJ 4140 (Yamada et al. 1973a).

Mol% G + C: 41.5–42.4, IFO 0460 and 5 additional strains (T_m : Nakase and Komagata 1970b); 44.3, CBS 107 (BD: Phaff et al. 1976).

Origin of the strains studied: Grape must (1); wine (1); vineyard soil (2); beer (1); raw material for sorghum brandy (1); lambic gueuse (1); feces (1); maize-cattle waste fermentation (3); unknown substrates (9).

Complementary mating types: CBS 5567 (NRRL Y-6775) and CBS 5568 (NRRL Y-6776), from Slooff (1964).

Type strain: CBS 107 (NRRL Y-2026).

Comments: Strains of *P. membranifaciens* show considerable variation in the amount of pseudomycelium produced, in the assimilation of several carbon compounds, in growth at 37°C and in their requirement for vitamins. However, there seems little correlation among the varying characteristics that would allow sub-grouping of the strains, and Kreger-van Rij (1970c) found mating between strains showing differences in one or more of these properties. Consequently, all of this phenotypic variation is considered typical for the species.

Reliance on phenotypic characters for the separation of *P. membranifaciens* from *P. galeiformis* and *P. kluveri* var. *eremophila* will result in misidentification of some strains (Table 32). *P. kluveri* var. *eremophila* is not known outside cactus habitats, but *P. membranifaciens* is cosmopolitan and the habitat range of *P. galeiformis* is insufficiently known. Strains that assimilate L-sorbose can be identified as *P. membranifaciens*, but the species

is variable for this character. Heavily sporulated cultures of *P. membranifaciens* are unique among the three taxa because they produce a noticeable reddish-brown color, but lightly sporulating strains cannot be discerned by this character. When strain identification is critical, molecular comparisons will be required.

42.50. *Pichia methanolica* Makiguchi (Kato et al. 1974)

Synonyms:

Pichia aganobii Urakami & Michimi (1977) nom. nud.

Pichia cellobiosa J.-D. Lee & Komagata (1980b)

Growth on 5% malt extract agar: After 3 days at 25°C, the cells are spheroidal to ovoidal, (1.9–6.0) × (2.0–8.8) μm, and occur singly, in pairs or in clusters. Growth is cream-colored, smooth, glistening and butyrous.

Growth on the surface of assimilation media: Pellicles are not formed.

Dalmu plate culture on morphology agar: After 7 days at 25°C, growth under the coverglass shows neither pseudohyphae nor true hyphae. Aerobic growth is pale tannish-white, smooth, glistening and butyrous with an entire to lobed margin. Some strains produce a faint odor of esters.

Formation of ascospores: Asci may show parent–bud conjugation or conjugation between independent cells. One to four hat-shaped spores are produced in each ascus, and the spores are freed soon after formation. Because conjugations between a cell and its bud are common in ascospore cultures, this species appears to be homothallic.

Ascospores were observed on 5% malt extract agar and Difco yeast morphology agar after 4–7 days at 25°C.

Fermentation:

Co-Q: 7 and 8 (nearly equal amounts), CBS 6515, type strain of *P. methanolica* (Lee and Komagata 1983); 7/8, CBS 8002, type strain of *P. cellobiosa* (Lee and Komagata 1980b).

Mol% G+C: 36.9, CBS 8002 (T_m : Lee and Komagata 1980b); 36.4, CBS 6515 (T_m : Billon-Grand 1981).

Origin of the strains studied: Soil, Japan (7); *P. methanolica* CBS 6515 (type strain) and one additional strain; *P. cellobiosa* CBS 8002 (type strain) and two additional strains; *P. aganobii* CBS 8053 (representative strain) and one additional strain.

Type strain: CBS 6515 (NRRL Y-7685).

Comments: Some differences were noted in the results obtained from fermentation and assimilation tests in the present study and those reported by Kato et al. (1974). In contrast to the original description, maltose was not fermented; however, L-sorbose and D-arabinose were assimilated, but citric and lactic acids were not utilized. Furthermore, growth was absent in vitamin-free medium. Kato et al. (1974) reported this species to be noteworthy because of its strong assimilation of methanol.

Lee and Komagata (1983) demonstrated that the electrophoretic profiles of 13 cellular enzymes were identical for *P. methanolica* and *P. cellobiosa* and proposed the two taxa to be conspecific. Kurtzman (1992b) showed 100% nDNA complementarity between type strains of *P. methanolica* and *P. cellobiosa* providing additional evidence that the two represent a single species. In other nDNA comparisons, *P. aganobii* showed 100% complementarity with *P. methanolica* (Kurtzman and Robnett, unpublished data).

42.51. *Pichia methylavora*² Kumamoto & Seriu (Kumamoto et al. 1986)

Anamorph: *Candida cariosilignicola* J.-D. Lee & Komagata

Synonym:

Candida cariosilignicola J.-D. Lee & Komagata (1980b)

Growth on 5% malt extract agar: After 3 days at 25°C, the cells are spheroidal to ellipsoidal, (1.3–3.5) × (1.9–4.1) μm, and single or in pairs. Growth is mucoid, glistening and tannish-white.

Growth on the surface of assimilation media: Pellicles are not formed.

Dalmu plate culture on morphology agar: After 7 days at 25°C, growth under the coverglass shows neither pseudohyphae nor true hyphae, but occasional “tree-like” outgrowths of undifferentiated cells develop. Aerobic growth is tannish-white, glistening, mucoid and convex in

² The original spelling of the species epithet *methylavora* has been treated as an orthographic error.

profile with a smooth margin. A faint musky, acidic odor is present.

Formation of ascospores: Ascospores were not observed in the present study. Kumamoto et al. (1986) presented photographs of hat-shaped ascospores and reported that two were produced per ascus on 5% malt extract agar after 7 days. Asci are deliquescent. It was not reported whether the species is homothallic or heterothallic.

Fermentation: absent.

Assimilation:

Glucose	+	<i>N</i> -Acetyl-D-glucosamine	+

Co-Q: 7 (Kumamoto et al. 1986).

Mol% G+C: 35.8, CBS 7300 (T_m : Kumamoto et al. 1986).

Origin of the strains studied: CBS 7300 (NRRL Y-17250), isolated from a rotted tree, Iwate Prefecture, Japan; CBS 8001 (NRRL Y-11996), type strain of *Candida cariosilignicola*, from decayed timber, Japan.

Type strain: CBS 7300.

Comments: Kumamoto et al. (1986) reported *P. methylivora* to ferment D-glucose, sucrose, trehalose and raffinose, but fermentation was not detected in the present study. Kurtzman and Robnett (unpublished) found *Candida cariosilignicola* and *P. methylivora* to have nearly identical nucleotide sequences in the variable 5' region of the large subunit rRNA gene indicating the two taxa to be conspecific.

42.52. *Pichia mexicana* Miranda, Holzschu, Phaff & Starmer (1982)

Anamorph: *Candida terebra* Sugiyama & S. Goto

Synonyms:

Yamadazyma mexicana (Miranda, Holzschu, Phaff & Starmer)

Billon-Grand (1989)

Candida terebra Sugiyama & S. Goto (1969)

Trichosporon veronae Florenzano (1953) nom. nud.

Candida veronae Florenzano ex van Uden & H.R. Buckley (1970)

Candida entomaea van der Walt, D.B. Scott & van der Klift (1972)

Growth on 5% malt extract agar: After 3 days at 25°C, the cells are ovoidal to cylindrical, (1.1–3.4) × (1.9–9.0) μ m, and occasionally tapered or curved. The cells occur singly, in pairs, or in small clusters. Growth is butyrous, dull-glistening and tannish-white.

Growth on the surface of assimilation media: Pellicles are not formed.

Dalmat plate culture on morphology agar: After 7 days at 25°C, growth under the coverglass shows numerous well-branched pseudohyphae with moderately abundant blastoconidia. True hyphae were not detected, but some of the pseudohyphae show almost no constriction at the septa. Aerobic growth is white, butyrous, and with a dull surface; the colonies are striated and with an irregular margin. There is a faint ester-like odor.

Formation of ascospores: This species is heterothallic. Miranda et al. (1982) reported that following conjugation of complementary mating types the resulting zygote served as the ascus and that it is infrequent that diploid cells budded from the zygote undergo ascospore formation. Asci form one to four hat-shaped ascospores that are released at maturity. In the present study, conjugation was observed between complementary mating types, but ascospore formation was not detected. Miranda et al. (1982) noted that zygote formation and ascospore formation were infrequent events that most often occurred on 1–2% malt extract agar after 7–14 days.

Fermentation:

Glucose	+	Lactose	-
Galactose	+/-	Raffinose	-
Sucrose	-	Trehalose	+
Maltose	-		

Assimilation:

Glucose	+	<i>N</i> -Acetyl-D-glucosamine	+

Additional assimilation tests and other growth characteristics:

2-Keto-D-gluconate	s	Starch formation	–
5-Keto-D-gluconate	–	Gelatin liquefaction	w
Saccharate	–	Growth at 37°C	+
10% NaCl/5% glucose	+		

Co-Q: 9, CBS 7066 (Miranda et al. 1982).

Mol% G+C: 42.2–42.5, CBS 7066 and 4 additional strains (BD: Miranda et al. 1982).

Origin of the strains studied: CBS 7066 (UCD-FST 76-308A, NRRL Y-11818), from agria cactus (*Stenocereus gummosus*), Palmilla, Baja California Sur, Mexico; CBS 7067 (UCD-FST 76-391B, NRRL Y-11819), from organ-pipe cactus (*Stenocereus thurberi*), Rancho Cuñaño, Baja California Sur; CBS 6023 (NRRL Y-17683), type strain of *Candida terebra*, from soil, Japan; CBS 5815 (NRRL Y-17672), type strain of *Candida veronae*, from grape must, Italy; CBS 6306 (NRRL Y-7785), type strain of *Candida entomaea*, from an insect tunnel in pine (*Pinus radiata*), South Africa.

Complementary mating types: CBS 7066 (h^+) and CBS 7067 (h^-).

Type strain: CBS 7066.

Comments: *P. mexicana*, which is found in cacti from Baja California, Mexico, as well as from the southwestern U.S.A., has been isolated only as haploid mating types. Miranda et al. (1982) raised the possibility that *Candida terebra* and *C. entomaea* represent anamorphs of *P. mexicana*. C.-F. Lee et al. (1993) demonstrated through comparisons of nDNA complementarity that *C. terebra*, *C. entomaea* and *C. veronae* are conspecific. Kurtzman and Robnett (unpublished) found the nucleotide sequences from the 5'-end of the large subunit rRNA genes for all three *Candida* species, as well as for *P. mexicana*, to be identical, thus confirming *C. terebra*, the species of taxonomic priority, to represent the anamorph of *P. mexicana*.

42.53. *Pichia meyeriae* van der Walt (1982a)

Anamorph: *Candida meyeriae* van der Walt

Synonym:

Candida meyeriae van der Walt (1982a)

Growth on 5% malt extract agar: After 3 days at 25°C, the cells are spheroidal to cylindrical, (1.5–3.6) × (1.6–6.2) μm, and occur singly, in pairs and in small clusters. Growth is butyrous, glistening and tannish-white.

Growth on the surface of assimilation media: Pellicles are not formed.

Dalmu plate culture on morphology agar: After 7 days at 25°C, growth under the coverglass shows some well-branched pseudohyphae with blastoconidia. True hyphae were not observed, but van der Walt (1982a) reported their occurrence on corn meal agar. Aerobic growth is tannish-white, glistening, butyrous, and low convex with margins that are smooth to lobed. Odors

produced by different strains range from faintly acid to faintly buttery.

Formation of ascospores: This species is heterothallic but it has been isolated from nature only in the diploid form. Asci from diploid strains are unconjugated and produce one to four hat-shaped ascospores that are released soon after formation. Van der Walt (1982a) obtained complementary mating types by heat treatment of an ascosporegenous culture of the type strain. Mixtures of complementary mating types are sexually agglutinative.

Ascosporeulation was observed on 5% malt extract agar after 3 days at 25°C.

Fermentation:

Glucose	+	Lactose	–
Galactose	–	Raffinose	–

2-Keto-D-gluconate	–	Starch formation	–
5-Keto-D-gluconate	–	Gelatin liquefaction	–
Saccharate	–	Growth at 37°C	+
10% NaCl/5% glucose	–		

Co-Q: 7, CBS 7076 (Billon-Grand 1985).

Mol% G+C: 48.5, 48.9, CBS 7077, 7078 (BD: Kurtzman, unpublished).

Origin of the strains studied: CBS 7076 (NRRL Y-17236), from rotting insect infested spurge (*Euphorbia ingens*), Groblersdal district, South Africa; CBS 7077 (NRRL Y-12777) and CBS 7078 (NRRL Y-12778), haploids from a heat-treated culture of CBS 7076.

Complementary mating types: CBS 7077 and CBS 7078, derived from CBS 7076.

Type strain: CBS 7076.

Comments: *P. meyeriae* is phenotypically similar to *P. euphorbiae*, *P. rhodanensis*, *P. wickerhamii*, *P. veronae*, *P. amylophila* and *P. mississippiensis*, which are heterothallic as well. In pairings among these species, van der Walt and Opperman (1983) detected a mating reaction

only between *P. meyerae* and *P. euphorbiae*, but the resulting zygotes failed to produce ascospores.

42.54. *Pichia minuta* (Wickerham) Kurtzman (1984a)

This species has two varieties:

Pichia minuta (Wickerham) Kurtzman var. *minuta* (1984a)

Synonyms:

Hansenula minuta Wickerham (1951)

Zygothansenula minuta (Wickerham) Krasil'nikov (1954a)

Ogataea minuta (Wickerham) Y. Yamada, Maeda & Mikata (1994c)

?*Torulopsis methanolovescens* Oki & Kouno (Oki et al. 1972)

?*Candida methanolovescens* (Oki & Kouno) S.A. Meyer & Yarrow (Yarrow and Meyer 1978)

Pichia lindneri Henninger & Windisch (1975a)

Pichia minuta var. *nonfermentans* (Wickerham) Kurtzman (1984a)

Synonyms:

Hansenula nonfermentans Wickerham (1969b)

Ogataea minuta (Wickerham) Y. Yamada, Maeda & Mikata var.

nonfermentans (Wickerham) Y. Yamada, Maeda & Mikata (1994c)

Growth on 5% malt extract agar: After 3 days at 25°C, the cells are spheroidal to ellipsoidal, (1.0–2.6) × (1.0–3.2) µm, and occur singly or in pairs.

Growth on the surface of assimilation media: Pellicles are not produced and generally there are no rings.

Dalmau plate culture on morphology agar: After 7 days at 25°C, neither hyphae nor pseudohyphae are detected under the coverglass. Aerobic growth is light tan, glistening, and butyrous to mucoid. Colony margins are entire. Some strains produce a faintly sweet odor.

Formation of ascospores: Ascospore formation is preceded by conjugation between a parent cell and a bud. Asci produce one to four hat-shaped ascospores and become deliquescent at maturity. The spores are quite small but increase in size following their release. Because of the mode of ascus formation and the observation that single-spore isolates from four-spored asci are sporogenous, the species is presumed to be homothallic (Kurtzman, unpublished). The variety *nonfermentans* is presumed to be homothallic for the same reasons.

Ascospores were observed for both varieties on 5% malt extract agar after 15–30 days at 25°C.

Fermentation:

Glucose	+w	Lactose	–
Galactose	–	Raffinose	–
Sucrose	–	Trehalose	w

2-Keto-D-gluconate	–	Starch formation	–
5-Keto-D-gluconate	–	Gelatin liquefaction	w/–
Saccharate	–	Growth at 37°C	–
10% NaCl/5% glucose	v		

Co-Q: 7, CBS 1708, CBS 5764 (Yamada et al. 1973a).

Mol% G + C: 47.5, CBS 1708 (T_m : Nakase and Komagata 1971b); 46.7, 47.7, CBS 1708, 6502 (BD: Kurtzman 1984a), var. *minuta*; 45.6, CBS 5764 (T_m : Nakase and Komagata 1971b); 45.1, 45.3, CBS 5764 (BD: Kurtzman 1984a, Phaff et al. 1983), var. *nonfermentans*.

Supplementary description of *P. minuta* var. *nonfermentans*: The variety *nonfermentans* is capable of growth at 37°C and can be separated from the variety *minuta* on this characteristic. Additionally, the variety *nonfermentans* does not ferment glucose.

Origin of the strains belonging to the variety *minuta*: Isolated from fermenting mushrooms (*Mycena pura* Fries) by A.T. Henrici (1); the type strain of *P. lindneri*, NRRL Y-10948 (CBS 6502), forest soil, Germany.

Type strain: CBS 1708 (NRRL Y-411), from fermenting mushrooms.

Origin of the strain belonging to the variety *nonfermentans*: The only known strain of this variety was isolated from Libby Creek near Laramie, Wyoming, U.S.A.

Type strain: CBS 5764 (NRRL YB-2203).

Comments: The species described as *Hansenula minuta*, *H. nonfermentans* and *P. lindneri* have uniquely small cells and give similar reactions on fermentation and assimilation tests. Because of this phenotypic likeness, Kurtzman (1984a) compared the nDNA complementarity of the taxa and found 75% relatedness between *H. minuta* and *P. lindneri* and 48% relatedness between *H. minuta* and *H. nonfermentans*. These data indicate *H. minuta* and *P. lindneri* to be somewhat divergent strains of the same species. *H. nonfermentans* was regarded as a variety of *H. minuta*, but these two species may be sibling

species instead. As discussed under Comments on the genus, these data show that nitrate assimilation is not a reliable character for the separation of species or genera and prompted the transfer of *Hansenula* species with hat-shaped ascospores to *Pichia* which has taxonomic priority.

42.55. *Pichia mississippiensis* Kurtzman, Smiley, Johnson, Wickerham & Fuson (1980a)

Synonym:

Candida obtusa (Dietrichson) van Uden & do Carmo-Sousa ex van Uden & H.R. Buckley var. *arabino*s Montrocher (1967)

Growth on 5% malt extract agar: After 3 days at 25°C, the cells, which are quite variable in size, are ellipsoidal to elongate, or infrequently spheroidal, (1.1–5.0)×(2.0–12.0) μm, and occur singly, in pairs or in clusters. Growth is butyrous and tannish-white in color.

Growth on the surface of assimilation media: Pellicles are not formed but rings occasionally develop.

Dalmay plate culture on morphology agar: After 7 days at 25°C, growth under the coverglass shows abundant and highly branched pseudohyphae as well as infrequent true hyphae. True hyphae show no evidence of a dolipore septum when viewed under the light microscope. Aerobic growth is light tan, glistening, and butyrous; the center is raised and the margin entire. A faint ester-like odor is produced.

Fig. 145. *P. mississippiensis*, CBS 7023. Ascospore culture after 3 days, 25°C, on 5% malt extract agar. Bar = 5 μm.

Formation of ascospores: Asci arise from diploid cells or from the pairing of complementary mating types and form two to four hat-shaped spores (Fig. 145). Asci are spheroidal to ellipsoidal and are free or attached to pseudohyphae. Infrequently, a pseudohyphal or hyphal cell may become an ascus. At maturity asci become deliquescent.

Ascospores were observed on 5% malt extract and YM agars after 5–8 days at 25°C.

Fermentation:

Glucose	+	Lactose	–
Galactose	–	Raffinose	–
Sucrose	–	Trehalose	–
Maltose	–		

Assimilation:

Glucose	+	<i>N</i> -Acetyl-D-glucosamine	–
Galactose	–	Methanol	–
L-Sorbose	–	Ethanol	+
Sucrose	+	Glycerol	+
Maltose	+	Erythritol	–

Inulin	–	D-Gluconate	+
Soluble starch	–	DL-Lactate	+
D-Xylose	+	Succinate	+
L-Arabinose	+	Citrate	v
D-Arabinose	w/–	Inositol	–
D-Ribose	–	Hexadecane	–
L-Rhamnose	v	Nitrate	–
D-Glucosamine	–	Vitamin-free	–

Additional assimilation tests and other growth characteristics:

2-Keto-D-gluconate	–	Starch formation	–
5-Keto-D-gluconate	–	Gelatin liquefaction	–
Saccharate	–	Growth at 37°C	+
10% NaCl/5% glucose	–		

Co-Q: 7, CBS 7023 (Billon-Grand 1985).

Mol% G + C: 47.2–48.0, CBS 7023 and three additional strains (BD: Kurtzman et al. 1980a).

Origin of the strains studied: Frass from shortleaf (*Pinus echinata*) and loblolly (*Pinus taeda*) pines, Mississippi, U.S.A. (9); laboratory contaminant (1); from a mushroom, France (1).

Complementary mating types: NRRL YB-1294-6 (CBS 7024) and NRRL YB-1294-7 (CBS 7025).

Type strain: CBS 7023 (NRRL YB-1294), from frass of a loblolly pine.

Comments: The relationship of this species with *P. amylophila* is discussed in the description of the latter species.

42.56. *Pichia naganishii* K. Kodama (Kodama & Kyono 1974a)

Growth on 5% malt extract agar: After 3 days at 25°C, the cells are spheroidal to ovoidal, (1.8–4.2)×(2.5–6.5) μm, and occur singly, in pairs or in small clusters. Growth is cream-colored, smooth, glistening and butyrous.

Growth on the surface of assimilation media: Thin rings are formed, but no pellicles.

Dalmay plate culture on morphology agar: After 7 days at 25°C, growth under the coverglass shows neither pseudohyphae nor true hyphae. Aerobic growth is faint tan

in color, smooth, glistening and butyrous with an entire to finely lobed margin. A faint acidic odor is produced.

Formation of ascospores: Ascus formation may be preceded by conjugation between independent cells or between parent and bud. Two to four hat-shaped ascospores are produced in each ascus, and they are readily liberated after formation. Single-spore isolates from four-spored asci are sporogenous, indicating the species to be homothallic.

Ascospores were observed on 5% malt extract and YM agars after 3–5 days at 25°C.

Fermentation:

Glucose	+	Lactose	–
Galactose	–	Raffinose	–
Sucrose	–	Trehalose	+
Maltose	–		

Assimilation:

Glucose	+	<i>N</i> -Acetyl-D-glucosamine	+
Galactose	+	Methanol	+
L-Sorbose	–	Ethanol	+
Sucrose	+	Glycerol	+
Maltose	+	Erythritol	+
Cellobiose	+	Ribitol	+
Trehalose	+	Galactitol	–
Lactose	–	D-Mannitol	+
Melibiose	–	D-Glucitol	+
Raffinose	–	α -Methyl-D-glucoside	w
Melezitose	+	Salicin	+
Inulin	–	D-Gluconate	–
Soluble starch	–	DL-Lactate	+
D-Xylose	+	Succinate	+
L-Arabinose	+	Citrate	–
D-Arabinose	–	Inositol	–
D-Ribose	+	Hexadecane	–
L-Rhamnose	+	Nitrate	–
D-Glucosamine	+	Vitamin-free	–

Additional assimilation tests and other growth characteristics:

2-Keto-D-gluconate	–	Starch formation	–
5-Keto-D-gluconate	–	Gelatin liquefaction	w
Saccharate	–	Growth at 37°C	+
10% NaCl/5% glucose	+		

Co-Q: 7, CBS 6429 (Billon-Grand 1985).

Mol% G+C: 46.1, CBS 6429 (T_m : Kodama and Kyono 1974a).

Origin of the strain studied: Exudate from the plant *Camellia japonica* L., Japan (1).

Type strain: CBS 6429 (NRRL Y-7654).

Comments: The original description of *P. naganishii* (Kodama and Kyono 1974a) is generally in agreement with the results obtained in the present study. However, growth on L-sorbose, galactitol and citric acid proved to be negative rather than positive as originally reported.

42.57. *Pichia nakasei* J.A. Barnett, Payne & Yarrow (1983)

Anamorph: *Candida citrea* Nakase

Synonym:

Candida citrea Nakase (1971c)

Growth on 5% malt extract agar: After 3 days at

25°C, the cells are spheroidal to elongate, (1.6–4.6) × (2.1–8.6) μ m, and single, in pairs, or small clusters. Growth is butyrous, dull-glistening and tannish-white.

Growth on the surface of assimilation media: Dry climbing pellicles are present.

Dalmat plate culture on morphology agar: After 7 days at 25°C, growth under the coverglass shows abundant well-branched pseudohyphae with relatively few blastoconidia. True hyphae are not produced. Aerobic growth is white to tannish-white, dull-glistening, butyrous, and convex in profile with margins entire to lobed. A faintly acidic odor is produced.

Formation of ascospores: This species is heterothallic. Ascospores may be formed directly by diploid strains or following conjugation between complementary mating types. Asci produce one to four hat-shaped ascospores that are freed at maturity.

Ascospores were observed on 5% malt extract agar after 10 days at 25°C.

Fermentation:

Glucose	+	Lactose	–
Galactose	–	Raffinose	–
Sucrose	–	Trehalose	–
Maltose	–		

Assimilation:

Glucose	+	<i>N</i> -Acetyl-D-glucosamine	–
Galactose	–	Methanol	–
L-Sorbose	–	Ethanol	+
Sucrose	–	Glycerol	+
Maltose	–	Erythritol	–
Cellobiose	–	Ribitol	–
Trehalose	–	Galactitol	–
Lactose	–	D-Mannitol	–
Melibiose	–	D-Glucitol	–
Raffinose	–	α -Methyl-D-glucoside	–
Melezitose	–	Salicin	–
Inulin	–	D-Gluconate	w/–
Soluble starch	–	DL-Lactate	–
D-Xylose	–	Succinate	+/w
L-Arabinose	–	Citrate	–
D-Arabinose	–	Inositol	–
D-Ribose	–	Hexadecane	–
L-Rhamnose	–	Nitrate	–
D-Glucosamine	–	Vitamin-free	–

Additional assimilation tests and other growth characteristics:

2-Keto-D-gluconate	–	Starch formation	–
5-Keto-D-gluconate	–	Gelatin liquefaction	w/–
Saccharate	–	Growth at 37°C	–
10% NaCl/5% glucose	+/w		

Co-Q: Not determined.

Mol% G+C: 32.9, 33.2, CBS 6374 (AJ 4769), CBS 6737 (AJ 4441) (T_m : Nakase 1971a).

Origin of the strains studied: CBS 5141 (NRRL Y-7686), from apple must, Chile; CBS 6374 (NRRL Y-17248), the type strain of *Candida citrea*, from a lemon (*Citrus* sp.) fruit, Japan; CBS 6737 (NRRL Y-17237), from the fruit of a banana (*Musa sapientum*), Japan; CBS 6738 (NRRL Y-17238), from a lemon fruit, Japan.

Complementary mating types: CBS 6374 (*a*) and CBS 6737 (*α*).

Type strain: CBS 5141.

Comments: The type strain of *P. nakasei* maintained at CBS was initially an ascosporegenous diploid but reverted to a haploid mating type following long-term serial cultivation (Barnett et al. 1990), a phenomenon that has been observed for certain other heterothallic species (Wickerham et al. 1970a,b, Kurtzman and Smiley 1976). In contrast, the type strain maintained in the ARS Culture Collection (NRRL), which was obtained from CBS in 1974 and immediately lyophilized, is still ascosporegenous.

42.58. *Pichia nakazawae* K. Kodama (1975)

This species has two varieties:

Pichia nakazawae K. Kodama var. *nakazawae* (1975)

Synonym:

Yamadazyma nakazawae (K. Kodama) Billon-Grand (1989)

Pichia nakazawae var. *akitaensis* K. Kodama (1975)

Growth on 5% malt extract agar: After 3 days at 25°C, the cells are spheroidal to ellipsoidal, (2.0–4.5) × (3.0–9.8) μm, and occur singly, in pairs and in clumps. Growth is cream-colored, smooth, glistening and butyrous.

Growth on the surface of assimilation media: Thin to moderately thick climbing pellicles are produced.

Dalmau plate culture on morphology agar: After 7 days at 25°C, growth under the coverglass shows occasional branching outgrowths of ovoidal cells, but no pseudohyphae or true hyphae. Aerobic growth is tannish-white, smooth or finely striated, glistening, and butyrous with entire to finely lobed margins. A faintly acidic odor is produced.

Formation of ascospores: Ascus formation may be preceded by either conjugation between a parent cell and a bud or by conjugation between independent cells. Asci contain two to four hat-shaped ascospores and these are released soon after formation (Fig. 146). Both varieties of *P. nakazawae* were found to be homothallic through examination of single-spore isolates from four-spored asci (Kurtzman 1984b).

Ascospores for both varieties were observed on 5% malt extract and YM agars after 3–5 days at 25°C.

Fermentation:

Glucose	+	Lactose	–
Galactose	+	Raffinose	–
Sucrose	–	Trehalose	+
Maltose	w		

Fig. 146. *P. nakazawae* var. *nakazawae*, CBS 6700. Ascosporegenous culture after 2 weeks, 25°C, on 5% malt extract agar. Bar = 5 μm.

Assimilation:

Glucose	+	<i>N</i> -Acetyl-D-glucosamine	+
Galactose	+	Methanol	–
L-Sorbose	+	Ethanol	+
Sucrose	+	Glycerol	+
Maltose	+	Erythritol	+
Cellobiose	+	Ribitol	+
Trehalose	+	Galactitol	–
Lactose	–	D-Mannitol	+
Melibiose	–	D-Glucitol	+
Raffinose	–	α-Methyl-D-glucoside	+
Melezitose	+	Salicin	+/w
Inulin	–	D-Gluconate	+
Soluble starch	+	DL-Lactate	+/w
D-Xylose	+	Succinate	+
L-Arabinose	+	Citrate	+
D-Arabinose	+	Inositol	–
D-Ribose	+	Hexadecane	s
L-Rhamnose	+	Nitrate	–
D-Glucosamine	+	Vitamin-free	–

Additional assimilation tests and other growth characteristics:

2-Keto-D-gluconate	+	Starch formation	–
5-Keto-D-gluconate	–	Gelatin liquefaction	–
Saccharate	–	Growth at 37°C	–
10% NaCl/5% glucose	+		

Co-Q: 9, CBS 6700 (Billon-Grand 1985).

Mol% G + C: 38.7 (T_m : Kodama 1975), 39.4 (BD: Kurtzman 1984b), CBS 6700, var. *nakazawae*; 39.5 (T_m : Kodama 1975), 39.9 (BD: Kurtzman 1984b), CBS 6701, var. *akitaensis*.

Supplementary description of *Pichia nakazawae* var. *akitaensis*:

The variety *akitaensis* differs from the variety *nakazawae* by its failure to ferment galactose, by the presence of weak and slow fermentations of sucrose and trehalose, and from inability to assimilate L-rhamnose and lactic acid. The fermentation rate of variety *akitaensis* is quite weak in comparison to the vigorous ability of variety *nakazawae*. Another difference between the two varieties is the formation of moderately well-developed pseudohyphae by variety *akitaensis*, which causes agar-grown colonies to appear dull and finely convoluted.

Origin of the strain belonging to the variety *nakazawae*: Exudate of an oak (*Quercus myrsinaeforia* Blume), Japan (1).

Type strain: CBS 6700 (NRRL Y-7903).

Origin of the strain belonging to the variety *akitaensis*: Exudate of a willow (*Salix* sp.), Japan (1).

Type strain: CBS 6701 (NRRL Y-7904).

Comments: The original description of this species agrees with the results of the present study except that the variety *nakazawae* was found to slowly assimilate D-ribose and to give a weak and latent reaction on lactic acid. In addition, both varieties assimilated L-sorbose, but neither grew in vitamin-free medium. nDNA relatedness between the two varieties is 41%, suggesting that they are either divergent varieties of a single species or that they are sibling species. Varietal designations were maintained pending evidence that the pair is reproductively isolated (Kurtzman 1984b).

42.59. *Pichia norvegensis* Leask & Yarrow (1976)

Anamorph: *Candida norvegensis* Dietrichson ex van Uden & H.R. Buckley

Synonyms:

Candida zeylanoides (Castellani) Langeron & Guerra var. *norvegensis* Dietrichson (1954) nom. nud.

Candida norvegensis (Dietrichson) van Uden & Farinha (1958) nom. nud.

Candida norvegensis Dietrichson ex van Uden & H.R. Buckley (1970) (incorrectly described as *Candida norvegensis* (Dietrichson) van Uden & Farinha ex van Uden & H.R. Buckley)

Candida trigonopsoides Dietrichson (1954) nom. nud.

Candida mycoderma (Reess) Lodder & Kreger-van Rij var. *annulata* Dietrichson (1954) nom. nud.

Growth on 5% malt extract agar: After 3 days at 25°C, the cells are ovoidal to ellipsoidal, (1.7–4.1) × (3.0–10.0) µm, and occur singly, in pairs or in clusters. Growth is yellowish-white, smooth, glistening and butyrous.

Growth on the surface of assimilation media: Thin pellicles are formed.

Dalmou plate culture on morphology agar: After 7 days at 25°C, growth under the coverglass shows abundant pseudohyphae. Some of the longer pseudohyphal cells are markedly curved. True hyphae are not produced. Aerobic growth is light tan in color, smooth, glistening, butyrous and with an entire margin. A faint acidic odor is produced.

Formation of ascospores: Asci are unconjugated and form one to four hat-shaped ascospores which are released at maturity. Leask and Yarrow (1976) reported that heat-treatment of sporogenous cultures gave only sporogenous colonies, indicating the species to be homothallic.

Spores were observed on Fowell's acetate agar after 10–15 days at 25°C.

Fermentation:

Glucose	s	Lactose	–
Galactose	–	Raffinose	–
Sucrose	–	Trehalose	–
Maltose	–		

Assimilation:

Glucose	+	<i>N</i> -Acetyl-D-glucosamine	–
Galactose	–	Methanol	–
L-Sorbose	–	Ethanol	+
Sucrose	–	Glycerol	+
Maltose	–	Erythritol	–
Cellobiose	+	Ribitol	–
Trehalose	–	Galactitol	–
Lactose	–	D-Mannitol	–
Melibiose	–	D-Glucitol	–
Raffinose	–	α-Methyl-D-glucoside	–
Melezitose	–	Salicin	+
Inulin	–	D-Gluconate	–
Soluble starch	–	DL-Lactate	w
D-Xylose	–	Succinate	+
L-Arabinose	–	Citrate	w
D-Arabinose	–	Inositol	–
D-Ribose	–	Hexadecane	–
L-Rhamnose	–	Nitrate	–
D-Glucosamine	+	Vitamin-free	–

Additional assimilation tests and other growth characteristics:

2-Keto-D-gluconate	–	Starch formation	–
5-Keto-D-gluconate	–	Gelatin liquefaction	–
Saccharate	–	Growth at 37°C	+
10% NaCl/5% glucose	+		

Co-Q: 7, CBS 6564 (Billon-Grand 1985).

Mol% G+C: 35.6, 36.6, IFO 1020, CBS 1922 (T_m : Nakase and Komagata 1971f), 35.5, 37.5, CBS 6564 (Billon-Grand 1981; BD: Kurtzman, unpublished).

Origin of the strain studied: Vagina of a pregnant woman (1).

Type strain: CBS 6564 (NRRL Y-7687).

Comments: Guého and Phaff (1983) demonstrated by nDNA reassociation that *Candida norvegensis* is the anamorph of *P. norvegensis*. These authors noted that in addition to its clinical association, *P. norvegensis* is commonly isolated from rots of opuntia cactus.

42.60. *Pichia ofunaensis* (Makiguchi & Y. Asai) Kurtzman (1996)

Synonym:

Hansenula ofunaensis Makiguchi & Y. Asai (Asai et al. 1976)

Growth on 5% malt extract agar: After 3 days at 25°C, the cells are spheroidal to elongate, (1.5–2.6) × (2.1–4.8) µm, and occasionally tapered or of irregular shapes. The cells occur singly, in pairs and in small clusters. Growth is butyrous, glistening and tannish-white.

Growth on the surface of assimilation media: Pellicles are not formed.

Dalmou plate culture on morphology agar: After 7 days at 25°C, growth under the coverglass shows branched pseudohyphae with blastoconidia. True hyphae appear to be absent. Aerobic growth is butyrous, tannish-white, glistening and convex with a depressed center. Colony margins are entire to broadly lobed. A faint acidic odor is present.

Formation of ascospores: Ascospores were not observed in the present study. Asai et al. (1976) and Barnett et al. (1990) illustrated unconjugated asci containing one

to four hat-shaped ascospores. Asci become deliquescent. It is not known whether the species is homothallic or heterothallic.

Ascospore germination was reported to occur on YM agar after 7 days at room temperature.

Fermentation:

Glucose	ws	Lactose	–
Galactose	ws	Raffinose	–
Sucrose	–	Trehalose	ws
Maltose	–

Additional assimilation tests and other growth characteristics:

2-Keto-D-gluconate	ws	Starch formation	–
5-Keto-D-gluconate	–	Gelatin liquefaction	–
Saccharate	–	Growth at 37°C	+
10% NaCl/5% glucose	s		

Co-Q: Not determined.

Mol% G + C: 32.6, CBS 8129 (HPLC: Miller and Baharaeen 1979).

Origin of the strain studied: Soil, Ofuna, Japan.

Type strain: CBS 8129 (CBS 6861, NRRL Y-10998).

Comments: This species was described as nonfermentative, but a small amount of gas (2–5%) was found in Durham tube inserts after 12–16 days for glucose, galactose and trehalose. Assimilation reactions listed as variable did not repeatedly show growth on the designated compounds.

42.61. *Pichia ohmeri* (Etchells & T.A. Bell) Kreger-van Rij (1964b)

Synonyms:

Endomycopsis ohmeri Etchells & T.A. Bell (1950a)

Yamadazyma ohmeri (Etchells & T.A. Bell) Billon-Grand (1989)

Kodamaea ohmeri (Etchells & T.A. Bell) Y. Yamada, Suzuki, Matsuda & Mikata (1995)

Endomycopsis ohmeri Etchells & T.A. Bell var. *minor* Etchells & T.A. Bell (1950a)

Candida guilliermondii (Castellani) Langeron & Guerra var. *membranaefaciens* Lodder & Kreger-van Rij (1952)

Trichosporon arenicola de Lima & Aciole de Queiroz (1972)

Growth on 5% malt extract agar: After 3 days at

25°C, the cells are ovoidal to cylindroidal, (1.7–6.5) × (2.5–25) μ m, and occur singly, in pairs and in short chains. Growth is somewhat pseudomycelial and cream-colored.

Growth on the surface of assimilation media: Pellicles are formed.

Dalmat plate culture on morphology agar: After 7 days at 25°C, growth under the coverglass shows abundant, moderately branched pseudohyphae. True mycelium was not observed. Aerobic growth is grayish-white, dull and nearly smooth to finely convoluted. Margins are irregularly lobed.

Formation of ascospores: Infrequently, diploid strains are isolated which form unconjugated asci, but this heterothallic species is normally isolated in the haploid form and requires conjugation of complementary mating types before sporulation. Asci form one to four spores and are deliquescent at maturity. Spore shape is determined by the mating types and may be either hat-shaped or spheroidal (Wickerham and Burton 1954b). Pairing of NRRL Y-2078 (CBS 2037) and NRRL Y-2079 (CBS 568) gives hat-shaped spores while the conjugation of NRRL Y-2078 and NRRL Y-2080 (CBS 2038) produces spheroidal spores.

Ascospores were observed on 5% malt extract agar after 3–5 days at 25°C, following pairing of complementary mating types.

Co-Q: 9, CBS 5367 and 2 additional strains (Yamada et al. 1973a).

Mol% G + C: 42.2, 42.4, CBS 5367, AJ 5088 (T_m : Nakase and

Komagata 1970b); 44.3–44.7, CBS 5367 and 3 additional strains (BD: Fuson et al. 1980).

Origin of the strains studied: Cucumber brine (3); pleural fluid (1); gooseberry jelly (1); sambal ulak (1); flowers (2); unknown substrates (3).

Complementary mating types: NRRL Y-2078 (CBS 2037) and NRRL Y-2079 (CBS 568).

Type strain: CBS 5367 (NRRL Y-1932), from cucumber brine.

Comments: *Pichia ohmeri* is an unusual species because, depending upon the mating types paired, ascospores may be either hat-shaped or spheroidal (Wickerham and Burton 1954b). Preliminary genetic studies suggest that only a few genes determine which spore shape results (Kurtzman, unpublished). These studies also demonstrated ascospore fertility through the F₂ generation, thus indicating the various mating types to be members of the same species. This premise was confirmed by the work of Fuson et al. (1980), which showed the *P. ohmeri* mating types to exhibit 98–100% DNA relatedness.

42.62. *Pichia onychis* Yarrow (1965)

Synonym:

?*Pichia xylopsoci* van der Walt & D.B. Scott (1971c)

Growth on 5% malt extract agar: After 3 days at 25°C, the cells are ovoidal, (2.0–4.5) × (2.8–7.8) μm, and occur singly or in pairs. Growth is cream-colored, glistening and butyrous.

Growth on the surface of assimilation media: Thin pellicles may be formed.

Dalmou plate culture on morphology agar: After 7 days at 25°C, growth under the coverglass shows a simple, sparingly branched pseudomycelium, but true hyphae are not formed. Aerobic growth is tannish-white, glistening, butyrous, and with an entire or occasionally lobed margin.

Formation of ascospores: Asci are unconjugated and produce one to four hat-shaped ascospores. The spores are liberated soon after formation. It has not been determined whether this species is homothallic or heterothallic.

Ascospores were observed on 5% malt extract, YM, and V8 agars after 10 days at 25°C.

Co-Q: 7 (Y. Yamada and H.J. Phaff, personal communication).

Mol% G+C: 40.8, 42.7, CBS 5587 (*T_m*: J.B. Fiol, cited by Billon-Grand 1981; BD: Kurtzman, unpublished).

Origin of the strains studied: Infected human nail (1); corn meal (1); dust (1).

Type strain: CBS 5587 (NRRL Y-7123), from an infected nail.

Comments: Results from the present study are in agreement with previous work (Yarrow 1965, Kreger-van Rij 1970c) except that growth on inulin was found to be positive for some strains. Yarrow (personal communication) identified the type strain of *P. xylopsoci* as *P. onychis*. Unfortunately, the culture was lost.

42.63. *Pichia opuntiae* Starmer, Phaff, Miranda, M.W. Miller & Barker (1979)

Growth on 5% malt extract agar: After 3 days at 25°C, the cells are ovoidal to ellipsoidal, (1.5–4.5) × (2.5–7.5) μm, and occur singly, in pairs or in short chains. Growth is butyrous and tannish-white.

Growth on the surface of assimilation media: Thin rings and incomplete pellicles are formed.

Dalmou plate culture on morphology agar: After 7 days at 25°C, growth under the coverglass shows infrequent rudimentary pseudohyphae but no true hyphae. Aerobic growth is light tannish-white, smooth, glistening, butyrous, and low convex with entire to finely lobed margins. A faintly acidic odor is present.

Formation of ascospores: This species is heterothallic and haploid mating types are usually isolated from nature, but occasionally diploids are found. The ascospores, which are hat-shaped, usually form in diploid cells that bud from zygotes following mixture of complementary

mating types. There are commonly two ascospores per deliquescent ascus, but occasionally four are produced.

Ascospores were observed on YM agar at 25°C within 5–7 days following mixture of complementary mating types.

Fermentation: absent.

Assimilation:

Glucose	+	<i>N</i> -Acetyl-D-glucosamine	–
Galactose	–	Methanol	–
L-Sorbose	–	Ethanol	+
Sucrose	–	Glycerol	+
Maltose	–	Erythritol	–

D-Ribose	–	Hexadecane	–
L-Rhamnose	s	Nitrate	–
D-Glucosamine	–	Vitamin-free	–

Additional assimilation tests and other growth characteristics:

2-Keto-D-gluconate	–	Starch formation	–
5-Keto-D-gluconate	–	Gelatin liquefaction	–
Saccharate	–	Growth at 37°C	–
10% NaCl/5% glucose	–		

Co-Q: 7, CBS 7010 (Billon-Grand 1985).

Mol% G+C: 32.9–33.4, CBS 7010 and 5 additional strains (BD: Holzschu et al. 1985).

Origin of the strains studied: CBS 7010 (UCD-FST 77-40, NRRL Y-11707) and CBS 7011 (UCD-FST 77-42, NRRL Y-11708), both from rotted prickly pear cactus (*Opuntia inermis*), Yarrowonga, Australia.

Complementary mating types: CBS 7010 (*h*⁺) and CBS 7011 (*h*[–]).

Type strain: CBS 7010.

Comments: Results from the current study are in good agreement with the original description. The relationship of *P. opuntiae* with other cactophilic yeasts is discussed in the treatments of *P. antillensis* and *P. thermotolerans*. Separation of *P. opuntiae* from *P. antillensis* is unreliable when using results from standard assimilation tests, but it differs from *P. antillensis* by being killer negative. At present, *P. opuntiae* is known only from *Opuntia* cacti in Australia whereas *P. antillensis* appears restricted to columnar cacti of the West Indies.

42.64. *Pichia pastoris* (Guilliermond) Phaff (1956)

Synonyms:

Zygosaccharomyces pastori Guilliermond (1919)

Saccharomyces pastori (Guilliermond) Lodder & Kreger-van Rij (1952)

Petasospora pastori (Guilliermond) Boidin & Abadie (1954)

Zygowillia pastori (Guilliermond) Kudryavtsev (1960)

Zymopichia pastori (Guilliermond) Novák & Zsolt (1961)

Komagataella pastoris (Guilliermond) Y. Yamada, Matsuda, Maeda & Mikata (1995)

Growth on 5% malt extract agar: After 3 days at 25°C, the cells are spheroidal to ovoidal, (2.0–4.0) × (2.2–5.8) μm, and occur singly or in pairs. Growth is cream-colored, dull to faintly glistening and butyrous.

Growth on the surface of assimilation media: Pellicles are not formed.

Dalmat plate culture on morphology agar: After 7 days at 25°C, growth under the coverglass shows neither pseudohyphae nor true hyphae. Aerobic growth is white, dull to faintly glistening and butyrous. Margins may be finely serrate or lobed.

Formation of ascospores: Asci may be unconjugated or show conjugation between parent cell and bud or between independent cells. One to four hat-shaped ascospores are formed in each ascus and they are soon liberated (Fig. 147). Single-spore isolates from four-spored asci are ascosporegenous, indicating this species to be homothallic.

Ascospores were observed on 5% malt extract, V8 and acetate agars after 10–20 days at 25°C.

Fermentation:

Glucose	+	Lactose	–
Galactose	–	Raffinose	–

Co-Q: 8, CBS 704, IFO 948, IFO 1013 (Yamada et al. (1973a).

Mol% G+C: 40.2, 41.0, IFO 1013, CBS 704 (*T*_m: Nakase and Komagata 1970b); 42.8, CBS 704 (BD: Kurtzman, unpublished).

Fig. 147. *P. pastoris*, CBS 704. Ascosporengous culture after 8 days, 25°C, on V8 agar. Bar = 5 µm.

Origin of the strains studied: Exudate of a chestnut tree (*Castanea* sp.), France (1); slime flux on oak (*Quercus kelloggii*), U.S.A. (1).

Type strain: CBS 704 (NRRL Y-1603), from a chestnut tree.

Comments: *P. pastoris* has become of considerable interest to biotechnologists because its gene expression system has been developed to produce large amounts of medically and industrially important proteins (Cregg et al. 1993). Two aspects of the species have contributed to its utility. First, fermentation techniques were developed for maintaining extremely high cell densities in excess of 100 g/l dry weight. Secondly, because *P. pastoris* assimilates methanol, the expression system is linked with alcohol oxidase which is abundantly produced in the presence of methanol.

42.65. *Pichia petersonii* (Wickerham) Kurtzman (1984a)

Synonym:

Hansenula petersonii Wickerham (1964b)

Growth on 5% malt extract agar: After 3 days at 25°C, the cells are ellipsoidal to elongate, (1.2–4.1) × (2.8–7.1) µm, and occur singly or in pairs. Growth is butyrous and light tan in color.

Growth on the surface of assimilation media: Smooth, mat pellicles and rings develop on certain media.

Dalmat plate culture on morphology agar: After 7 days at 25°C, abundant, highly branched pseudohyphae are formed under the coverglass. True hyphae are also produced by the mat oxidative forms of this species, but not by the smooth glistening types, such as NRRL YB-3807. Aerobic growth is light tan, smooth, dull to glistening, and butyrous. Margins of single colonies may be entire or lobed and surrounded by hyphal outgrowth.

Formation of ascospores: Vegetative cells directly convert to asci without prior conjugation. Asci form one to four hat-shaped ascospores which are freed

through deliquescence of the ascus. Both heat-treated sporogenous cultures and single-spore isolates give rise to sporogenous colonies and the species is presumed to be homothallic. Wickerham (1964b) reported the presence of glistening colony forms, such as NRRL YB-3807, that were asporogenous.

Ascospores were observed on 5% malt extract and YM agars after 5–10 days at 25°C.

Fermentation:

Glucose	+	Lactose	–
Galactose	–	Raffinose	w
Sucrose	+	Trehalose	–
Maltose	–		

Assimilation:

Glucose	+	<i>N</i> -Acetyl-D-glucosamine	–
Galactose	–	Methanol	–
L-Sorbose	–	Ethanol	+
Sucrose	+	Glycerol	+
Maltose	+	Erythritol	+
Cellobiose	+	Ribitol	–
Trehalose	+	Galactitol	–
Lactose	–	D-Mannitol	+
Melibiose	–	D-Glucitol	+
Raffinose	+	α-Methyl-D-glucoside	+
Melezitose	+	Salicin	+
Inulin	–	D-Gluconate	+
Soluble starch	–	DL-Lactate	+
D-Xylose	+	Succinate	+
L-Arabinose	–	Citrate	+
D-Arabinose	–	Inositol	–
D-Ribose	–	Hexadecane	–
L-Rhamnose	+	Nitrate	+
D-Glucosamine	–	Vitamin-free	–

Additional assimilation tests and other growth characteristics:

2-Keto-D-gluconate	–	Starch formation	–
5-Keto-D-gluconate	–	Gelatin liquefaction	–
Saccharate	–	Growth at 37°C	+
10% NaCl/5% glucose	–		

Co-Q: 7, CBS 5555, CBS 5556 (Yamada et al. 1973a).

Mol% G+C: 43.9, 44.1, CBS 5556, CBS 5555 (T_m : Nakase and Komagata 1971b); 44.9, CBS 5555 (BD: Kurtzman et al. 1979).

Origin of the strains studied: Human cadavers preserved with embalming fluid (2).

Type strain: CBS 5555 (NRRL YB-3808).

Comments: Wickerham (1964b, 1970a) discussed the similarities of *P. petersonii*, *P. jadinii* and *C. utilis* and suggested that their primary habitat may be warm-blooded animals. All three species are resistant to toxic chemicals, especially embalming fluid, and van der Walt and Johannsen (1975b) observed a similar chemotolerance for *P. lynferdii*. As noted earlier, Kurtzman et al. (1979) demonstrated through nDNA reassociation studies that *P. jadinii* and *C. utilis* are conspecific whereas *P. petersonii* is a separate species.

42.66. *Pichia philodendri* (van der Walt & D.B. Scott) Kurtzman (1984a)

Synonyms:

Hansenula philodendri (as *H. philodendra*) van der Walt & D.B. Scott (Scott & van der Walt 1970b)

Ogataea philodendri (van der Walt & D.B. Scott) Y. Yamada, Maeda & Mikata (1994c)

Growth on 5% malt extract agar: After 3 days at 25°C, the cells are spheroidal to ellipsoidal, (1.8–4.8) × (1.8–6.9) μm, and single, in pairs, or less frequently, in small clusters. Growth is butyrous and tannish-white.

Growth on the surface of assimilation media: Pellicles are not formed.

Dalmu plate culture on morphology agar: After 7 days at 25°C, neither true hyphae nor pseudohyphae are detected under the coverglass. Aerobic growth is white, smooth to finely striated, glistening, and butyrous. Colony margins are usually lobed. A faintly acidic odor is present.

Formation of ascospores: Vegetative cells may convert directly to asci, or more frequently, ascus formation is preceded by conjugation between independent cells. Asci form one to four hat-shaped ascospores, and the spores are released through ascus deliquescence. Single-spore isolates from four-spored asci gave ascosporegenous colonies and the species is presumed to be homothallic (Kurtzman, unpublished).

Ascospores were observed on 5% malt extract, YM, and V8 agars after 3 days at 25°C.

Fermentation: absent.

Co-Q: 7, CBS 6075 (Lee and Komagata 1980a).

Mol% G + C: 44.0, 49.7, CBS 6075 (HPLC: Miller and Bahareen 1979; T_m : Lee and Komagata 1980a).

Origin of the strains studied: Frass from tunnels

of the Bostrichid beetle (*Xylion adustus* Fahr.), which was infesting a moribund fig (*Ficus sycomorus* L.), near St. Lucia, Natal, South Africa (2).

Type strain: CBS 6075 (NRRL Y-7210).

42.67. *Pichia philogaea* van der Walt & E. Johannsen (1975c)

Synonym:

Yamadazyma philogaea (van der Walt & E. Johannsen) Billon-Grand (1989)

Growth on 5% malt extract agar: After 3 days at 25°C, the cells are spheroidal, ellipsoidal or cylindroidal, (2.8–7.5) × (3.0–10.0) μm, and occur singly, in pairs or in short chains. Growth is butyrous and cream-colored.

Growth on the surface of assimilation media: Thin pellicles are formed.

Dalmu plate culture on morphology agar: After 7 days at 25°C, growth under the coverglass shows pseudohyphae to be common but relatively unbranched. True hyphae are not formed. Aerobic growth is tannish-white, glistening and smooth or finely striated. The margin is entire or occasionally lobed. A faintly acid odor is produced.

Formation of ascospores: Ascus formation is preceded by conjugation between a parent cell and a bud. Asci produce one to four hat-shaped ascospores which are released at maturity. Van der Walt and Johannsen (1975c) reported that heat-treated ascosporegenous cultures yielded only sporogenous isolates, and the species appears homothallic.

Ascospores were observed on 5% malt extract and YM agars after 3 days at 25°C.

Fermentation:

Glucose	+	Lactose	–
Galactose	w	Raffinose	–
Sucrose	–	Trehalose	+
Maltose	w/–		

Assimilation:

Glucose	+	<i>N</i> -Acetyl-D-glucosamine	+
Galactose	+	Methanol	–
L-Sorbose	+	Ethanol	+
Sucrose	+	Glycerol	+
Maltose	+	Erythritol	+
Cellobiose	+	Ribitol	+
Trehalose	+	Galactitol	–
Lactose	–	D-Mannitol	+
Melibiose	–	D-Glucitol	+

D-Arabinose	+	Inositol	–
D-Ribose	+	Hexadecane	+
L-Rhamnose	–	Nitrate	–
D-Glucosamine	+	Vitamin-free	–

Additional assimilation tests and other growth characteristics:

2-Keto-D-gluconate	+	Starch formation	–
5-Keto-D-gluconate	–	Gelatin liquefaction	w/–
Saccharate	–	Growth at 37°C	w
10% NaCl/5% glucose	+		

Co-Q: 9, CBS 6696 (Billon-Grand 1985).

Mol% G + C: 42.0, CBS 6696 (T_m : Billon-Grand 1981).

Origin of the strain studied: Grassland soil, South Africa (2).

Type strain: CBS 6696 (NRRL Y-7813).

Comments: The results reported in the original description are generally in agreement with the findings of the present study. Van der Walt and Johannsen (1975c) noted sucrose fermentation to be slow but strong. It was negative in the present tests as was growth on salicin, originally reported as positive. *P. philogaea* shows considerable resemblance to *P. nakazawae* var. *nakazawae*, but differs by its inability to assimilate soluble starch, L-rhamnose and salicin.

42.68. *Pichia pijperi* van der Walt & Tscheuschner (1957a)**Synonym:**

Hanseniaspora pijperi (van der Walt & Tscheuschner) Ditlevsen & Hjort (1964)

Growth on 5% malt extract agar: After 3 days at 25°C, the cells are ovoidal to cylindrical, (3.0–5.8) × (5.0–20.0) μm, and occur singly, in pairs or in short chains. Growth is butyrous and cream-colored.

Growth on the surface of assimilation media: Dry, climbing pellicles are formed.

Dalmau plate culture on morphology agar: After 7 days at 25°C, growth under the coverglass shows poorly to moderately well-developed pseudohyphae but no true hyphae. Aerobic growth is light tan, dull, generally smooth, and with an entire or finely lobed margin. A faint ester-like odor is produced.

Formation of ascospores: Asci are unconjugated and produce one to four hat-shaped ascospores. The spores are readily released at maturity. It is not known whether the species is homothallic or heterothallic.

Ascospores were observed on YM and 5% malt extract agars after 8–10 days at 25°C.

Co-Q: 7, CBS 2887 (Yamada et al. 1973a).

Mol% G + C: 40.7, 42.5, CBS 2887 (T_m : Nakase and Komagata 1970b; BD: Fuson et al. 1980).

Origin of the strains studied: Buttermilk (1); *Drosophila melanogaster* (1).

Type strain: CBS 2887 (NRRL YB-4309), from buttermilk.

Comments: Despite the appearance of bipolar budding by *P. pijperi*, Kreger-van Rij (1970c) reported that bud scars observed under the transmission electron microscope were not the typical multiple scars of *Hanseniaspora*, but were like those seen in other species of *Pichia*.

42.69. *Pichia pini* (Holst) Phaff (1956)**Synonyms:**

Zygosaccharomyces pini Holst (1936)

Petasospora pini (Holst) Boidin & Abadie (1954)

Saccharomyces pini (Holst) Shifrine & Phaff (1956)

Zygowillia pini (Holst) Kudryavtsev (1960)

Ogataea pini (Holst) Y. Yamada, Matsuda, Maeda & Mikata (1995)

Growth on 5% malt extract agar: After 3 days at 25°C, the cells are spheroidal to ovoidal, (1.6–4.2) × (2.2–6.0) μm, and occur singly, in pairs and occasionally in small clusters. Growth is tannish-white, smooth, dull to glistening, and butyrous to somewhat mucoid.

Growth on the surface of assimilation media: Pellicles are not formed.

Dalmau plate culture on morphology agar: After 7 days at 25°C, growth under the coverglass shows either no pseudomycelium or only a few poorly developed

pseudohyphae. True hyphae are not formed. Aerobic growth is tannish-white, smooth to finely striated, dull to glistening, and butyrous. Margins range from entire to lobed. A faint acidic odor is often produced.

Formation of ascospores: Asci may be unconjugated or show conjugation between a parent cell and a bud or between independent cells. Asci contain two to four hat-shaped ascospores which are liberated soon after formation. The presence of conjugation between cells and their buds suggests the species to be homothallic.

Ascospores were observed on 5% malt extract, V8 and corn meal agars after 2–10 days at 25°C.

Co-Q: 7, CBS 744 (Yamada et al. 1973a).

Mol% G + C: 44.4, 43.0, CBS 744 (T_m : Nakase and Komagata 1970b; BD: Fuson et al. 1980).

Origin of the strains studied: From the bark beetle *Dendroctonus brevicomis* (1), *D. pseudosugae* (2), *D. frontalis* (1), larvae of *D. monticolae* (1); Curculionidae larvae (1); *Hylugonotus brunneus* (1); *Araucaria araucana* (1); frass in shortleaf pine (*Pinus echinata*) (1); frass in loblolly pine (*Pinus taeda*) (1); frass from *Pinus* sp. (2); frass from pine (*Pinus contorta*) (4); frass from ponderosa pine (*Pinus ponderosa*) (1); frass from fir (*Abies firma*) (1); bark of a dead birch (*Betula* sp.) (1).

Type strain: CBS 744 (NRRL Y-11528), from *Dendroctonus brevicomis*.

Comments: As noted earlier, *P. pini* and *P. glucozyma* show great phenotypic similarity, and Kreger-van Rij (1964b) reported some strains of *P. pini* to assimilate nitrite. However, Kurtzman (unpublished) found the type strains of the two species to have only 3% rDNA relatedness.

42.70. *Pichia populi* (Phaff, Y. Yamada, Tredick & Miranda) Kurtzman (1984a)

Synonym:

Hansenula populi Phaff, Y. Yamada, Tredick & Miranda (1983)

Growth on 5% malt extract agar: After 3 days at 25°C, the cells are spheroidal, ellipsoidal or occasionally elongate, (1.5–4.1) × (2.1–5.6) μ m, and occur singly, in pairs and in small clusters. Growth is butyrous, semi-glistening and tannish-white.

Growth on the surface of assimilation media: Pellicles are not formed.

Dalmau plate culture on morphology agar: After 7 days at 25°C, growth under the coverglass shows a few outgrowths of pseudohyphae comprised of undifferentiated cells. True hyphae are not formed. Aerobic growth is butyrous, tannish-white, glistening, and low convex with a raised center. Colony margins range from entire to lobed. A faintly acidic odor is present.

Fig. 148. *P. populi*, CBS 8094. Ascospore culture after 2 weeks, 25°C, on 5% malt extract agar. Bar = 5 μ m.

Formation of ascospores: This species is homothallic. Asci may arise from unconjugated cells or form after conjugation between independent cells or after conjugation between a cell and its bud. Asci produce one to four hat-shaped ascospores which are released by ascus deliquescence (Fig. 148).

Ascospores were observed on 5% malt extract agar after 7 days at 25°C.

Fermentation: absent.

Assimilation:

Glucose	+	<i>N</i> -Acetyl-D-glucosamine	-
Galactose	-	Methanol	-
L-Sorbose	-	Ethanol	+
Sucrose	-	Glycerol	+
Maltose	-	Erythritol	-

Co-Q: 7 (Y. Yamada and H.J. Phaff, personal communication).

Mol% G+C: 43.8–44.2, CBS 8094 and 4 additional strains (BD: Phaff et al. 1983).

Origin of the strain studied: CBS 8094 (UCD-FST 68-628C, NRRL Y-12728) was isolated from the slime flux of a cottonwood tree (*Populus trichocarpa*) northwest of Dawson Creek, British Columbia, Canada.

Type strain: CBS 8094.

Comments: Phaff et al. (1983) noted *P. populi* to be phenotypically similar to *P. minuta* var. *nonfermentans* and *P. dryadoides*, but demonstrated no significant nDNA binding with either of these two taxa. Of the five strains of *P. populi* examined, all exhibited high nDNA relatedness except UCD-FST 68-603, which showed 77% complementarity with the type strain.

42.71. *Pichia pseudocactophila* Holzschu, Phaff, Tredick & Hedgecock (1983)

Growth on 5% malt extract agar: After 3 days at 25°C, the cells are spheroidal, ellipsoidal to elongate, (1.6–5.0) × (1.9–6.6) μ m, and single, in pairs and small clusters. Growth is tannish-white, dull-glistening and butyrous.

Growth on the surface of assimilation media: Dull, climbing pellicles are formed.

Dalmau plate culture on morphology agar: After 7 days at 25°C, growth under the coverglass shows a few outgrowths of poorly differentiated pseudohyphae. True hyphae are not formed. Aerobic growth is white to tannish-white, glistening and butyrous with a lobed margin. In profile, colonies are low convex with a depressed center. A faint acidic odor is produced.

Formation of ascospores: This species is heterothallic. Newly isolated strains may be ascosporegenous diploids or haploid mating types. Asci form four hat-shaped ascospores that are liberated soon after formation.

Ascospore formation was observed on YM agar after 5–7 days at 25°C.

Fermentation: absent.

Assimilation:

Glucose	+	<i>N</i> -Acetyl-D-glucosamine	-
Galactose	-	Methanol	-
L-Sorbose	-	Ethanol	+
Sucrose	-	Glycerol	+
Maltose	-	Erythritol	-

Additional assimilation tests and other growth characteristics:

2-Keto-D-gluconate	-	Starch formation	-
5-Keto-D-gluconate	-	Gelatin liquefaction	w/-
Saccharate	-	Growth at 37°C	+
10% NaCl/5% glucose	-		

Co-Q: Not determined.

Mol% G+C: 36.4–36.8, CBS 6929 and 5 additional strains (BD: Holzschu et al. 1983).

Origin of the strain studied: CBS 6929 (UCD-FST 77-427, NRRL Y-10966) was isolated from hecho cactus (*Pachycereus pecten-aboriginum*), Navojoa, Sonora, Mexico.

Complementary mating types: CBS 8095 (UCD-FST 77-427a, NRRL Y-17240) and CBS 8096 (UCD-FST 77-427b, NRRL Y-17723), derived from the type strain.

Type strain: CBS 6929.

Comments: Results from the present study are in good agreement with the original description. Holzschu et al. (1983) reported that most strains of *P. pseudocactophila* do not ferment glucose but a few of the isolates that they tested gave a late and weak fermentation of this sugar.

Strains of *P. pseudocactophila* were initially included among those described as *P. cactophila*. Isolates of *P. pseudocactophila* proved heterothallic and are noted for asci with four ascospores in contrast to the two-spored asci seen for *P. cactophila*. The two species show diminished nDNA relatedness (35%) and quite different allozyme profiles (Holzschu et al. 1983). Although *P. cactophila* is common to many species of cacti, *P. pseudocactophila* is generally recovered only from cardon cactus and its near

relatives. Shen and Lachance (1993) identified a strain of *P. cactophila* by restriction fragment mapping that was initially classified as *P. pseudocactophila* because it produced four-spored asci and was isolated from senita cactus. This report suggests that accurate identification of cactus yeasts will probably require molecular methods.

42.72. *Pichia quercuum* Phaff & Knapp (1956)

Synonym:

Zymopichia quercibus (Phaff & Knapp) Novák & Zsolt (1961)

Growth on 5% malt extract agar: After 3 days at 25°C, the cells are spheroidal to ovoidal, (1.8–5.0) × (2.0–5.0) μm, and occur singly or in pairs. Growth is tannish-yellow, smooth, glistening and butyrous.

Growth on the surface of assimilation media:

Pellicles are not formed.

Dalmay plate culture on morphology agar: After 7 days at 25°C, growth under the coverglass shows very poorly differentiated pseudohyphae and no true hyphae. Aerobic growth is grayish-white, smooth, glistening, and butyrous with an entire to finely lobed margin. A faint acidic odor is present.

Formation of ascospores: Asci are generally conjugated with the pairing between parent cell and bud or between independent cells. One to four hat-shaped ascospores are produced in each ascus, and they are liberated soon after formation. The presence of conjugations between cells and their buds suggests the species is homothallic.

Ascospores were observed on 5% malt extract agar after 3 days at 25°C.

Co-Q: 7, CBS 2283 (Yamada et al. 1973a).

Mol% G + C: 40.0, 42.7, CBS 2283 (T_m : Nakase and Komagata 1970b; BD: Kurtzman, unpublished).

Origin of the strain studied: From a slime flux of oak (*Quercus kelloggii*) (1).

Type strain: CBS 2283 (NRRL YB-4281).

42.73. *Pichia rabaulensis* Soneda & S. Uchida (1971)

Growth on 5% malt extract agar: After 3 days at 25°C, the cells are ovoidal to elongate, (2.0–5.2) × (3.0–9.0) μm, and occur singly, in pairs or occasionally in short chains. Growth is tannish-white, dull and finely wrinkled.

Growth on the surface of assimilation media: Heavy, dry, climbing pellicles are formed.

Dalmay plate culture on morphology agar: After 7 days at 25°C, growth under the coverglass shows abundant well-branched pseudohyphae, but relatively few blastoconidia are produced. True hyphae are not formed. Aerobic growth is tannish-white, dull, and almost powdery, and with fine striations. Margins may be entire, serrate or lobed. A faint ester-like odor is sometimes produced.

Formation of ascospores: Asci are unconjugated and produce one to four hat-shaped spores. The spores are liberated soon after formation. It is not known whether the species is homothallic or heterothallic.

Ascospores were observed on 5% malt extract and YM agars after 3–10 days at 25°C.

Fermentation:

Glucose	+	Lactose	–
Galactose	–	Raffinose	w
Sucrose	+	Trehalose	w
Maltose	–		

Assimilation:

Glucose	+	<i>N</i> -Acetyl-D-glucosamine	–

Additional assimilation tests and other growth characteristics:

2-Keto-D-gluconate	–	Starch formation	–
5-Keto-D-gluconate	–	Gelatin liquefaction	–
Saccharate	–	Growth at 37°C	+
10% NaCl/5% glucose	+		

Co-Q: 7, CBS 6797 (Billon-Grand 1985).

Mol% G+C: 41.4, 44.2, CBS 6797 (T_m : Billon-Grand 1981; BD: Kurtzman, unpublished).

Origin of the strain studied: Feces of an African snail, Rabaul, New Britain, Papua New Guinea (1).

Type strain: CBS 6797 (NRRL Y-7945).

Comments: The present findings are in agreement with the original description of *P. rabaulensis*. Soneda and Uchida (1971) reported growth on galactose to be positive whereas the response to erythritol was variable. In the present study, growth on both of these compounds was negative.

42.74. *Pichia rhodanensis* (C. Ramírez & Boidin) Phaff (1956)**Synonyms:**

Saccharomyces rhodanensis C. Ramírez & Boidin (1953a) (also in C. Ramírez & Boidin 1953b)

Petasospora rhodanensis (C. Ramírez & Boidin) Boidin & Abadie (1954)

Zymopichia rhodanensis (C. Ramírez & Boidin) Novák & Zsolt (1961)

Endomycopsis balearica Socias, C. Ramírez & Genestar (1954a)

Endomycopsis fibuligera (Lindner) Dekker var. *energica* Verona & Zardetto de Toledo (1959a)

Growth on 5% malt extract agar: After 3 days at 25°C, the cells are ovoidal to elongate, (2.6–6.0) × (4.0–10.0) μm, and occur singly, in pairs or in chains. Growth is light tan, dull or glistening, and smooth or wrinkled, depending upon the abundance of pseudohyphae.

Growth on the surface of assimilation media: Pellicles are sometimes present.

Dalmou plate culture on morphology agar: After 7 days at 25°C, growth under the coverglass shows abundant branched pseudohyphae with occasional verticillate clusters of blastoconidia. True hyphae are produced by some strains but not abundantly. Aerobic growth is light tan and may be dull or glistening and butyrous or somewhat tough and wrinkled, depending upon the abundance of hyphae and pseudohyphae. Colony margins are usually entire.

Formation of ascospores: This heterothallic species is frequently isolated from nature in the diploid form, and the unconjugated asci produce one to four hat-shaped ascospores. The spores are liberated soon after formation.

Ascospores were observed on 5% malt extract agar after 10–20 days.

Fermentation:

Glucose	+	Lactose	–
Galactose	–	Raffinose	–

Co-Q: 7, CBS 5518 (Yamada et al. 1973a).

Mol% G+C: 50.2, 51.9, CBS 5518 (T_m : Nakase and Komagata 1970b; BD: Fuson et al. 1980, Kurtzman et al. 1980a).

Origin of the strains studied: Tanning liquor (4); stained leather (1); fermenting canaigre (1); palm nuts (1).

Complementary mating types: NRRL YB-651 sm-14 (CBS 4839) and NRRL Y-7854 Re-1 (CBS 7102).

Type strain: CBS 5518 (NRRL Y-7854), from tanning liquor.

Comments: As noted earlier, *P. rhodanensis* is phenotypically similar to *P. amylophila*, *P. euphorbiae*, *P. mississippiensis*, *P. meyeriae*, *P. wickerhamii* and *P. veronae*, but none of these heterothallic species shows any mating response when paired with *P. rhodanensis*. Furthermore, *P. rhodanensis* shows little DNA relatedness with these other species (Kurtzman et al. 1980a).

42.75. *Pichia salicaria*³ Phaff, M.W. Miller & Spencer (1964)

Growth on 5% malt extract agar: After 3 days at 25°C, the cells are ovoidal, (1.7–4.5) × (2.3–7.2) μm, and occur singly or in pairs. Growth is tannish-yellow, smooth, dull-glistening and butyrous.

Growth on the surface of assimilation media: Heavy, climbing pellicles are formed.

Dalmou plate culture on morphology agar: After 7 days at 25°C, growth under the coverglass has neither

³ The original spelling of the species epithet *salictaria* has been treated as an orthographic error.

Fig. 149. *P. salicaria*, CBS 5456. Ascosporeogenous culture after 3 days, 25°C, on 5% malt extract agar. Bar = 5 µm.

pseudohyphae nor true hyphae. Aerobic growth is tannish-white, smooth, dull-glistening, and butyrous. Margins are generally lobed. A faintly acidic odor is produced.

Formation of ascospores: Asci may be unconjugated or show conjugation between a parent cell and a bud, or between independent cells. One to four hat-shaped spores are formed per ascus and they are quickly liberated (Fig. 149). The presence of conjugation between cells and their buds suggests the species to be homothallic.

Ascospores were observed on 5% malt extract agar after 3 days at 25°C.

Fermentation: absent.

Type strain: CBS 5456 (NRRL Y-6780).

42.76. *Pichia scolyti* (Phaff & Yoneyama) Kreger-van Rij (1964b)

Synonyms:

Endomycopsis scolyti Phaff & Yoneyama (1961)

Yamadazyma scolyti (Phaff & Yoneyama) Billon-Grand (1989)

Growth on 5% malt extract agar: After 3 days at 25°C, the cells are ovoidal to ellipsoidal, (1.2–3.2) × (2.0–7.8) µm, and occur singly, in pairs and in chains. Growth is white to cream-colored, dull to glistening, and frequently finely wrinkled.

Growth on the surface of assimilation media: Rings and, occasionally, thin pellicles may form.

Dalmat plate culture on morphology agar: After 7 days at 25°C, growth under the coverglass shows abundant moderately branched pseudohyphae with occasional dense clusters of blastoconidia. Some blastoconidia have an elongated triangular appearance. True hyphae may also be present. Aerobic growth is white to tannish-white, dull or glistening, frequently finely wrinkled, and occasionally papillate. Margins are irregularly serrate.

Formation of ascospores: This species is heterothallic and usually isolated from nature in the haploid form, although at least one diploid has been recovered as a natural isolate. Many of the haploids show little mating and such pairs form few ascospores. Asci produce one to four hat-shaped ascospores which are liberated soon after formation.

Ascospores were observed on 5% malt extract agar after 2–20 days at 25°C.

Co-Q: 9, CBS 4802 and 3 additional strains (Yamada et al. 1973a).

Mol% G+C: 36.3, 40.1, CBS 4802 (T_m : J.B. Fiol cited by Billon-Grand 1981; BD: Fuson et al. 1980).

Origin of the strains studied: From frass of the bark beetle *Scolytus ventralis* in fir (*Abies concolor*), California (3); frass in Balsam fir (*Abies balsamea*), Ontario, Canada (1); from Douglas fir beetle (*Dendroctonus pseudotsugae*), Washington (2).

Complementary mating types: NRRL Y-5512 (CBS 4802) and NRRL Y-5513 (CBS 4803), from Phaff and Yoneyama (1961); NRRL YB-1403-1 (CBS 5731) and NRRL YB-1403-2 (CBS 5732), isolated by Wickerham from frass obtained in Ontario, Canada. These latter haploids seem to have greater mating competence.

Type strain: CBS 4802 (NRRL Y-5512), from frass of *Scolytus ventralis*.

42.77. *Pichia segobiensis* Santa María & García Aser (1977)**Synonym:**

Yamadazyma segobiensis (Santa María & García Aser) Billon-Grand (1989)

Growth on 5% malt extract agar: After 3 days at 25°C, the cells are spheroidal to ovoidal, (2.0–4.5) × (2.5–6.3) µm, and occur singly and in pairs. Growth is tannish-white, smooth, glistening, and butyrous.

Growth on the surface of assimilation media: Rings and, occasionally, thin pellicles are formed.

Dalmu plate culture on morphology agar: After 7 days at 25°C, growth under the coverglass shows infrequent and poorly differentiated pseudohyphae. True hyphae are not formed. Aerobic growth is light tannish-white, smooth to occasionally slightly papillate, moderately glistening, butyrous, and with an entire to sparingly lobed margin. A faint acidic odor is formed.

Formation of ascospores: Conjugation between a parent cell and a bud or between independent cells may precede ascus formation. One, but usually two hat-shaped ascospores are formed in each ascus, and they are readily liberated. The mode of conjugation suggests the species to be homothallic.

Ascospores were observed on 5% malt extract agar after 3–10 days at 25°C.

10% NaCl/5% glucose	–		

Co-Q: 9, CBS 6857 (Billon-Grand 1985).

Mol% G+C: 41.0, 42.0, CBS 6857 (T_m : Billon-Grand 1981; BD: Kurtzman, unpublished).

Origin of the strains studied: From an adult larva of the insect *Calophora mariana massiliensis* in Scotch pine (*Pinus silvestris*) (1); insect frass in the bark of *P. silvestris* (1); larva of the long-horned beetle *Rhagium inquisitor* (1).

Type strain: CBS 6857 (NRRL Y-11571), from a larva of *Calophora mariana massiliensis*.

Comments: Results from the present study are in good agreement with the original description of *P. segobiensis*. The only difference noted was that Santa María and García Aser (1977) reported growth on D-arabinose to be negative, whereas it was slow but positive in the current examination.

P. segobiensis, *P. stipitis*, *Candida shehatae* and *Pachysolen tannophilus* are of interest to biotechnologists because of their ability to fermentatively produce ethanol from D-xylose, a major pentose in plant biomass (Toivola et al. 1984). With the exception of *P. segobiensis*, the phylogenetic relationships among xylose-fermenting species are discussed under *P. stipitis*. More recently, comparisons of rDNA complementarity have shown ca. 40% relatedness between *P. segobiensis* and *P. stipitis*, demonstrating the two taxa to be sibling species (Kurtzman and Robnett, unpublished).

42.78. *Pichia silvicola* (Wickerham) Kurtzman (1984a)**Synonyms:**

Hansenula silvicola Wickerham (1951)

Endomycopsis muscicola Nakase & Komagata (1966)

Hansenula muscicola (Nakase & Komagata) Yarrow (1972)

Pichia muscicola (Nakase & Komagata) Kurtzman (1984a)

Growth on 5% malt extract agar: After 3 days at 25°C, the cells are ellipsoidal to elongate, (1.0–4.0) × (1.2–9.5) μm and occur singly, in pairs, or in small clusters. Growth is butyrous to mycelial and tannish-white in color.

Growth on the surface of assimilation media: Exceptionally thin pellicles are formed by some isolates and thin rings may be produced.

Dalmou plate culture on morphology agar: After 7 days at 25°C, growth under the coverglass shows abundant and highly branched pseudohyphae. True hyphae are occasionally detected. Aerobic growth is white to tannish-white, smooth, glistening or dull, and butyrous. Colony margins are entire or occasionally lobed and may show hyphal outgrowths. An ester-like odor is usually present.

Formation of ascospores: Asci may be unconjugated or show conjugation between parent and bud, or between independent cells. Asci form one to four hat-shaped ascospores that are freed when the ascus deliquesces (Fig. 150). Single-spore isolates obtained from four-spored asci of the type strain formed ascosporegenous colonies, and the species is presumed to be homothallic (Kurtzman, unpublished).

Ascospores were observed on 5% malt extract agar after 5–20 days at 25°C.

Fermentation:

Glucose	+	Lactose	–
Galactose	+/w	Raffinose	–

Co-Q: 7, CBS 1705, CBS 5800, and 3 additional strains (Yamada et al. 1973a).

Mol% G + C: 34.1–35.1, CBS 1705 and 3 additional strains (T_m : Nakase and Komagata 1971b); 36.5, CBS 1705 (BD: Kurtzman, unpublished).

Fig. 150. *P. silvicola*, CBS 1705. Ascosporegenous culture after 8 days, 25°C, on 5% malt extract agar. Bar = 5 μm.

Origin of the strains studied: Gums from wild black cherry trees (*Prunus serotina* Ehrh.), Peoria, Illinois, U.S.A. (3); gums from wild pin cherry trees (*Prunus pensylvanica* Linn.), Wisconsin and Vermont, U.S.A. (4); the type strain of *P. muscicola* (CBS 5800, NRRL Y-7005) and two additional strains of this taxon, from moss, Tottori Prefecture, Japan.

Type strain: CBS 1705 (NRRL Y-1678), isolated from gum of *P. serotina*, Peoria, Illinois.

Comments: In a comparison of sequences from the 5'-end of large subunit rRNAs, Kurtzman and Robnett (manuscript in preparation) noticed that *P. silvicola* and *P. muscicola* differed by just one nucleotide in this variable region. On the basis of earlier work, this result indicates that *P. muscicola* and *P. silvicola* are conspecific.

42.79. *Pichia spartinae* Ahearn, Yarrow & Meyers (1970)

Synonym:

Yamadazyma spartinae (Ahearn, Yarrow & Meyers) Billon-Grand (1989)

Growth on 5% malt extract agar: After 3 days at 25°C, the cells are spheroidal to ellipsoidal, (2.5–5.3) × (3.3–6.5) μm, and occur singly, in pairs or occasionally in short chains. Growth is butyrous and tannish-white in color.

Growth on the surface of assimilation media: Thin rings are formed and occasionally pellicles are present.

Dalmou plate culture on morphology agar: After 7 days at 25°C, growth under the coverglass shows only occasional pseudohyphae, but these are moderately branched and may bear blastoconidia. True hyphae are not formed. Aerobic growth is light tan, smooth, glistening and butyrous. Margins are entire to lobed.

Formation of ascospores: Asci are unconjugated or conjugated if formed from the pairing of complementary mating types. Occasionally one, but usually, two, hat-shaped ascospores form in one of the conjugants while the other remains empty. Asci become deliquescent at maturity. The type strain, NRRL Y-7322 (CBS 6059), is

now asporogenous, but conjugates and sporulates when paired with mating type NRRL Y-7665-3.

Ascospores were observed on 5% malt extract agar after 5–7 days at 25°C.

Fermentation:

Glucose	+	Lactose	–
Galactose	–	Raffinose	–

Additional assimilation tests and other growth characteristics:

2-Keto-D-gluconate	+	Starch formation	–
5-Keto-D-gluconate	–	Gelatin liquefaction	–
Saccharate	–	Growth at 37°C	+
10% NaCl/5% glucose	+		

Co-Q: 9 (Billon-Grand 1989).

Mol% G+C: 38.0, 41.1, CBS 6059 (T_m : Billon-Grand 1981; BD: Kurtzman, unpublished).

Origin of the strains studied: From oyster grass (*Spartina alterniflora* Loisel) marshes, Barataria Bay, Louisiana, U.S.A. (7).

Complementary mating types: NRRL Y-7665-1 (CBS 6666) and NRRL Y-7665-3 (CBS 6669).

Type strain: CBS 6059 (NRRL Y-7322).

Comments: In the original description, ascospores of *P. spartinae* were reported to be spheroidal or infrequently oval with a slight ledge (Ahearn et al. 1970). Later, Kurtzman and Ahearn (1976) showed a high incidence of malformed spores among strains of *P. spartinae*, and that mature spores were hat-shaped rather than spheroidal.

Pichia spartinae is phenotypically similar to several other heterothallic species of *Pichia* and to certain species of *Candida*. However, there was no mating response between *P. spartinae* and *P. angophorae*, *P. rhodanensis*, *P. wickerhamii*, *P. veronae*, *Candida freyschussii*, *C. maritima*, *C. obtusa*, or *C. oregonensis* (Kurtzman and Ahearn 1976).

42.80. *Pichia stipitis* Pignal (1967)

Synonym:

Yamadazyma stipitis (Pignal) Billon-Grand (1989)

Growth on 5% malt extract agar: After 3 days at 25°C, the cells are spheroidal to ovoidal, (2.2–4.5) × (2.5–6.0) μ m, and occur singly or in pairs. Growth is cream-colored, dull-glistening, smooth to faintly wrinkled and butyrous.

Growth on the surface of assimilation media: Rings and incomplete pellicles may form.

Dalmat plate culture on morphology agar: After 7 days at 25°C, growth under the coverglass shows abundant and well-branched pseudohyphae with occasional blastoconidia. True hyphae are not formed. Aerobic growth is light tan, smooth to finely wrinkled, dull-glistening, butyrous, and with an entire to lobed margin. A faintly acidic odor is often present.

Formation of ascospores: Preceding ascus formation, there may be conjugation between a parent cell and a bud or between independent cells, or the ascus may be unconjugated but with a protuberance. Ascus produce two hat-shaped ascospores that are released soon after formation (Fig. 151). Single-spore isolates produce ascosporegonous colonies, but because only two ascospores are formed in each ascus, it is not certain whether meiosis has occurred (Kurtzman 1990b). The presence of parent cell–bud conjugation suggests the species is homothallic.

Ascospores were observed on 5% malt extract agar after 3–5 days at 25°C.

Fig. 151. *P. stipitis*, CBS 5773. Ascosporegonous culture after 1 week, 25°C, on 5% malt extract agar. Bar = 5 μ m.

Fermentation:

Glucose	+	Lactose	–
Galactose	w	Raffinose	–

2-Keto-D-gluconate	+	Starch formation	-
5-Keto-D-gluconate	-	Gelatin liquefaction	-
Saccharate	-	Growth at 37°C	v
10% NaCl/5% glucose	v		

Co-Q: 9, CBS 5773 (Billon-Grand 1989).

Mol% G+C: 42.6, CBS 5773 (BD: Miranda et al. 1982); 43.2–43.6, CBS 5773 and 4 additional strains (BD: Kurtzman 1990b).

Origin of the strains studied: From larvae of the insects *Cetonia* sp., *Dorcus parallelipipedus* and *Laphria* (4); from J. Santa María (1).

Type strain: CBS 5773 (NRRL Y-7124), from insect larvae.

Comments: *P. stipitis*, *P. segobiensis*, *Candida shehatae* and *Pachysolen tannophilus* are of industrial interest because they ferment D-xylose to ethanol. On the basis of phenotypic similarity, Kreger-van Rij (1970c) suggested that *P. stipitis* and *C. shehatae* may represent teleomorphic and anamorphic states of the same species. Vaughan-Martini (1984), however, found that there was little nDNA relatedness between type strains of the two taxa. Kurtzman (1990b) showed from rRNA sequence comparisons that *P. stipitis* and *C. shehatae* are closely related but separate species. In contrast, *P. tannophilus* is more distantly related.

42.81. *Pichia strasburgensis* (C. Ramírez & Boidin) Phaff (1956)**Synonyms:**

Saccharomyces strasburgensis C. Ramírez & Boidin (1953a) (also in C. Ramírez & Boidin 1953b)

Petasospora strasburgensis (C. Ramírez & Boidin) Boidin & Abadie (1954)

Zymopichia strasburgensis (C. Ramírez & Boidin) Novák & Zsolt (1961)

Growth on 5% malt extract agar: After 3 days at 25°C, the cells are ovoidal to ellipsoidal, (1.5–4.5) × (2.9–14.0) μ m, and occur singly or in pairs. Growth is cream-colored, smooth, faintly glistening and butyrous.

Growth on the surface of assimilation media:

Pellicles are not formed.

Dalmat plate culture on morphology agar: After 7 days at 25°C, growth under the coverglass shows pseudohyphae but no true hyphae. Some strains produce only occasional, sparingly branched pseudohyphae while others form considerable pseudomycelium that may be well-branched and bear clusters of blastoconidia. Aerobic growth is pale tannish-white, smooth to finely wrinkled, dull-glistening and butyrous. Margins may be serrate or lobed. A faint ester-like odor is often present.

Formation of ascospores: Asci form without prior conjugation and contain one to four hat-shaped ascospores which are readily liberated. Kreger-van Rij (1964b) reported this species to be heterothallic.

Ascospores were observed on 5% malt extract agar after 3 days at 25°C.

Fermentation:

Glucose	+	Lactose	-
Galactose	+/w	Raffinose	w
Sucrose	+	Trehalose	-

Co-Q: 7, CBS 2939 (Yamada et al. 1973a).

Mol% G+C: 40.2, 40.6, CBS 2039 (T_m : Nakase and Komagata 1970b; BD: Fuson et al. 1980).

Origin of the strains studied: Stained leather, from Ramírez (2) and from Boidin (1).

Complementary mating types: CBS 2039 (NRRL Y-11980) and CBS 5005 (NRRL Y-11981).

Type strain: CBS 2939 (NRRL Y-2383), from stained leather.

42.82. *Pichia subpelliculosa* Kurtzman (1984a)**Synonyms:***Hansenula subpelliculosa* Bedford (1942) nom. nud.*Endomycopsis subpelliculosa* (Bedford) Novák & Zsolt (1961) nom. nud.*Hansenula anomala* (E.C. Hansen) H. & P. Sydow var. *subpelliculosa* K. Kodama, Kyono & S. Kodama (1957) nom. nud.*Hansenula subpelliculosa* Bedford ex J.A. Barnett, Payne & Yarrow (1983)*Pseudohansenula peiping* Mogi (1942) nom. nud.*Hansenula arabitolgenes* Fang nom. nud.? (Chang et al. 1963)

Growth on 5% malt extract agar: After 3 days at 25°C, the cells are ellipsoidal, (1.9–5.1) × (3.4–9.2) μm, and occur singly or in pairs. Growth is white to tannish-white and butyrous.

Growth on the surface of assimilation media: Thin pellicles are occasionally formed.

Dalmau plate culture on morphology agar: After 7 days at 25°C, growth under the coverglass usually shows abundant and highly branched pseudohyphae, although some strains fail to produce any pseudohyphae. True hyphae are formed, but they are not common. Aerobic growth is white to tannish-white, smooth, glistening, and butyrous. Colony margins are usually lobed and devoid of pseudohyphal outgrowths. A faint, pleasant odor may be detected.

Formation of ascospores: Asci are unconjugated and form one to four hat-shaped ascospores. The asci become deliquescent at maturity. Wickerham and Burton (1954a) demonstrated this species to be heterothallic by heat-treatment of sporogenous cultures.

Ascospores were observed on 5% malt extract and V8 agars after 5–10 days at 25°C.

Fermentation:

2-Keto-D-gluconate	–	Starch formation	–
5-Keto-D-gluconate	–	Gelatin liquefaction	w/–
Saccharate	–	Growth at 37°C	v
10% NaCl/5% glucose	+		

Co-Q: 7, CBS 5767 and 3 additional strains (Yamada et al. 1973a).

Mol% G + C: 33.4–33.9, AJ 5343, AJ 5344, AJ 5345 (T_m : Nakase and Komagata 1971b); 34.0, CBS 5767 (BD: Kurtzman, unpublished).

Origin of the strains studied: Bedford's strains from sugar-egg concentrate (1), syrup (1), grape juice (1), and dried prunes (1); Etchell's strains from fermenting cucumbers and from brined unshelled peas and green beans (27); soy sauce manufacturing, China (1); miso (1); NRRL YB-3328, *Pseudohansenula peiping*; CBS 7164 (NRRL Y-17244), *Hansenula arabitolgenes*.

Complementary mating types: NRRL Y-1683-11 (CBS 1997) and NRRL Y-1822-12 (CBS 1996).

Type strain: CBS 5767 (NRRL Y-1683), from fermenting cucumbers.

Comments: *Hansenula subpelliculosa* was described by Bedford (1942) without benefit of a Latin diagnosis or the designation of a type strain. In the transfer of hat-spored species of *Hansenula* to *Pichia*, Kurtzman (1984a) provided the requisite Latin description and designated as type strain an isolate from fermenting cucumber brines that Wickerham (1951) found to be typical of the species. Barnett et al. (1983) also provided a Latin description of this species, but their validation was for *Hansenula subpelliculosa* and would require further emendation if it were to be used.

P. subpelliculosa, *P. anomala* and *P. fabianii* are quite similar when compared by the standard tests. *P. anomala* is separated from the other two species by growth in vitamin-free medium, and *P. subpelliculosa* is separated from *P. fabianii* by ability to assimilate erythritol. Wickerham and Burton (1954a) indicated that these three heterothallic taxa do not interbreed.

Kurtzman and Robnett (manuscript in preparation) compared the 5'-end sequences of large subunit rRNAs for all known species of *Pichia*. *P. subpelliculosa* and *Hansenula arabitolgenes* have identical sequences suggesting that they are conspecific. *H. arabitolgenes* appears to have been published without a Latin description.

42.83. *Pichia sydowiorum* (D.B. Scott & van der Walt) Kurtzman (1984a)

Anamorph: *Candida nitrativorans* van der Walt, D.B. Scott & van der Klift

Synonyms:*Hansenula sydowiorum* D.B. Scott & van der Walt (1970a)*Candida nitrativorans* van der Walt, D.B. Scott & van der Klift (1972)

Growth on 5% malt extract agar: After 3 days at 25°C, the cells are spheroidal to ellipsoidal, (1.8–5.3) × (2.7–7.8) μm, and occur singly or in pairs. Growth is butyrous and light tannish-white in color.

Growth on the surface of assimilation media: Pellicles form and are smooth and waxy.

Dalmou plate culture on morphology agar: After 7 days at 25°C, growth under the coverglass shows abundant and well-branched pseudohyphae. True hyphae are not produced. Aerobic growth is white, smooth, dull to moderately glistening, and butyrous. Colony margins are generally lobed.

Formation of ascospores: Asci are unconjugated. Scott and van der Walt (1970a) reported vegetative cells to first become lipid-rich and thick-walled, and following a dormant period, an outer membrane is shed to form the ascus. One to four hat-shaped ascospores are formed per ascus, and asci are deliquescent. Heat-treatment of sporogenous cultures gave only sporogenous colonies, and the species is presumed to be homothallic (Scott and van der Walt 1970a).

Ascospores were observed on YM and 5% malt extract agars after 10 days at 15°C.

D-Ribose	+	Hexadecane	–
L-Rhamnose	+	Nitrate	+
D-Glucosamine	–	Vitamin-free	+

Additional assimilation tests and other growth characteristics:

2-Keto-D-gluconate	–	Starch formation	–
5-Keto-D-gluconate	–	Gelatin liquefaction	w/–
Saccharate	–	Growth at 37°C	–

10% NaCl/5% glucose +

Co-Q: Not determined.

Mol% G + C: 36.2, CBS 5995 (HPLC: Miller and Baharaeen 1979).

Origin of the strains studied: Frass from tunnels of the Bostrichid beetle (*Sinonylon ruficorne* Fahr.), infesting *Combretum apiculatum* Sond. (3); frass from tunnels in *Mimusops caffra* (1), all from South Africa.

Type strain: CBS 5995 (NRRL Y-7130), from tunnels in *S. ruficorne*.

Comments: *P. sydowiorum* is similar to *P. ciferrii* and *P. anomala* but the three species can be separated by their assimilation reactions on L-rhamnose and melibiose.

As noted earlier, *P. ciferrii* forms crystals of tetraacetyl-phytosphingosine whereas *P. sydowiorum* synthesizes 2-D-hydroxyhexadecanoic acid (Vesonder et al. 1970). Crystalline compounds have not been observed in cultures of *P. anomala*.

In contrast to the original description which reported the assimilation of soluble starch and D-xylose to be positive, two of the four strains of *P. sydowiorum* examined in the present study gave negative reactions on these compounds. In addition, two of the strains failed to ferment maltose.

42.84. *Pichia tannicola* F.H. Jacob (1969a)

Synonym:

Pichia abadieae F.H. Jacob (1969b)

Growth on 5% malt extract agar: After 3 days at 25°C, the cells are spheroidal to ellipsoidal, (1.2–4.1) × (2.0–5.4) μ m, and occur singly or in pairs. Growth is butyrous and tannish-white in color.

Growth on the surface of assimilation media: Thin climbing pellicles are formed.

Dalmou plate culture on morphology agar: After 7 days at 25°C, growth under the coverglass shows occasional, sparingly branched pseudohyphae, but no true hyphae. Aerobic growth is light tannish-white in color, smooth, glistening and butyrous with a finely serrate margin.

Formation of ascospores: Ascospores were not observed in the present study. Jacob (1969a,b) reported the asci, which became deliquescent, to produce one to four subspheroidal ascospores devoid of surface ornamentation. Asci were unconjugated or showed conjugation between a cell and its bud.

Ascospores were observed on sterilized carrot slices (Jacob 1969a,b).

Fermentation:

Glucose	+/w	Lactose	–
Galactose	ws	Raffinose	–
Sucrose	–	Trehalose	+/w
Maltose	–		

Assimilation:

Glucose	+	<i>N</i> -Acetyl-D-glucosamine	+
Galactose	+	Methanol	–
L-Sorbose	–	Ethanol	+
Sucrose	–	Glycerol	+
Maltose	–	Erythritol	w/–
Cellobiose	–	Ribitol	+
Trehalose	+	Galactitol	s
Lactose	v	D-Mannitol	s
Melibiose	+	D-Glucitol	+

2-Keto-D-gluconate	–	Starch formation	–
5-Keto-D-gluconate	–	Gelatin liquefaction	–
Saccharate	–	Growth at 37°C	–
10% NaCl/5% glucose	–		

Co-Q: Not determined.

Mol% G+C: 40.7, CBS 6065 (T_m : J.B. Fiol cited by Billon-Grand 1981); 46.0, 43.0, CBS 6067 (T_m : Fiol and Billon-Grand 1981; BD: Kurtzman, unpublished).

Origin of the strains studied: CBS 6067 (NRRL Y-7499), type strain, *P. abadieae*; CBS 6065 (NRRL Y-17392), type strain, *P. tannicola*; both from tanning fluid, France.

Type strain: CBS 6065.

Comments: *P. abadieae* and *P. tannicola* were separated from one another because of differences in their assimilation of lactose, erythritol, D-gluconate and inositol. However, Kurtzman and Robnett (unpublished) determined that type strains of the two species showed 100% nDNA complementarity. Because of taxonomic priority, *P. abadieae* is a synonym of *P. tannicola*.

42.85. *Pichia thermotolerans* (Starmer, Phaff, Miranda, M.W. Miller & Barker) Holzschu, Phaff, Tredick & Hedgecock (1985)

Synonym:

Pichia opuntiae Starmer, Phaff, Miranda, M.W. Miller & Barker var. *thermotolerans* Starmer, Phaff, Miranda, M.W. Miller & Barker (1979)

Growth on 5% malt extract agar: After 3 days at 25°C, the cells are ovoidal to ellipsoidal, (1.5–4.5) × (2.5–7.5) μm, and occur singly, in pairs or in short chains. Growth is butyrous and tannish-white in color.

Growth on the surface of assimilation media: Thin rings and incomplete pellicles are formed.

Dalmau plate culture on morphology agar: After 7 days at 25°C, growth under the coverglass shows infrequent rudimentary pseudohyphae but no true hyphae. Aerobic growth is light tannish-white, smooth, glistening, butyrous, and low convex with entire to finely lobed margins. A faintly acidic odor is present.

Formation of ascospores: This species is heterothallic, and the majority of strains isolated from nature are asporogenous haploids. Following the pairing of complementary mating types, zygotes usually bud diploid cells which become asci. Each ascus contains two to four hat-shaped ascospores which are liberated soon after formation. Ascospores were not seen in the present study, and Starmer et al. (1979) commented that formation of asci is extremely rare.

Fermentation: absent.

Assimilation:

Glucose	+	<i>N</i> -Acetyl-D-glucosamine	–
Galactose	–	Methanol	–
L-Sorbose	–	Ethanol	+
Sucrose	–	Glycerol	+
Maltose	–	Erythritol	–
Cellobiose	+	Ribitol	–
Trehalose	–	Galactitol	–
Lactose	–	D-Mannitol	+
Melibiose	–	D-Glucitol	v
Raffinose	–	α-Methyl-D-glucoside	–
Melezitose	–	Salicin	+
Inulin	–	D-Gluconate	–
Soluble starch	–	DL-Lactate	+
D-Xylose	–	Succinate	+
L-Arabinose	–	Citrate	–
D-Arabinose	–	Inositol	–
D-Ribose	–	Hexadecane	–
L-Rhamnose	v	Nitrate	–
D-Glucosamine	–	Vitamin-free	–

Additional assimilation tests and other growth characteristics:

2-Keto-D-gluconate	–	Starch formation	–
5-Keto-D-gluconate	–	Gelatin liquefaction	–
Saccharate	–	Growth at 37°C	+
10% NaCl/5% glucose	–		

Co-Q: Not determined.

Mol% G+C: 32.8–33.0, CBS 7012 and 5 additional strains (BD: Holzschu et al. 1985).

Origin of the strains studied: CBS 7012 (UCD-FST 76-211, NRRL Y-11709), from senita cactus (*Lophocereus schottii*), Rancho Cuñaño, Baja California Sur, Mexico; CBS 7013 (UCD-FST 76-385B, NRRL Y-11710), from soil under cardon cactus (*Pachycereus pringlei*), Mulegé, Baja California Sur, Mexico.

Complementary mating types: CBS 7012 (h^+) and CBS 7013 (h^-).

Type strain: CBS 7012.

Comments: *P. thermotolerans* was initially described as a variety of *P. opuntiae* because some mating was shown between the two taxa (Starmer et al. 1979). Holzschu et al. (1985) reexamined the relationship, noting that intervarietal matings produced only a few ascospores of unknown viability, that the varieties averaged 28% nDNA complementarity, and that allozyme patterns suggested the two varieties to be genetically isolated. From these data, the variety *thermotolerans* was elevated to species status.

P. antillensis is closely related to *P. opuntiae* and *P. thermotolerans*, showing 50% and 26% nDNA complementarity, respectively, to the two species (Starmer et al. 1984). However, *P. antillensis* exhibited no mating response when paired with either *P. opuntiae* or *P. thermotolerans*. Lachance et al. (1988) and Starmer et al. (1990) reviewed the genetics and biogeography of the cactus yeasts.

42.86. *Pichia toletana* (Socias, C. Ramírez & Peláez) Kreger-van Rij (1964b)

Synonyms:

Debaryomyces toletanus Socias, C. Ramírez & Peláez (1954b)

Zymodebaryomyces toletanus (Socias, C. Ramírez & Peláez) Novák & Zsolt (1961)

Growth on 5% malt extract agar: After 3 days at 25°C, the cells are ovoidal, (1.5–5.0)×(3.0–9.7) μm, and occur singly and in pairs. Growth is yellowish-white, smooth to wrinkled and dull-glistening.

Growth on the surface of assimilation media: Thin pellicles are formed by some strains.

Dalmau plate culture on morphology agar: After 7 days at 25°C, growth under the coverglass shows abundant, branched pseudohyphae with blastoconidia in a verticillate arrangement. True hyphae are not formed. Aerobic growth is tannish-white, smooth to wrinkled, dull-glistening and butyrous. Margins are usually lobed.

Formation of ascospores: Conjugation of a parent cell and a bud usually precedes ascus formation. Asci contain one to four hat-shaped ascospores which may be quickly or slowly liberated. Single-spore isolates from four-spored asci are sporogenous, indicating the species to be homothallic.

Ascospores were observed on 5% malt extract agar after 2–7 days at 25°C.

Fermentation:

Additional assimilation tests and other growth characteristics:

2-Keto-D-gluconate	–	Starch formation	–
5-Keto-D-gluconate	–	Gelatin liquefaction	–
Saccharate	–	Growth at 37°C	–
10% NaCl/5% glucose	–		

Co-Q: 7, CBS 2504 (Yamada et al. 1973a).

Mol% G + C: 39.3, 39.6, CBS 2504 (T_m : Nakase and Komagata 1970b; BD: Kurtzman 1987a).

Origin of the strains studied: Tanning fluid (1); *Drosophila miranda* (1); frass of dead pine (*Pinus* sp.) (1); diseased fir (*Abies nobilis*) (1).

Type strain: CBS 2504 (NRRL YB-4247), from tanning fluid.

42.87. *Pichia trehalophila* Phaff, M.W. Miller & Spencer (1964)

Growth on 5% malt extract agar: After 3 days at 25°C, the cells are spheroidal to ellipsoidal, (2.1–6.8)×(3.5–7.5) μm, and occur singly and in pairs. Growth is tannish-yellow, smooth, glistening and butyrous.

Growth on the surface of assimilation media: Pellicles are not formed.

Dalmau plate culture on morphology agar: After 7 days at 25°C, growth under the coverglass shows neither pseudohyphae nor true hyphae. Aerobic growth is tannish-white, smooth, glistening and butyrous. Margins are entire.

Formation of ascospores: Ascus formation may be preceded by conjugation between a parent cell and a bud or between independent cells. Cells with protuberances are also found in sporulating cultures. Two to four hat-shaped ascospores are formed per ascus and they are quickly liberated. The presence of conjugation between cells and their buds suggests that the species is homothallic.

Ascospores were observed on 5% malt extract and YM agars after 7–10 days at 25°C.

Fermentation:

Glucose	+	Lactose	–
Galactose	–	Raffinose	–
Sucrose	–	Trehalose	v

Co-Q: 7, CBS 5361 (Yamada et al. 1973a).

Mol% G + C: 34.6, 37.6, CBS 5361 (T_m : Nakase and Komagata 1970b; BD: Kurtzman, unpublished).

Origin of the strains studied: Slime flux of cottonwood (*Populus trichocarpa*), California (2).

Type strain: CBS 5361 (NRRL Y-6781).

42.88. *Pichia triangularis* M.Th. Smith & Batenburg-van der Vegte (1986a)

Anamorph: *Candida polymorpha* Ohara & Nonomura ex M.Th. Smith & Batenburg-van der Vegte

Synonyms:

Candida polymorpha Ohara & Nonomura (1954c) nom. nud.

Candida polymorpha Ohara & Nonomura ex M.Th. Smith & Batenburg-van der Vegte (1986a)

Growth on 5% malt extract agar: After 3 days at 25°C, the cells are ovoidal to ellipsoidal to elongate, (2.1–4.3) × (3.1–9.5) μm, and often with irregular shapes, which most commonly are somewhat triangular or obpyriform. The cells occur singly, in pairs and in small clusters. Growth is butyrous, white to tannish-white, and dull-glistening.

Growth on the surface of assimilation media: Pellicles are not formed.

Dalmou plate culture on morphology agar: After 7 days at 25°C, growth under the coverglass shows only poorly developed pseudohyphae. True hyphae are not formed. Aerobic growth is butyrous, white to tannish-white, dull, and with a finely striated surface that becomes convoluted. Colonies are raised but with a generally flat surface. A faintly acidic odor is produced.

Formation of ascospores: Asci are unconjugated and form one to four hat-shaped ascospores. Asci deliquesce at maturity. It is unknown whether the species is homothallic or heterothallic.

Ascospore formation was observed on 5% malt extract agar and Difco yeast morphology agar after 5–7 days at 25°C.

Fermentation:

Glucose	w/–	Lactose	–
Galactose	–	Raffinose	–
Sucrose	–	Trehalose	–
Maltose	–		

Assimilation:

Glucose	+	<i>N</i> -Acetyl-D-glucosamine	+
Galactose	+	Methanol	–
L-Sorbose	–	Ethanol	+
Sucrose	+	Glycerol	+
Maltose	+	Erythritol	+
Cellobiose	+	Ribitol	+
Trehalose	+	Galactitol	w
Lactose	–	D-Mannitol	+
Melibiose	–	D-Glucitol	+

Co-Q: 9, *Candida polymorpha* (Yamada and Kondo 1972a).

Mol% G + C: 32.4, 36.6, CBS 4094 (*T_m*: Nakase and Komagata 1971f, Meyer and Phaff 1972).

Origin of the strain studied: The isolate of Ohara and Nonomura (1954c), from tamari soya, Japan.

Type strain: CBS 4094 (NRRL Y-5714).

Comments: Results from the present study are in agreement with the description of Smith and Batenburg-van der Vegte (1986a) except that salicin was not assimilated. The unusually shaped vegetative cells of *P. triangularis* are somewhat similar to those of *Candida diddensiae*.

42.89. *Pichia veronae* K. Kodama (Kodama & Kyono 1974b)

Growth on 5% malt extract agar: After 3 days at 25°C, the cells are spheroidal to ellipsoidal, (2.5–6.5) × (4.9–8.0) μm, and occur singly or in pairs. Growth is cream colored, faintly glistening and butyrous.

Growth on the surface of assimilation media: Thin climbing pellicles are present.

Dalmou plate culture on morphology agar: After 7 days at 25°C, growth under the coverglass shows well-branched pseudohyphae with abundant blastoconidia. True hyphae are not formed. Aerobic growth is white, smooth, faintly glistening and butyrous. Margins may be entire or finely lobed. A faintly acidic odor is produced.

Formation of ascospores: Asci are unconjugated and produce two to four hat-shaped ascospores (Fig. 152). The spores are liberated soon after formation. This species is heterothallic.

Ascospores were observed on 5% malt extract and YM agars after 3–5 days at 25°C.

Fig. 152. *P. veronae*, CBS 6591. Ascospore formation after 3 days, 25°C, on 5% malt extract agar. Bar = 5 μm.

10% NaCl/5% glucose	-		

Co-Q: 7, CBS 6591 (Billon-Grand 1985).

Mol% G+C: 46.6, 49.5, CBS 6591 (T_m : Kodama and Kyono 1974b; BD: Kurtzman 1987a).

Origin of the strain studied: Exudate of the horse chestnut *Aesculus turbinata*, Japan (1).

Complementary mating types: NRRL Y-7818-1 (CBS 6895) and NRRL Y-7818-10 (CBS 6896), derived as single-spore isolates from the type strain (Kurtzman, unpublished).

Type strain: CBS 6591 (LKB-325, NRRL Y-7818).

Comments: Results obtained in the present study correspond well with the original description. Exceptions concern raffinose and L-arabinose on which Kodama (Kodama and Kyono 1974b) found no growth, but which were latently utilized in the present comparison. No mating response has been observed between *P. veronae* and the phenotypically similar species *P. rhodanensis*, *P. wickerhamii*, *P. amylophila* and *P. mississippiensis*.

42.90. *Pichia wickerhamii* (van der Walt) Kreger-van Rij (1964b)**Synonym:**

Endomycopsis wickerhamii van der Walt (1959b)

Growth on 5% malt extract agar: After 3 days at 25°C, the cells are ovoidal to elongate, (1.7–5.0) × (2.5–12.0) μ m, and occur singly, in pairs and in chains. Growth is tannish-yellow, somewhat wrinkled, and dull to faintly glistening.

Growth on the surface of assimilation media:

Pellicles are present.

Dalmat plate culture on morphology agar: After 7 days at 25°C, growth under the coverglass shows abundant well-branched pseudohyphae bearing blastoconidia that may be single or in small verticillate clusters. The presence of true hyphae is questionable. All hyphae examined seemed to have slight constrictions at the septa rather than parallel walls as would be expected of true hyphae. Aerobic growth is light tannish-white, usually dull, wrinkled and somewhat mycelial. Margins are generally entire. An ester-like odor is present.

Formation of ascospores: Asci are unconjugated when formed by diploid strains of this heterothallic species, or conjugated if produced by the pairing of complementary mating types. Two to four hat-shaped ascospores form in each ascus and they are readily liberated.

Ascospores were observed on 5% malt extract agar after 3–7 days at 25°C.

Fermentation:

Glucose	+	Lactose	-
Galactose	-	Raffinose	-
Sucrose	-	Trehalose	-
Maltose	-		

Assimilation:

Glucose	+	<i>N</i> -Acetyl-D-glucosamine	-

Co-Q: 7, CBS 4107 (Yamada et al. 1973a).

Mol% G+C: 43.2, 45.6, 46.5, CBS 4107 (T_m : Nakase and Komagata 1970b; BD: Fuson et al. 1980, Kurtzman et al. 1980a).

Origin of the strains studied: Frass of snout moth (Pyralidae) larvae in *Encephalartos* sp. (3).

Complementary mating types: NRRL Y-2435-9 (CBS 7100) and NRRL Y-2435-10 (CBS 7101), derived as single-spore isolates from the type strain.

Type strain: CBS 4107 (NRRL Y-2435).

Comments: In comparisons of phenotypically similar

species, *P. wickerhamii* failed to show any mating response with *P. amylophila*, *P. mississippiensis*, *P. rhodanensis* or *P. veronae*. Furthermore, *P. wickerhamii* showed only minimal nDNA relatedness with these other species (Kurtzman et al. 1980a).

42.91. *Pichia xylosa* Phaff, M.W. Miller & Shifrine (1956)

Synonym:

Zymopichia xylosa (Phaff, M.W. Miller & Shifrine) Novák & Zsolt (1961)

Growth on 5% malt extract agar: After 3 days at 25°C, the cells are ovoidal, (1.5–5.0) × (3.0–9.7) µm, and occur singly and in pairs. Growth is yellowish-white, smooth to wrinkled, and dull-glistening.

Growth on the surface of assimilation media: Thin pellicles are formed by some strains.

Dalmou plate culture on morphology agar: After 7 days at 25°C, growth under the coverglass shows abundant, branched pseudohyphae with blastoconidia in a verticillate arrangement. True hyphae are not formed. Aerobic growth is tannish-white, smooth to wrinkled, dull-glistening and butyrous. Margins are usually lobed.

Formation of ascospores: Conjugation of a parent cell and a bud usually precedes ascus formation. Asci contain one to four hat-shaped ascospores and these may be quickly or slowly liberated. Single-spore isolates from four-spored asci are ascosporeogenous, indicating the species to be homothallic.

Ascospores were observed on 5% malt extract agar after 3–7 days at 25°C.

2-Keto-D-gluconate	–	Starch formation	–
5-Keto-D-gluconate	–	Gelatin liquefaction	–
Saccharate	–	Growth at 37°C	–
10% NaCl/5% glucose	–		

Co-Q: 7, IFO 950 (Yamada et al. 1973a).

Mol% G + C: 39.9–40.4, CBS 2286, 7206, 7207 (BD: Kurtzman 1987a, unpublished).

Origin of the strains studied: CBS 2286 was isolated by Phaff et al. (1956) from a fruit fly (*Drosophila miranda*) in California. NRRL Y-5987, from Boidin, may be a subculture of the type strain. NRRL YB-3884 (CBS 7206) and NRRL YB-3887 (CBS 7207) were isolated by Wickerham from, respectively, the Tuolumne River, Yosemite National Park, California, and a river near Lake Tahoe, California.

Type strain: CBS 2286 (NRRL Y-12939), from *Drosophila miranda*.

Comments: On standard tests, *P. xylosa* is phenotypically indistinguishable from *P. toletana*, which led Kreger-van Rij (1970c) and subsequent workers to consider the taxa to be conspecific. In a comparison of nDNA relatedness between species of *Pichia*, Kurtzman (1992b) found 30% complementarity between *P. xylosa* and *P. toletana*, thus demonstrating the two taxa to be separate but closely related species. The species can be separated from extent of nDNA relatedness, nucleotide divergence in the 26S rRNA gene, or from differences in electrophoretic patterns of cellular proteins (Kurtzman 1992b).

Comments on the genus

Since Hansen established the genus *Pichia* in 1904, the definition of this taxon has changed considerably to accommodate the ever increasing number of new species assigned to it. A historical account of the genus, named in honor of Professor P. Pichi, may be found in the treatments of Lodder and Kreger-van Rij (1952) and Kreger-van Rij (1970c). Many aspects of the earlier taxonomic evolution of *Pichia*, such as ploidy, the presence or absence of a mating system, the type of conjugation, if any, preceding ascus formation, presence of pellicles and the occurrence of gaseous fermentation, were discussed in detail by Kreger-van Rij (1970c).

Electron microscopic and biochemical comparisons have been used to redefine *Pichia* since preparation of the last two major monographs of this genus (Kreger-van Rij 1970c, Kurtzman 1984c,d). Kurtzman and Smiley (1974, 1979) and Kurtzman et al. (1975, 1980b) observed by scanning electron microscopy that, with the exception of *P. carsonii* and *P. etchellsii*, the “round-spored” species of *Pichia* had roughened surfaces. This prompted the reassignment of those species having Co-Q 7 to *Issatchenkia* (Kurtzman et al. 1980b), and those species with Co-Q 9 to *Debaryomyces* (Price and Phaff 1979). *P. carsonii* and *P. etchellsii*, each with Co-Q 9, remained in *Pichia* because their ascospores were glabrous, and

P. fluxuum (Co-Q 7) was retained in *Pichia* because its roughened ascospores, unlike species of *Issatchenkia*, have a subequatorial ring. Nonetheless, use of ascospore morphology as a criterion for the definition of taxa has been uncertain since the demonstration by Wickerham and Burton (1954b) that *P. ohmeri* forms ascospores that are either hat-shaped or spheroidal, depending on which mating types are paired.

As proposed by Stelling-Dekker in 1931, *Hansenula* and *Pichia* were separated from each other primarily on the basis of ability to assimilate nitrate as a sole source of nitrogen. This distinction between the genera was further emphasized by Wickerham (1951). The wisdom of separating the genera on only this one point of difference was discussed (Mrak et al. 1942b, Lodder and Kreger-van Rij 1952, Wickerham 1970a), but because nitrate-variable strains had not been detected among species in either genus, both *Hansenula* and *Pichia* were maintained. In comparisons of nDNA complementarity between phenotypically similar species of *Pichia* and *Hansenula*, Kurtzman (1984a) found 75% relatedness between *P. lindneri* and *H. minuta*, thus demonstrating nitrate assimilation to be a species-variable character. This finding prompted the transfer of *Hansenula* species with hat-shaped ascospores to *Pichia*, the genus of taxonomic priority. The preceding observation concerning nitrate assimilation is not unique and differences in ability to assimilate nitrate also have been detected between the following pairs that show high nDNA relatedness: *Williopsis saturnus* var. *mrakii* (*H. mrakii*) and *W. saturnus* var. *sargentensis* (*P. sargentensis*) (68%, Kurtzman 1991a), strains of *P. canadensis* (95%, Comments on the species, this chapter), and *Sterigmatomyces halophilus* and its synonym *S. indicus* (99%, Kurtzman 1990a).

In 1977, von Arx et al. reintroduced the genus *Williopsis* for saturn-spored species that had been assigned to *Hansenula* (Wickerham 1970a). It was anticipated that the saturn-spored species of *Pichia* would be placed in *Williopsis* as well (Kurtzman 1984a), but comparisons of rRNA sequence divergence demonstrated that this group of species was phylogenetically divergent from *Williopsis*, which prompted their assignment to the newly described genus *Saturnispora* (Liu and Kurtzman 1991).

Billon-Grand (1989) pointed out that species of *Pichia* may be divided into three groups based on the type of coenzyme Q produced (Q-7, Q-8, Q-9), and in view of this, transferred all Q-9 producing species that form hat-shaped ascospores to the newly described genus *Yamadazyma*. *P. carsonii* and *P. etchellsii*, which also produce Co-Q 9, were left in *Pichia* because they form spheroidal ascospores. Yamada et al. (1992b,d) showed from rRNA sequence comparisons that *P. carsonii* and *P. etchellsii* are closely related to species of *Debaryomyces* and proposed their reassignment to this genus. Kurtzman and Robnett (manuscript in preparation) also compared the rRNA sequences of Co-Q 9-forming yeasts and found species of *Debaryomyces* and some species of

Yamadazyma to be quite closely related. Because of the uncertain circumscription of these two genera and their unresolved relationships with other genera that produce Co-Q 9, the genus *Yamadazyma* has not been accepted in the present treatment.

Yamada et al. (1994c) compared partial rRNA sequences of nitrate-assimilating species of *Pichia* (species formerly assigned to *Hansenula*), and argued that nitrate assimilation provided an initial grouping that served as a starting point for further dissection by molecular methods. The study revealed seven groupings, three of which were described as the genera *Ogataea*, *Kuraishia* and *Nakazawaea*. Following this, Yamada et al. (1995a,b) described *Komagataella* for *P. pastoris* and *Kodamaea* for *P. ohmeri*. These genera are not accepted in the present treatment because rRNA comparisons that included all species presently assigned to *Pichia* demonstrated the genus to be comprised of six major clades distributed across the ascomycetous yeast domain, and two of the clades contain closely related nitrate-assimilating and non-assimilating species (Kurtzman and Robnett, manuscript in preparation). Furthermore, there is some overlap with other extant genera that requires resolution.

Although each of the 91 species accepted in the present treatment appears genetically isolated from one another as predicted from genetic crosses, nDNA reassociation, and/or rRNA sequence analyses, it is clear from the foregoing discussions that the genus *Pichia* is polyphyletic, and therefore artificial. Placement of *Pichia* species into phylogenetically defined genera must await molecular comparisons in which all known ascomycetous yeasts are included. The promise of molecular comparisons to provide a phylogenetic framework to yeast systematics has yet to be realized because sequencing studies are laborious and most comparisons to date have focused on phenotypically defined genera, thus inadvertently overlooking other phylogenetically related taxa. For example, the initial characterization of *Debaryomyces* resulted in the inclusion of *Schwanniomyces* (Kurtzman and Robnett 1991). This was followed by the addition of *P. carsonii* and *P. etchellsii* to the genus (Yamada et al. 1992b,d), and *Wingea* was then recognized as a synonym (Kurtzman and Robnett 1994b). In continuation, the relationships of *Pichia* species having hat-shaped ascospores and Co-Q 9 will need to be examined relative to *Debaryomyces*. Further problems that will impact presently accepted genera include the close relationships shown by rRNA/rDNA comparisons for *P. membranifaciens*, *Issatchenkia orientalis* and *Saturnispora dispersa* (Wilmotte et al. 1993, Kurtzman and Robnett 1994a).

Several other methodologies have been used to examine relationships among species assigned to *Pichia*. The application of numerical analysis, proton magnetic resonance, and serology of cell wall mannans has been discussed previously (Kurtzman and Phaff 1987). The use of cellular long-chain fatty acid profiles for recognizing species has been examined in detail by Muller et al. (1987)

and Viljoen et al. (1986a,b, 1988) who reported that it was possible to differentiate between 43 strains representing 33 *Pichia* species. Groupings of species reported in this work do not correspond well with those derived either from rRNA/rDNA comparisons or from coenzyme Q determinations. However, the broader relationships shown by fatty acid profiles for representatives of the entire yeast clade (Botha and Kock 1993) are reasonably congruent with relationships proposed from rRNA/rDNA analyses (Kurtzman and Robnett 1994a, 1995, unpublished). Shen and Lachance (1993) examined the phylogeny of cactophilic *Pichia* species from analysis of rDNA restriction maps. Cactus yeasts that form Co-Q 7 were shown to be closely related to one another and to *P. membranifaciens*, a species common to many habitats.

Species not accepted in the genus

Species for which no strains were available:

Hansenula ellipsoidospora Luteraan (1954)

Pichia moniliformis Nishimura (1910)

Pichia ovaria Nishimura (1910)

Pichia californica (Seifert) Guilliermond (1912)

Pichia megalospora Kuraishi (1958)

Pichia orientalis (Beijerinck) Guilliermond (1912)

Pichia radaisii (Lutz) Guilliermond (1912)

Pichia tamarindorum (Seifert) Guilliermond (1912)

Pichia taurica (Seifert) Guilliermond (1912)

Pichia (Zygopichia) uwarum Verona & Luchetti (1941)

Pichia methanothermo Minami & Yamamura (Minami et al. 1978)

Species for which a validly published description was not located:

Hansenula misumaiensis Sasaki & Yoshida (1958) nom. nud. Strains [CBS 8062 (NRRL Y-17389), CBS 8063 (NRRL Y-17390)] of this taxon did not form ascospores in the present study, and the species has not been transferred to *Pichia*.

Species represented by a mixed culture:

Pichia labacensis Cimerman & Kocková-Kratochvílová (1984). Cultures of this species were reported to be a mixture of *P. membranifaciens* and *Saccharomyces cerevisiae* (Barnett et al. 1990).

43. *Protomyces* Unger

C.P. Kurtzman

Diagnosis of the genus

Asexual reproduction is by budding on a narrow base near the poles of the cell. The cells are ovoidal to elongate, and elongate cells may be asymmetrical. Pseudohyphae and true hyphae are not formed in culture.

The ascospore state is confined to the tissue of infected plants. Heavy walled spheroidal structures, variously termed ascogenous cells, synasci, and 'chlamyospores' appear to be the site of meiosis. Following nuclear division, which may occur after a resting period, 50–200 ellipsoidal ascospores are formed. Ascospore release may be directly through a slit in the ascogenous cell or an ascus-like vesicle containing the ascospores may emerge through a slit in the ascogenous cell. Ascospores form a yeastlike budding stage. Infection of the host seems only to occur by hyphae which result following conjugation of compatible yeast cells.

Sugars are not fermented. Nitrate is assimilated by most species. Diazonium blue B reaction is negative. Carotenoid pigments are produced. Formation of extracellular starch-like compounds is strong, weak or variable for some species.

Type species

Protomyces macrosporus Unger

Species examined

See Comments on the genus for additional described species.

1. *Protomyces gravidus* Davis (1907)
2. *Protomyces inouyei* Hennings (1902)
3. *Protomyces inundatus* Dangeard (1906)
4. *Protomyces lactucaedebilis* Sawada (1922)
5. *Protomyces macrosporus* Unger (1833)
6. *Protomyces pachydermus* von Thümen (1874)

<i>P. lactucaedebilis</i>	+	+	+	–	?
<i>P. macrosporus</i>	–	–	–	–	?
<i>P. pachydermus</i>	–	–	+	–	yes

^a Ascogenous cells require/do not require a rest period before ascospore formation.

Systematic discussion of the species

43.1. *Protomyces gravidus* Davis (1907)

Growth on 5% malt extract agar: After 3 days at 20°C, the cells are ellipsoidal to elongate, (2.5–4.0) × (2.5–10.0) µm, and may be tapered or curved. The cells occur singly, in pairs, and in small clusters. Growth is butyrous and dark salmon in color.

Growth on the surface of assimilation media: Incomplete pellicles may form on some media.

Dalmau plate culture on morphology agar: After 7 days at 25°C, growth under the coverglass shows neither pseudohyphae nor true hyphae. Aerobic growth is butyrous and glistening with a tannish-orange color. Colony margins are finely and irregularly lobed. A faint acidic odor is present.

Fermentation: absent.

Assimilation (25°C, 28 days):

Glucose	+	<i>N</i> -Acetyl-D-glucosamine	–

Comments on the genus

Species of the genus *Protomyces* are plant pathogens causing tissue distortion similar to that produced by *Taphrina* spp. Members of both genera show budding, yeastlike growth on laboratory media but do not develop hyphae or sexual states unless infecting their host plants (Tubaki 1957, Valadon et al. 1962, von Arx et al. 1982). Recently, species of *Protomyces* became of interest as weed biocontrol organisms (Valverde and Templeton 1984, Cartwright and Templeton 1988).

Species of *Protomyces* generally have a reddish, salmon-like color in culture whereas *Taphrina* species often show lighter shades of red, lavender or yellow. The colors arise from the presence of carotenoids. Van Eijk and Roeymans (1982) compared the carotenoid content of representative species of *Protomyces* and *Taphrina*, and concluded that the two genera cannot be reliably separated from quantitative differences in carotenoid content.

The placement of *Protomyces* among the fungi has been problematical, and Reddy and Kramer (1975) have reviewed earlier ideas on relationships noting that more recent workers have suggested that *Protomyces* is a primitive ascomycete. Molecular comparisons have brought a more definitive perspective to the phylogenetic

placement of *Protomyces*. Walker (1985a) analyzed 5S rRNA sequences and placed *Protomyces* near *Schizosaccharomyces* rather than with either the budding yeasts or the euascomycetes. Kurtzman (1993c) confirmed this placement from analysis of partial 18S and 26S rRNA sequences and noted that *Taphrina* and *Protomyces* are closely related. Nishida and Sugiyama (1994) proposed from comparisons of 18S rDNA gene sequences that *Protomyces*, *Taphrina*, *Saitoella*, *Schizosaccharomyces* and *Pneumocystis* represent a major lineage within the Ascomycota that is basal to the budding yeasts and euascomycetes, and suggested the name Archiascomycetes for this group.

Reddy and Kramer (1975) placed the genera *Burenia*, *Protomyces*, *Protomylopsis*, *Taphridium* and *Volkaria* in the Protomycetaceae, the only family of the Protomycetales, but questioned whether the genus *Mixia* was

a member of this family. Since then, Nishida et al. (1995) showed from 18S rDNA comparisons that *Mixia osmundae* is actually a basidiomycete.

Species of *Protomyces* are primarily defined from morphology and host range. Reddy and Kramer (1975) accepted 10 species and listed 61 other described species as doubtful or unavailable for study. These authors also transferred *P. inundatus* to the genus *Burenia*.

The present treatment of *Protomyces* is not intended to be definitive, nor is it certain that the six species described are biologically distinct from one another. The six taxa listed are available from culture collections and serve to illustrate the cultural characteristics of some better known members of the genus. Genetic and molecular comparisons will be needed to understand species boundaries, and for this reason no synonyms are given with the species listed.

44. *Saccharomyces* Meyen ex Reess

Ann Vaughan-Martini and Alessandro Martini

Diagnosis of the genus (Yarrow 1984a)

Vegetative reproduction is by multilateral budding. Cells are globose, ellipsoidal or cylindrical. Pseudohyphae may be formed but not septate hyphae.

The vegetative phase is predominantly diploid (or of higher ploidy), conjugation occurs on or soon after germination of the ascospores; diploid ascospores may be formed. Ascospores are globose to short ellipsoidal, with a smooth wall and usually one to four per ascus. Asci are persistent.

Vigorous fermentation of sugars. Starch-like compounds are not produced. Absence of growth with nitrate as a sole source of nitrogen. Diazonium blue B reaction is negative.

Type species

Saccharomyces cerevisiae Meyen ex Hansen

Species accepted

1. *Saccharomyces barnettii* Vaughan-Martini (1995)
2. *Saccharomyces bayanus* Saccardo (1895)
3. *Saccharomyces castellii* Capriotti (1966)
4. *Saccharomyces cerevisiae* Meyen ex E.C. Hansen (1883)
5. *Saccharomyces dairenensis* Naganishi (1917)
6. *Saccharomyces exiguus* Reess ex E.C. Hansen (1888)
7. *Saccharomyces kluyveri* Phaff, M.W. Miller & Shifrine (1956)
8. *Saccharomyces paradoxus* Bachinskaya (1914)
9. *Saccharomyces pastorianus* E.C. Hansen (1904)
10. *Saccharomyces rosinii* Vaughan-Martini, Barcaccia & Pollacci (1996)
11. *Saccharomyces servazzii* Capriotti (1967)
12. *Saccharomyces spencerorum* Vaughan-Martini (1995)
13. *Saccharomyces transvaalensis* van der Walt (1956)
14. *Saccharomyces unisporus* Jörgensen (1909)

Key to species

See Table 37.

1. a Maximum growth temperature above 30°C → 3
b Growth absent above 30°C → 2
- 2(1). a Sucrose, raffinose and trehalose fermented *S. barnettii*: p. 359
b Sucrose, raffinose and trehalose not fermented *S. rosinii*: p. 367
- 3(1). a Ethylamine-HCl assimilated → 4
b Ethylamine-HCl not assimilated → 6
- 4(3). a Growth in the presence of 1000 ppm cycloheximide *S. unisporus*: p. 370
b Absence of growth in the presence of 1000 ppm cycloheximide → 5
- 5(4). a Maltose, raffinose and ethanol assimilated *S. kluyveri*: p. 365
b Maltose, raffinose and ethanol not assimilated *S. spencerorum*: p. 368
- 6(3). a Maltose assimilated → 7
b Maltose not assimilated → 10
- 7(6). a Growth in vitamin-free medium *S. bayanus*: p. 360
b Absence of growth in vitamin-free medium → 8
- 8(7). a D-Mannitol assimilated; maximum growth temperature 37°C or greater *S. paradoxus*: p. 366
b D-Mannitol not assimilated; maximum growth temperature less than 37°C or variable at 37°C → 9
- 9(8). a Active transport mechanism for fructose present; maximum growth temperature 34°C or below *S. pastorianus*: p. 367
b Active transport mechanism for fructose not present; maximum growth temperature variable *S. cerevisiae*: p. 361
- 10(6). a Sucrose, raffinose and trehalose fermented *S. exiguus*: p. 364
b Sucrose, raffinose and trehalose not fermented → 11
- 11(10). a Growth in the presence of 1000 ppm cycloheximide *S. servazzii*: p. 368
b Absence of growth in the presence of 1000 ppm cycloheximide → 12

- 12(11). a D-Ribose normally assimilated; 8–10 chromosomes 600 → 3000 kilobases *S. castellii*: p. 360
 b D-Ribose not assimilated, mostly single, highly refringent ascospores on acetate agar; 8 chromosomes 400 → 2200 kilobases
 *S. transvaalensis*: p. 369
 c D-Ribose normally not assimilated; 7–9 chromosomes 750 → 3000 kilobases *S. dairenensis*: p. 363

Table 37

^a Abbreviations: Su, sucrose; Raf, raffinose; Tr, trehalose; Ma, maltose; D-Ri, D-ribose; Eth, ethanol; DM, D-mannitol; Cad, cadaverine-2HCl; Ety, ethylamine-HCl; Lys, L-lysine; Cychx 1000, indicates resistance to 1000 ppm cycloheximide in the medium; Vit-free, growth in vitamin-free medium.

^b Presence of a fructose transport system; n, not determined.

Systematic discussion of the species

44.1. *Saccharomyces barnettii* Vaughan-Martini (1995)

Growth in 5% malt extract: After 3 days at 25°C, the cells are globose, ovoidal or elongate, (2.2–6.0) × (3.5–10.5) μm, and are usually isolated, or in pairs. After one month at 20°C, a sediment is present.

Growth on 5% malt agar: After one month at 20°C, the streak culture is butyrous and light cream-colored. The surface is smooth, usually flat, occasionally raised or folded and opaque.

Growth on the surface of assimilation media: Pellicles are not formed.

Dalmu plate culture on morphology agar: Pseudo-hyphae are not present.

Formation of ascospores: Vegetative cells are transformed directly into persistent asci containing one or two, rarely four, globose to short ellipsoidal ascospores.

Ascospores were observed on acetate agar usually after 20–40 days at 25°C.

Fermentation:

Glucose	+	Lactose	-
Galactose	+	Raffinose	s
Sucrose	+	Trehalose	s
Maltose	-	Melibiose	-

Assimilation:

Glucose	+	N-Acetyl-D-glucosamine	-
Galactose	+	Methanol	-
L-Sorbose	-	Ethanol	-
Sucrose	+	Glycerol	-
Maltose	-	Erythritol	-
Cellulobiose	-	Ribitol	-
Trehalose	+	Galactitol	-
Lactose	-	D-Mannitol	-
Melibiose	-	D-Glucitol	-
Raffinose	+	α-Methyl-D-glucoside	-
Melezitose	-	Salicin	-
Inulin	-	D-Gluconate	+
Soluble starch	-	DL-Lactate	+
D-Xylose	-	Succinate	+
L-Arabinose	-	Citrate	-
D-Arabinose	-	Inositol	-
D-Ribose	-	Hexadecane	-
L-Rhamnose	-	Nitrate	-
D-Glucosamine	-	Vitamin-free	-

Additional assimilation tests and other growth characteristics:

Cadaverine-HCl	-	100 ppm Cycloheximide	-
L-Lysine	-	Growth at 37°C	-
Ethylamine-HCl	-		

Co-Q: Not determined.

Mol% G + C: 33.4, CBS 6946 (T_m : Yarrow 1978).

Origin of the strains studied: DBVPG 6365 (CBS 5648), sauerkraut; DBVPG 6370 (CBS 6946), soft drink.

Type strain: CBS 5648 (DBVPG 6365) isolated from sauerkraut.

Comments: Strains of this species require biotin for growth (Yarrow, personal communication). For additional comments see the general discussion under *S. exiguus*.

44.2. *Saccharomyces bayanus* Saccardo (1895)

Synonyms:

Saccharomyces uvarum Beijerinck (1898b)

Saccharomyces globosus Osterwalder (1924a)

Saccharomyces heterogenicus Osterwalder (1924a)

Saccharomyces intermedius E.C. Hansen var. *valdensis* Osterwalder (1924a)

Saccharomyces tubiformis Osterwalder (1924a)

Saccharomyces inusitatus van der Walt (1965b)

Saccharomyces abuliensis Santa Maria (1978)

Growth in 5% malt extract: After 3 days at 25°C, the cells are globose, ovoidal or elongate, (2.2–6.0) × (3.5–10.5) µm, and are usually isolated, but can be in groups of 3–20 cells (Fig. 154). After one month at 20°C, a sediment is present.

Fig. 154. *S. bayanus*, CBS 380. Vegetative cells after 2 days, on YEPG agar at 25°C. Bar = 10 µm.

Growth on 5% malt agar: After one month at 20°C, the streak culture is butyrous and light cream-colored. The surface is smooth, usually flat, occasionally raised or folded and opaque.

Growth on the surface of assimilation media: Pellicles are not formed.

Dalmou plate culture on morphology agar: After 5 days at 25°C, well-developed pseudohyphae are usually present.

Formation of ascospores: Vegetative cells are transformed directly into persistent asci containing one to four globose to short ellipsoidal ascospores.

Ascospores were observed only on acetate agar. After 14 days at 25°C, sporulation is usually below 10% and ascospores are rarely viable.

Fermentation:

Glucose	+	Lactose	–
Galactose	v	Raffinose	+

Co-Q: 6 (Yamada et al. 1976b).

Mol% G + C: 37–40, NRRL Y-409, NRRL Y-969 (T_m : Bicknell and Douglas 1970); 38.8–40.5, AJ 4068, AJ 5274, AJ 5308, AJ 5309, AJ 5351, AJ 5357 (T_m : Nakase and Komagata 1971e); 41.6–42.1, CBS 380, CBS 395, CBS 1546 (BD: Vaughan-Martini and Kurtzman 1985); 37.8–41.5, CBS 380, CBS 395, CBS 431 (T_m : Vaughan-Martini, unpublished data).

Origin of the strains studied: DBVPG 6032 (CBS 378), unknown; DBVPG 6131 (CBS 431), type strain of *S. tubiformis*, fermenting pear juice; DBVPG 6171 (CBS 380), beer; DBVPG 6179 (CBS 395), type strain of *S. uvarum*, berries; DBVPG 6253 (CBS 1546), type strain of *S. inusitatus*, beer; DBVPG 6259 (CBS 1604), perry; DBVPG 6260 (CBS 1505), type strain of *S. intermedius* var. *valdensis*, grape must; DBVPG 6347 (NCYC 374), unknown.

Type strain: CBS 380 (DBVPG 6171, IFO 1127, NRRL Y-12624), isolated from beer, received by CBS from the Central Laboratory of the South Manchuria Railway Company.

44.3. *Saccharomyces castellii* Capriotti (1966)

Growth in 5% malt extract: After 3 days at 25°C, the cells are globose, ovoidal or elongate, (3.0–5.5) × (3.5–7.0) µm, single or in pairs. After one month at 20°C, a sediment is present.

Growth on 5% malt agar: After one month at 20°C, the streak culture is butyrous and light cream-colored. The surface is smooth and glossy and the margin is entire or crenate.

Growth on the surface of assimilation media: Pellicles are not formed.

Dalmou plate culture on morphology agar: Pseudohyphae are not formed.

Formation of ascospores: Vegetative cells are transformed directly into persistent asci containing one or two, rarely four, globose ascospores.

Sporulation was observed on acetate agar and YM agar in some strains after 7–9 days at 25°C.

Fermentation:

Glucose	+	Lactose	–
Galactose	+	Raffinose	–
Sucrose	–	Trehalose	–
Maltose	–	Melibiose	–

Assimilation:

Glucose	+	<i>N</i> -Acetyl-D-glucosamine	–
Galactose	+	Methanol	–
L-Sorbose	–	Ethanol	–
Sucrose	–	Glycerol	–
Maltose	–	Erythritol	–

Melibiose	–	D-Glucitol	–
Raffinose	–	α -Methyl-D-glucoside	–
Melezitose	–	Salicin	–
Inulin	–	D-Gluconate	+
Soluble starch	–	D,L-Lactate	–
D-Xylose	–	Succinate	v
L-Arabinose	–	Citrate	–
D-Arabinose	–	Inositol	–
D-Ribose	v	Hexadecane	–
L-Rhamnose	–	Nitrate	–
D-Glucosamine	–	Vitamin-free	–

Additional assimilation tests and other growth characteristics:

Cadaverine-HCl	–	100 ppm Cycloheximide	–
L-Lysine	–	Growth at 37°C	v
Ethylamine-HCl	–		

Co-Q: Not determined.

Mol% G+C: 38.8, CBS 4309 (T_m : Yarrow and Nakase 1975); 36.7–39.1, CBS 4309, CBS 4310 (BD: Vaughan-Martini and Kurtzman 1988).

Origin of the strains studied: DBVPG 6298 (CBS 4309), type strain of *S. castellii*, soil; DBVPG 6352 (CBS 3007), DBVPG 6353 (CBS 2913), and DBVPG 6356 (CBS 3006), fermenting cucumber brine; DBVPG 6361 (CBS 4310), soil; DBVPG 6410 (CBS 1579), buttermilk; DBVPG 6751 (CBS 7188), ensiled maize; DBVPG 6758 (CBS 2248), soil; DBVPG 6759 (CBS 4906), caecal contents of a baboon.

Type strain: CBS 4309 (DBVPG 6298, IFO 1992, NRRL Y-12 630) isolated by Capriotti from Finnish soil.

Comments: Spectrophotometric DNA reassociation studies (Vaughan-Martini and Kurtzman 1988) revealed that the nucleotide sequences of *S. dairenensis* and *S. castellii* were not homologous, therefore indicating the presence of two separate taxa despite essentially identical physiological responses.

44.4. *Saccharomyces cerevisiae* Meyen ex E.C. Hansen (1883)

Anamorph: *Candida robusta* Diddens & Lodder

Synonyms:

Saccharomyces ellipsoideus Meyen ex E.C. Hansen (1883)

Saccharomyces cerevisiae Meyen ex E.C. Hansen var. *ellipsoideus* (E.C. Hansen) Dekker (Stelling-Dekker 1931)
Saccharomyces ilicis Grönlund (1892)
Saccharomyces vini-muntz Kayser (1892)
Saccharomyces vordermanii Went & Prinsen Geerligs (1894)

- Saccharomyces hispalensis* Santa Maria (1978)
- Saccharomyces cerevisiae* Meyen ex E.C. Hansen var. *pelliculosa* S. Goto (Barnett et al. 1983)
- Saccharomyces boulardii* Surawicz, Elmer, Speelman, McFarland, Chinn & van Beele (1989) nom. nud.

Fig. 155. *S. cerevisiae*, CBS 1171. Vegetative cells after 2 days, on YEPG agar, 25°C. Bar = 10 µm.

Growth on 5% malt agar: After one month at 20°C, growth is butyrous and light cream-colored. The surface is smooth, usually flat, occasionally raised or folded and opaque.

Growth on the surface of assimilation media: Pellicles are not formed.

Dalmat plate culture on morphology agar: Pseudo-hyphae are either not formed or are rudimentary.

Formation of ascospores: Vegetative cells are transformed directly into persistent asci containing one to four globose to short ellipsoidal ascospores (Fig. 156).

Ascospore formation, observed almost exclusively on acetate agar, was usually below 10% except in highly fertile homothallic strains where sporulation ranged from 40–95% in 6–10 days at 20°C.

Fermentation:

Glucose	+	Lactose	–
Galactose	v	Raffinose	+
Sucrose	+	Trehalose	–
Maltose	v	Melibiose	v

Assimilation:

Glucose	+	<i>N</i> -Acetyl-D-glucosamine	–

L-Lysine	–	Active fructose transport	–
Ethylamine-HCl	–	Growth at 37°C	v

Growth in 5% malt extract: After 3 days at 25°C, the cells are globose, ovoidal or elongate, (3.0–8.0) × (5.0–10.0) µm, and are usually isolated or in small groups (Fig. 155). After one month at 20°C, a sediment is present.

Co-Q: 6 (Yamada et al. 1976b).

Mol% G+C: 39–41, NRRL Y-123, NRRL Y-379, NRRL Y-1345, NRRL Y-1356, NRRL Y-1373, (T_m : Bicknell and Douglas 1970); 38.5–40.7, 30 strains (T_m : Nakase and Komagata 1971e); 39.0–40.2, CBS 1395, CBS 2247, CBS 3081, CBS 3093, CBS 4903, CBS 5155, CBS 5835 (T_m : Yarrow and Nakase 1975); 39.9, UCD-FST 74-83 (BD: Price et al. 1978); 40.1–41.1, CBS 400, CBS 459, CBS 1171, CBS 1636, CBS 4054, NRRL Y-11846 (BD: Vaughan-Martini and Kurtzman 1985).

Origin of the strains studied: DBVPG 1357, DBVPG 1360, DBVPG 1361, DBVPG 1772, DBVPG 1776, DBVPG 1789 and DBVPG 1793, vineyard soil; DBVPG 1948 and DBVPG 1950, cavern soil; DBVPG 6029 (CBS 1907), type strain of *C. robusta*, DBVPG 6037 (CBS 2980), *Drosophila*; DBVPG 6039 (CBS 1395), type strain of *S. ellipsoideus*, DBVPG 6042 (CBS 403), type strain of *S. lindneri*, ginger beer; DBVPG 6043 (CBS 382), type strain of *S. logos*, brewery; DBVPG 6046 (CBS 422), type strain of *S. odessa*, beer; DBVPG 6048 (CBS 423), type strain of *S. steineri*, wine; DBVPG 6173 (CBS 1171), beer; DBVPG 6220 (CBS 6503), brewery killer; DBVPG 6248 (CBS 2354) (NCYC 74) used for assay of pyridoxine and pantothenic acid; DBVPG 6249 (CBS 2444), distillery; DBVPG 6250 (CBS 4734), sugar cane; DBVPG 6251 (CBS 1250) type strain of *S. cheresiensis*, sherry; DBVPG 6254 (CBS 429) type strain of *S. oviformis*, grape must.

Fig. 156. *S. cerevisiae*, CBS 403. Un conjugated asci with ascospores after 7 days on McClary's acetate agar, 25°C. Bar = 10 μ m.

Complementary mating types: CBS 1782.1 and CBS 1782.2 or CBS 2354.1 and CBS 2354.2.

Type strain: CBS 1171 (ATCC 18824, DBVPG 6173, NCYC 505, NRRL Y-12632), isolated by van Wijk from the top yeast used in the Oranjeboom Brewery at Rotterdam, and designated as the type strain by Lodder and Kreger-van Rij (1952).

Comments: A large number of ecological and technological investigations have set forth the hypothesis that *S. cerevisiae* is the principal species responsible for the

alcoholic fermentation of fruit juices. The traditional epithets such as *S. ellipsoideus*, *S. oviformis*, *S. cheresiensis* or *S. chevalieri*, retained over the years as the main species in this process, have been shown to be strains of *S. cerevisiae* with particular technological capabilities. In addition, other members of the *sensu stricto* complex: *S. bayanus*, *S. paradoxus*, and *S. pastorianus* (*sensu* Vaughan-Martini and Martini 1987a, Vaughan-Martini 1989), while at times found in these man-created environments, do not appear to be the most capable starters for the process.

Since the discovery that some strains of *S. cerevisiae* are capable of producing a "killer" toxin lethal to other members of the same species (Bevan and Makover 1963), many investigations have been carried out on the mode of action and the chemical and physical properties of the toxin as well as the biology of the "killer" plasmid. It has been asserted that this phenomenon can be technologically useful, and numerous studies have been tested in this regard. On the other hand, it is not possible to apply this character in yeast classification since studies have shown that this is a strain- rather than species-related character (Vaughan-Martini and Rosini 1989).

The *nomen nudum* *S. bouldardii*, cited in recent years as an anti-diarrhea agent (Surawicz et al. 1989), is homologous with *S. cerevisiae* for 95% of its genome (Vaughan-Martini, unpublished data).

44.5. *Saccharomyces dairenensis*¹ Naganishi (1917)

Growth in 5% malt extract: After 3 days at 25°C, the cells are globose, ovoidal or elongate, (3.0–5.5) × (3.5–7.0) μ m, single or in pairs. After one month at 20°C, a sediment is present.

Growth on 5% malt agar: After one month at 20°C, the streak culture is butyrous and light cream-colored. The surface is smooth and glossy and the margin is entire or crenate.

Growth on the surface of assimilation media: Pellicles are not formed.

Dalmay plate culture on morphology agar: No pseudohyphae are formed.

Formation of ascospores: Vegetative cells are transformed directly into persistent asci containing one or two, rarely four, globose ascospores.

Sporulation was observed on acetate agar and YM agar in some strains after 7–9 days at 25°C.

Fermentation:

Glucose	+	Lactose	–
Galactose	+	Raffinose	–
Sucrose	–	Trehalose	–
Maltose	–	Melibiose	–

¹ The original spelling of the species epithet *dairensis* has been treated as an orthographic error.

Assimilation:

Glucose	+	<i>N</i> -Acetyl-D-glucosamine	–
Galactose	+	Methanol	–
L-Sorbose	–	Ethanol	v
Sucrose	–	Glycerol	v
Maltose	–	Erythritol	–
Cellobiose	–	Ribitol	–
Trehalose	+	Galactitol	–
Lactose	–	D-Mannitol	–
Melibiose	–	D-Glucitol	–

Additional assimilation tests and other growth characteristics:

Cadaverine-HCl	–	100 ppm Cycloheximide	–
L-Lysine	–	Growth at 37°C	v
Ethylamine-HCl	–		

Co-Q: Not determined.

Mol% G + C: 37, NRRL Y-1353 (T_m : Bicknell and Douglas 1970); 35.9–38.5, 8 strains (T_m : von Arx 1977b, 1978); 36.7, CBS 421 (BD: Vaughan-Martini and Kurtzman 1988).

Origin of the strains studied: DBVPG 6357 (CBS 6904), soil; DBVPG 6359 (CBS 6463), fermenting grapes; DBVPG 6366 (CBS 421), dry fruit of a persimmon; DBVPG 6752 (CBS 6334), fermenting mushroom.

Type strain: CBS 421 (ATCC 10597, DBVPG 6366, IFO 1168, NRRL Y-1353) isolated by Naganishi.

Comments: DNA/DNA reassociation (Vaughan-Martini and Barcaccia 1996) has shown that many strains previously classified as *S. dairenensis* are homologous to the type strain of the species *S. castellii* with which they must now be considered synonymous. The same study demonstrated that none of the strains examined shared significant DNA base sequences with the type strain of *S. dairenensis*. Nevertheless, due to the limited response of strains of this group to the tests of conventional taxonomy, it is not possible at the present time to establish a clear distinction between all but one of these separate species. As a consequence, until satisfactory criteria are determined for their separation, these species will have to be considered under the *S. dairenensis* complex. One pair of homologous strains, which can be distinguished by a few simple tests, has been designated as the new species *S. rosinii* (Vaughan-Martini et al. 1996).

44.6. *Saccharomyces exiguus* Reess ex E.C. Hansen (1888a)

Anamorph: *Candida holmii* (Jörgensen) S.A. Meyer & Yarrow

Synonyms:

Torula holmii Jörgensen (1909)

Torulopsis holmii (Jörgensen) Lodder (1934)

Cryptococcus holmii (Jörgensen) Skinner (1950)

Candida holmii (Jörgensen) S.A. Meyer & Yarrow (Yarrow and Meyer 1978)

?*Torula alactosa* Harrison (1928)

Growth in 5% malt extract: After 3 days at 25°C, the cells are subglobose to ellipsoidal, elongate, (2.5–5.0) × (3.5–6.5) μ m, single or in pairs. After one month at 20°C, a sediment is present and occasionally a ring.

Growth on 5% malt agar: After one month at 20°C, the streak culture is butyrous, cream-colored to tan, smooth with light striations, flat and rather spreading, glossy, margin usually entire.

Growth on the surface of assimilation media: Pellicles are not formed.

Dalmeu plate culture on morphology agar: Pseudo-hyphae are not formed.

Formation of ascospores: Vegetative cells are transformed directly into asci containing one to two, rarely four, globose to ellipsoidal ascospores.

Sporulation was observed on acetate agar and V8 agar after 7–10 days at 25°C.

Fermentation:

Glucose	+	Lactose	–
Galactose	+	Raffinose	s
Sucrose	+	Trehalose	+
Maltose	–	Melibiose	–

Assimilation:

Glucose	+	<i>N</i> -Acetyl-D-glucosamine	–
Galactose	+	Methanol	–
L-Sorbose	–	Ethanol	s

L-Rhamnose	–	Nitrate	–
D-Glucosamine	–	Vitamin-free	–

Additional assimilation tests and other growth characteristics:

Cadaverine-HCl	–	100 ppm Cycloheximide	v
L-Lysine	–	1000 ppm Cycloheximide	v
Ethylamine-HCl	–	Growth at 37°C	–

Co-Q: 6 (Yamada et al. 1976b).

Mol% G + C: 30.5, AJ 4075 (T_m : Nakase and Komagata 1968a); 33.2–33.7, AJ 4075, AJ 4349 (T_m : Nakase and Komagata 1971e); 35.2, CBS 379 (T_m : Yarrow and Nakase 1975); 32.9–34.9, 10 strains (T_m : Yarrow 1984a); 34.7–36.3, CBS 134, CBS 135, CBS 397, CBS 2141 (BD: Vaughan-Martini and Kurtzman 1988).

Origin of the strains studied: DBVPG 6252 (CBS 379), unknown; DBVPG 6354 (CBS 1515), fermenting cucumber brine; DBVPG 6358 (CBS 2141), soil; DBVPG 6367 (CBS 1514), fermenting cucumber brine; DBVPG

6369 (CBS 6388), fruit of *Fragaria ananassa*; DBVPG 6402 (CBS 4660), grape must; DBVPG 6413 (CBS 134), unknown; DBVPG 6468 (CBS 8135) and DBVPG 6469 (CBS 8134), soil; DBVPG 6481 (CBS 135), type strain of *Candida holmii*, buttermilk; DBVPG 6484 (CBS 6440), sewage slick; DBVPG 6749 (CBS 4661), grape must.

Type strain: CBS 379 (ATCC 10599; DBVPG 6252; IFO 1128; NRRL Y-1538) from Naganishi, and chosen as type strain by Lodder and Kreger-van Rij (1952).

Comments: DNA reassociation studies (Vaughan-Martini and Kurtzman 1988) revealed 76% nucleotide sequence relatedness between the type strains of *S. exiguus* and *Candida holmii*, therefore confirming this teleomorphic–anamorphic relationship. On the other hand, low relatedness between these strains and others designated as *S. exiguus* led to the hypothesis that the latter are different species. The possible presence of more than one species within the group of strains commonly designated as *S. exiguus* was also supported by other workers (van der Walt 1970d, Yarrow 1978, Kaneko et al. 1989). This has been confirmed by a second study of DNA base sequence homology enlarged to a greater number of strains. Three separate groups have been identified: the main *S. exiguus* complex comprised of a number of variably related strains and two new separate species: *S. barnettii* and *S. spencerorum* (Vaughan-Martini 1995).

44.7. *Saccharomyces kluyveri* Phaff, M.W. Miller & Shifrine (1956)

Synonyms:

Saccharomyces smittii Capriotti (1958d)

Saccharomyces silvestris Jensen (1967)

Growth in 5% malt extract: After 3 days at 25°C, the cells are globose, ellipsoidal or cylindrical, (3.5–7.0)×(4.0–11.0)µm, single, in pairs or in clusters (Fig. 157). After one month at 20°C, a sediment and a ring are present.

Growth on 5% malt agar: After one month at 20°C, the streak culture is cream-colored to tan, fairly flat and smooth to raised and wrinkled or folded, often sectored, glossy or dull, margin undulating or lobate and sometimes fringed with pseudohyphae.

Growth on the surface of assimilation media: Pellicles are not formed.

Fig. 157. *S. kluyveri*, CBS 3082. Vegetative cells after 3 days, on YEPG agar, 25°C. Bar = 10 µm.

Dalmou plate culture on morphology agar: Pseudohyphae are usually formed.

Formation of ascospores: Vegetative cells are transformed directly into asci containing one to four globose to subglobose ascospores.

Sporulation was observed on acetate agar after 4 days at 25°C.

Fermentation:

Glucose	+	Lactose	–
Galactose	+	Raffinose	+
Sucrose	+	Trehalose	–
Maltose	–	Melibiose	+

Assimilation:

Glucose	+	<i>N</i> -Acetyl-D-glucosamine	–

Additional assimilation tests and other growth characteristics:

Cadaverine-HCl	+	100 ppm Cycloheximide	–
L-Lysine	+	Growth at 37°C	+
Ethylamine-HCl	+		

Co-Q: Not determined.

Mol% G+C: 41.9, one strain, CBS 3082, (BD: Vaughan-Martini and Kurtzman 1985).

Origin of the strains studied: DBVPG 3103, 3108, 3109, 3452 and 3453, soil; DBVPG 6177 (CBS 3082), *Drosophila*; DBVPG 6362 (CBS 6545), slime flux; DBVPG 6363 (CBS 6626), tree exudate; DBVPG 6403 (CBS 5828), water-logged soil; DBVPG 6412 (CBS 6548), *Drosophila*; DBVPG 6430 (CBS 4104), soil; DBVPG 6444 (CBS 4570), unknown; DBVPG 6467 (CBS 4569), unknown.

Type strain: CBS 3082 (DBVPG 6177, IFO 1685, NRRL Y-12 651, UCD-FST 51-242) isolated from *Drosophila pinicola* at Mather, California, U.S.A.

Comments: *Saccharomyces kluyveri* was provisionally included in group 2 of the genus *Saccharomyces sensu* van der Walt (1970d). Meyer and Phaff (1969), however, suggested that it fit better into group 1, *Saccharomyces sensu stricto*, because of its apparent close resemblance to *Saccharomyces cerevisiae*. This was in part due to the results of Barker and Miller (1969), who had observed the formation of a few infertile zygotes between haploid strains of *S. kluyveri* and *S. cerevisiae*. McCullough

and Herskowitz (1979) also noted physiological cross-reactions of pheromones between the two species.

Later, Johnston and Mortimer (1986) expressed doubts that *S. kluyveri* is a true member of the group. In fact, results of an OFAGE (orthogonal field inversion gel electrophoresis) analysis revealed that while typical strains of *Saccharomyces sensu stricto* have 12–15 variably-sized chromosomes, *S. kluyveri* has only 3 (later seen to be 5–6, Vaughan-Martini et al. 1993) large-sized (>1000 kb) chromosomes. That later study also revealed that all other species of *Saccharomyces*, with the exception of *S. dairenensis*, are characterized by the presence of at least 10 chromosomes covering all size ranges: small (<500 kb), medium (500–1000 kb), and large (>1000 kb). In addition, studies of ribosomal RNA sequences (Kurtzman and Robnett 1991) showed that *S. kluyveri* is the most divergent member of the genus.

44.8. *Saccharomyces paradoxus* Bachinskaya (1914)

Synonyms:

Zygosaccharomyces paradoxus (Bachinskaya) Klöcker (1924)

Zygosaccharomyces paradoxus (Bachinskaya) Nishiwaki (1929)

Saccharomyces mangini Guilliermond var. *tetraspora* (Beijerinck ex Dekker) Stelling-Dekker (1931)

Saccharomyces cerevisiae Meyen ex E.C. Hansen var. *tetraspora* (Beijerinck ex Dekker) Phaff, M.W. Miller & Shifrine (1956)

Saccharomyces cerevisiae Meyen ex E.C. Hansen var. *terrestris* Jensen (1967)

Saccharomyces douglasii Hawthorne & Philippsen (1994) nom. nud.

Growth in 5% malt extract: After 3 days at 25°C, the cells are globose, ellipsoidal or cylindrical, (2.5–7.0) × (3.0–8.5) µm, single, in pairs or in clusters. After one month at 20°C, a sediment and a ring are present.

Growth on 5% malt agar: After one month at 20°C, the streak culture is cream-colored to tan, smooth to raised and dull; the margin is undulating or lobate and sometimes fringed or smooth.

Growth on the surface of assimilation media: Pellicles are not formed.

Dalmau plate culture on morphology agar: Pseudo-hyphae are occasionally formed.

Formation of ascospores: Vegetative cells are transformed directly into asci containing one to four globose to subglobose ascospores. In most strains over 50% of the cells sporulate and ascospores are highly viable.

Sporulation, when observed, occurs on almost any medium such as malt extract agar, yeast extract, glucose agar (YEPG), potato agar and acetate agar in 2–4 days at 25°C.

Fermentation:

Glucose	+	Lactose	–
Galactose	+	Raffinose	+
Sucrose	+	Trehalose	–
Maltose	v	Melibiose	–

Assimilation:

Additional assimilation tests and other growth characteristics:

Cadaverine-HCl	–	100 ppm Cycloheximide	–
L-Lysine	–	Active fructose transport	–
Ethylamine-HCl	–	Growth at 37°C	+

Co-Q: Not determined.

Mol% G+C: 42.0–43.1, CBS 432, CBS 5829, DBVPG 6304 (T_m : Vaughan-Martini, unpublished data).

Origin of the strains studied: DBVPG 6045 (CBS 406), type strain of *S. mangini* var. *tetraspora*, oak exudate; DBVPG 6303 (UCD-FST 52-153) and DBVPG 6304 (UCD-FST 51-186), *Drosophila*; DBVPG 6411 (CBS 432), tree exudate; DBVPG 6466 (CBS 5829) type strain of *S. cerevisiae* var. *terrestris*, soil; DBVPG 6487, DBVPG 6490, DBVPG 6491, DBVPG 6493 and DBVPG 6494, tree exudates.

Type strain: CBS 432 (DBVPG 6411, IFO 10609, IGC 4570, NRRL Y-17217) was designated as the neotype.

Comments: Recent ecological, taxonomic and genetic studies have led to the hypothesis that *S. paradoxus* is the natural parent species of the domesticated species of the *Saccharomyces sensu stricto* group which includes *S. bayanus*, *S. cerevisiae* and *S. pastorianus*. This premise is supported in part by the results of DNA reassociation studies which showed that while *S. paradoxus* and *S. cerevisiae* are related for about 50% of their nucleotide sequences, relatedness with *S. bayanus* and *S. pastorianus* is less than 20% (Vaughan-Martini 1989). In addition, Naumov (1986b, 1987c) found that effective mating does not occur between *S. paradoxus* and *S. bayanus* or with *S. cerevisiae*.

In light of the above results, and considering the ecological separation of *S. paradoxus* from the other three species (only natural sources in contrast to mostly artificial fermentation environments for the other three, Phaff et al. 1956, Rosini et al. 1982a, Rosini 1984, Naumov and Nikonenko 1988), it seems appropriate that this species be considered a separate member of the *Saccharomyces sensu stricto* complex.

44.9. *Saccharomyces pastorianus* E.C. Hansen (1904)

Synonyms:

Saccharomyces carlsbergensis E.C. Hansen (1908)

Saccharomyces monacensis E.C. Hansen (1908)

Growth in 5% malt extract: After 3 days at 25°C, the cells are globose, ellipsoidal or cylindrical, (2.2–8.0)×(3.5–13.5) μm, single, in pairs or in clusters. After one month at 20°C, a sediment is present.

Growth on 5% malt agar: After one month at 20°C, the streak culture is cream-colored to light tan, fairly flat and smooth with the margin slightly undulating or lobate and sometimes fringed or smooth.

Growth on the surface of assimilation media: Pellicles are not formed.

Dalmay plate culture on morphology agar: Pseudohyphae are generally not present.

Formation of ascospores: Vegetative cells are transformed directly into asci containing one to four globose to subglobose ascospores. In most strains sporulation is less than 2% and ascospores are usually not viable.

Sporulation, when observed, occurs only on acetate agar after 10–14 days at 25°C.

Co-Q: 6 (Yamada et al. 1976b).

Mol% G+C: 38.5–39.5, AJ 4033, AJ 4034, AJ 4059, AJ 53137 (T_m : Nakase and Komagata 1971e); 41.1, CBS 1513, (BD: Vaughan-Martini and Kurtzman 1985); 41.2–42.0, CBS 1513, CBS 1538 (T_m : Vaughan-Martini, unpublished data).

Origin of the strains studied: DBVPG 6033 (CBS 1513), type strain of *S. carlsbergensis*, brewery; DBVPG

6047 (CBS 1538), unknown; DBVPG 6257 (CBS 1260), unknown; DBVPG 6258 (CBS 1486), beer; DBVPG 6261 (CBS 1503), type strain of *S. monacensis*, beer; DBVPG 6282 (Carlsberg BK 2233), DBVPG 6283 (Carlsberg BK 2230), DBVPG 6284 (Carlsberg AJL 248) and DBVPG 6285 (Carlsberg M 1563), all probably from beer.

Type strain: CBS 1538 (ATCC 12752, DBVPG 6047, IFO 0613, NCYC 392, NRRL Y-1551), has been designated as the type strain and is probably isolated from beer.

Comments: Some problems have been encountered distinguishing between the species *S. cerevisiae* and *S. pastorianus* since the two are phenotypically close. While the large majority of strains belonging to *S. cerevisiae* grow at temperatures up to 40°C, a sole exception was seen for the type strain of *S. oviformis*, now a synonym of *S. cerevisiae*. None of the strains of *S. pastorianus* studied were able to grow above 34°C. As a result, temperature can be a reliable criterion for the separation of strains growing above 34°C. A recent study on the ability to actively transport fructose has shown that strains belonging to *S. paradoxus* and *S. cerevisiae* are consistently characterized by a negative fructose transport system. By contrast, strains of *S. bayanus* and *S. pastorianus* actively transport fructose (Rodrigues de Sousa et al. 1990).

Extensive genetic and molecular studies of numerous brewery yeasts appear to indicate that *S. pastorianus* is the most favorable species for beer making. This is in spite of the fact that the type strains of two of the other species of the *Saccharomyces sensu stricto* complex (*S. cerevisiae* and *S. bayanus*) were originally isolated from beer.

44.10. *Saccharomyces rosinii* Vaughan-Martini, Barcaccia & Pollacci (1996)

Growth in 5% malt extract: After 3 days at 25°C, the cells are ovoidal or elongate, (3.0–5.5)×(3.5–7.0) μm, and single or in pairs. After one month at 20°C, a sediment is present.

Growth on 5% malt agar: After one month at 20°C, the streak culture is butyrous and light cream-colored. The surface is smooth and glossy and the margin is entire or crenate.

Growth on the surface of assimilation media: Pellicles are not formed.

Dalmay plate culture on morphology agar: No pseudohyphae are formed.

Formation of ascospores: Vegetative cells are transformed directly into persistent asci containing one to two globose ascospores.

Very limited sporulation was observed with asci containing one or two globose ascospores. Sporulation was obtained after 9–14 days on acetate agar at 20°C or in YEPG at 5°C for 20–25 days.

Co-Q: Not determined.

Mol% G+C: Not determined.

Origin of the strains studied: DBVPG 6747 (CBS 7127) and DBVPG 6750 (CBS 7128), both of unknown origin.

Type strain: CBS 7127 (DBVPG 6747).

Comments: See Comments under *S. dairenensis*.

44.11. *Saccharomyces servazzii* Capriotti (1967)

Growth in 5% malt extract: After 3 days at 25°C, the cells are subglobose to ellipsoidal, (3.0–4.5) × (4.0–5.5) μ m, and single or in pairs. After one month at 20°C, a sediment and a thin ring are present.

Growth on 5% malt agar: After one month at 20°C, the streak culture is tan, flat, smooth with faint striations, waxy and glossy; the margin is slightly crenate.

Growth on the surface of assimilation media: Pellicles are not formed.

Dalmou plate culture on morphology agar: Pseudo-hyphae are not formed.

Formation of ascospores: Vegetative cells are transformed directly into asci containing one to four globose to short ellipsoidal ascospores.

Sporulation was observed on acetate agar after 7 days at 25°C.

Fermentation:

Glucose	+	Lactose	-
Galactose	+	Raffinose	-
Sucrose	-	Trehalose	-
Maltose	-	Melibiose	-

Assimilation:

Glucose	+	<i>N</i> -Acetyl-D-glucosamine	-

Cadaverine-HCl	-	100 ppm Cycloheximide	+
L-Lysine	-	1000 ppm Cycloheximide	+
Ethylamine-HCl	-	Growth at 37°C	-

Co-Q: Not determined.

Mol% G+C: 33.9, CBS 4311 (T_m : Yarrow and Nakase 1975); 34.4–35.9, 2 strains (T_m : Yarrow 1984a); 36.6, CBS 4311 (BD: Vaughan-Martini and Kurtzman 1988).

Origin of the strains studied: DBVPG 6355 (CBS 4311), from soil; DBVPG 6360 (CBS 6865) of unknown origin.

Type strain: CBS 4311 (DBVPG 6355, NRRL Y-12 661). Since a type was not designated for this species by Capriotti (1967), one of the isotypes was chosen by Yarrow (1984a) as the lectotype.

Comments: See Comments under *S. unisporus*.

44.12. *Saccharomyces spencerorum* Vaughan-Martini (1995)

Growth in 5% malt extract: After 3 days at 25°C, the cells are subglobose to ellipsoidal, elongate, (2.5–5.0) × (3.5–6.5) μ m, single or in pairs. After one month at 20°C, a sediment is present and often also a ring and a film.

Growth on 5% malt agar: After one month at 20°C, the streak culture is butyrous, cream-colored to tan, smooth with light striations, flat and rather spreading, glossy, and the margin usually entire.

Growth on the surface of assimilation media: Pellicles are not formed.

Dalmou plate culture on morphology agar: Pseudo-hyphae are not formed.

Formation of ascospores: Vegetative cells are transformed directly into asci containing one or two, rarely four, globose to ellipsoidal ascospores.

Sporulation was observed on acetate agar and V8 agar after 7–10 days at 25°C.

Cadaverine-HCl	v	100 ppm Cycloheximide	–
L-Lysine	v	Growth at 37°C	+
Ethylamine-HCl	–		

Co-Q: 6 (Yamada et al. 1976b).

Mol% G+C: 32.0, CBS 2186 (Yarrow & Nakase 1975); 34.1–34.4, 3 strains (von Arx 1977b, 1978).

Origin of the strains studied: DBVPG 6756 (CBS 7662) and DBVPG 6757 (CBS 2186), soil.

Type strain: CBS 2186 (DBVPG 6757), isolated by van der Walt from soil in Mozambique.

Comments: Although the species *transvaalensis* was originally classified under the genus *Saccharomyces* (van der Walt 1956c), a subsequent study showed an absence of interfertility between mating types of *S. transvaalensis* and two strains classified as the most phenotypically similar species, *S. dairenensis* (van der Walt and Liebenberg 1973b). This prompted van der Walt (1978) to create the genus *Pachytichospora* to accommodate *S. transvaalensis* with its distinctive ascospores, which upon examination by transmission electron microscopy (TEM), appeared different from those of the type strain of *S. dairenensis* (van der Walt and Liebenberg 1973b). A recent study of DNA sequence relatedness (Vaughan-Martini and Barcaccia 1996) has demonstrated that while two of the four known strains of *S. transvaalensis* are homologous

to the type strain of *S. castellii*, the other two show an intermediate relationship with both that species and the type strain of *S. dairenensis*. In view of this intermediate position between two unrelated taxa, it was deemed appropriate to reestablish the species *S. transvaalensis* (Vaughan-Martini and Pollacci 1996). This separation is supported by the finding that interspecific rRNA sequence differences between the type strains of *S. castellii*, *S. dairenensis* and *S. transvaalensis* averaged 10% (Kurtzman, personal communication). The same study also noted no intraspecific variation in 600 nucleotides of rRNA between the same strains, which should further justify the abolition of the genus *Pachytichospora*. It should be recognized that it is difficult to clearly separate the taxa *S. castellii*, *S. dairenensis* and *S. transvaalensis* solely on the basis of conventional taxonomic criteria. A definite resolution is possible with the use of techniques of molecular taxonomy such as nucleotide base sequence relatedness as determined by DNA/DNA reassociation experiments, examination of comparable rRNA sequences, or the determination of electrophoretic karyotypes obtained by PFGE (pulsed field gel electrophoresis).

44.14. *Saccharomyces unisporus* Jørgensen (1909)

Synonym:

Saccharomyces mongolicus Naganishi (1928)

Growth in 5% malt extract: After 3 days at 25°C, the cells are globose to short ellipsoidal, (2.5–4.5) × (3.0–6.0) μm, and single or in pairs. After one month at 20°C, a sediment and a ring are present.

Growth on 5% malt agar: After one month at 20°C, the streak culture is cream-colored, flat, usually glossy, smooth, sometimes with light striations, and the margin is entire or undulating.

Growth on the surface of assimilation media: Pellicles are not formed.

Dalmay plate culture on morphology agar: Pseudo-hyphae are not formed.

Formation of ascospores: Vegetative cells are transformed directly into asci containing one, occasionally two, globose to subglobose ascospores.

Sporulation was observed on acetate agar and YM agar after 7–10 days at 25°C.

Fermentation:

Glucose	+	Lactose	–
Galactose	+	Raffinose	–
Sucrose	–	Trehalose	–
Maltose	–	Melibiose	–

Assimilation:

Glucose	+	<i>N</i> -Acetyl-D-glucosamine	–
Galactose	+	Methanol	–
L-Sorbose	–	Ethanol	+
Sucrose	–	Glycerol	–
Maltose	–	Erythritol	–
Cellobiose	–	Ribitol	–
Trehalose	v	Galactitol	–
Lactose	–	D-Mannitol	–
Melibiose	–	D-Glucitol	–
Raffinose	–	α-Methyl-D-glucoside	–
Melezitose	–	Salicin	–
Inulin	–	D-Gluconate	–
Soluble starch	–	DL-Lactate	–

Additional assimilation tests and other growth characteristics:

Cadaverine-HCl	+	100 ppm Cycloheximide	+
L-Lysine	+	1000 ppm Cycloheximide	+
Ethylamine-HCl	+	Growth at 37°C	v

Co-Q: 6 (Yamada et al. 1976b).

Mol% G+C: 32.4–32.7, AJ 4085, AJ 5248, AJ 5253 (T_m : Nakase and Komagata 1971e); 35.4–35.7, DBVPG 6368 (CBS 398), DBVPG 6414 (CBS 399) (BD: Vaughan-Martini and Kurtzman 1988)

Origin of the strains studied: DBVPG 6368 (CBS 398), unknown; DBVPG 6414 (CBS 399), naichin; DBVPG 6429 (CBS 2422), kefir grains; DBVPG 6445 (CBS 3004), feces; DBVPG 6482 (CBS 1543), unknown; DBVPG 6483 (CBS 1575), cheese.

Type strain: CBS 398 (ATCC 10612, DBVPG 6368, IFO 0316, NRRL Y-1556), received from the Carlsberg laboratories in 1924, was designated as the type strain.

Comments: Even though Yarrow and Nakase (1975) noted that *S. unisporus* has many phenotypic similarities with the other species of *Saccharomyces sensu lato* (*sensu* van der Walt 1970d) i.e., *S. castellii*, *S. dairenensis* and *S. servazzii*, *S. unisporus* is easily distinguishable by having predominantly one-spored asci, as well as by the ability to grow on ethylamine, cadaverine and L-lysine as sole nitrogen sources. The results of a DNA reassociation study (Vaughan-Martini and Kurtzman 1988) supported the retention of these taxa as separate biological species since nucleotide sequence similarities between them were never greater than 19%.

Comments on the species included in the complex *Saccharomyces sensu stricto*

The collective group of species denominated as *Saccharomyces cerevisiae* (*sensu* Yarrow 1984a) includes the most industrially exploited microorganisms known to man as well as the organism of choice as a model system of the eukaryotic cell (Mortimer and Schild 1985, Silverman 1987, Clark-Walker 1989). The variable physiological behavior often observed for *Saccharomyces sensu stricto* (Scheda and Yarrow 1966, 1968) has resulted over the

years in the proposal of innumerable new epithets for conspecific strains. Genetic analysis has shown that the variable phenotypic expression exhibited by these strains is the result of the presence of multiple gene loci (Carlson 1987), which can be active, silent or missing, rather than because of the existence of genetically distinct species. It has also been demonstrated that these species, for the most part domesticated as a result of millennia of exploitation in man-created environments, are often polyploid or aneuploid. This explains why conventional mating as a tool for genetic study and strain improvement has been arduous and also why definite identification of a strain of *S. cerevisiae* or some other related species is often an almost impossible task.

A series of DNA hybridization analyses (Rosini et al. 1982b, Vaughan-Martini and Kurtzman 1985, Vaughan-Martini and Martini 1987a, 1993, Vaughan-Martini 1989), as well as traditional genetic studies (Naumov 1986b, Banno and Kaneko 1989) have shown that *Saccharomyces sensu stricto* includes four variably related species: *S. bayanus*, *S. cerevisiae*, *S. paradoxus* and *S. pastorianus*. Intermediate values of nucleotide sequence homology

have been found between some species of this complex: 72% between *S. bayanus* and *S. pastorianus* and about 50% between *S. cerevisiae* and both *S. pastorianus* and *S. paradoxus*. Low nucleotide sequence homology was seen between *S. bayanus* and *S. cerevisiae* and between *S. paradoxus* and *S. bayanus* or *S. pastorianus*. These results were in part confirmed by studies of chromosomal and gene loci polymorphisms (Holmberg 1982, Johnston and Mortimer 1986, Johnston et al. 1988, Nilsson-Tillgren et al. 1981, 1983, 1986, Pedersen 1983, 1986). Later studies of ribosomal RNA sequence divergence (Kurtzman and Robnett 1991) have further supported the hypothesis that this is a group of taxa in the early stages of the speciation process.

Note in proof

James et al. (1997) analyzed relationships among *Saccharomyces* species from divergence in 18S rDNA. Included in this study was the description of two new species of *Saccharomyces*: *S. kunashirensis* James, Cai, Roberts & Collins and *S. martiniae* James, Cai, Roberts & Collins.

45. *Saccharomycodes* E.C. Hansen

M.W. Miller and H.J. Phaff

Diagnosis of the genus

Large, diploid, lemon-shaped (apiculate) or elongate cells, which reproduce by bipolar budding on a very broad base (bud-fission). Pseudomycelium is absent or poorly developed.

The spores are spheroidal with an apparently smooth wall; a narrow subequatorial ledge and irregularly spaced surface nodules may be visible. Asci usually contain four spores, occurring in two pairs; upon germination members of each pair ordinarily conjugate. In some strains spores may germinate without conjugation.

Sugars are fermented. Nitrate is not assimilated. In liquid media a sediment and a ring are formed. Diazonium blue B reaction is negative.

Type species

Saccharomycodes ludwigii E.C. Hansen

Species accepted

1. *Saccharomycodes ludwigii* E.C. Hansen (1904)

Systematic discussion of the species

45.1. *Saccharomycodes ludwigii* E.C. Hansen (1904)

Synonyms:

Saccharomyces ludwigii E.C. Hansen (1889)

Saccharomycodes ludwigii (E.C. Hansen) E.C. Hansen var. *vini* Kroemer & Heinrich (1922)

Saccharomycodes vini (Kroemer & Heinrich) ex Kudryavtsev (1960)

Saccharomycodes bisporus Castelli (1942)

Saccharomycodes ludwigii (E.C. Hansen) E.C. Hansen var. *bisporus* (Castelli) Hjort (1954)

Saccharomycodes lipophora Bachinskaya (1941)

Saënkia bispora Castelli ex Kudryavtsev (1960)

Growth in 5% malt extract: After 3 days at 25°C, the cells are lemon-shaped with blunt tips, sausage-shaped, curved, broad-oval, or elongated with a swelling in the middle, (4–7) × (8–23) μm, and occasionally longer; the cells are single or in pairs and sometimes in groups of three. Reproduction occurs by bipolar budding on a broad base, followed by fission (bud-fission). Cells in the process of budding resemble bowling pins (Fig. 158). A sediment

and a slight ring are present. After approximately one month, a sediment and a ring are in evidence.

Growth on 10% malt agar: After 3 weeks the streak culture is cream-colored to tan, nearly smooth, semi-glossy, and low convex with an irregular border.

Dalmat plate culture on potato agar: Aerobically there are a few short chains of cells. Under the coverslip the pseudomycelium is somewhat better developed, consisting of branched chains of elongated cells.

Formation of ascospores: The spores are spheroidal, smooth with a narrow subequatorial ledge which is visible in sections viewed in the electron microscope (Kreger-van Rij 1969b); in freeze-fracture replicas the outer surface of the spores shows irregularly spaced nodules (Simmons and Ahearn 1985); usually there are four spores per ascus in two groups of two (Fig. 159). Some strains produce two spores per ascus. Ascus walls do not rupture or lyse when the spores are mature. For germination of spores see Diagnosis of the genus.

Good sporulation was obtained on Gorodkova agar, in 3 days at 18°C.

Fig. 158. *S. ludwigii*, CBS 821. Vegetative cells grown on 10% malt agar after 3 days. Bar = 10 μm.

Origin of the strains studied: CBS 821, diploid strain from A.J. Kluyver; CBS 2624, type strain of *Saccharomycodes bisporus* Castelli; 2 diploids, 3 short-celled haploids, 3 long-celled haploids from Carlsberg Laboratory in Copenhagen; UCD-FST 72-128, exudate of *Quercus gambelii*, Arizona; UCD-FST 77-13, exudate from swamp chestnut oak, *Quercus prinus* (= *Q. michauxii*), Virginia, U.S.A.

Type strain: CBS 821 (ATCC 11313), origin M.W. Beijerinck.

Species not accepted in the genus

We did not accept *Saccharomycodes sinensis* Yue (1977) because its characteristics are very different from those of *Saccharomycodes* E.C. Hansen. It does not assimilate ammonium sulfate as a sole source of nitrogen but requires a complex mixture of amino acids as is present in yeast autolyzate. Although the yeast reproduces by a kind of bud fission, the cells are only about one fourth as long as those of *S. ludwigii*. We were unable to detect ascospore formation on Gorodkova agar or on Kleyn's acetate agar as recommended by Yue (1977). We believe that further studies are required to place this species in an appropriate genus.

Note in proof

The nucleotide sequences for *Saccharomycodes sinensis* and *Nadsonia fulvescens* var. *elongata* are identical in the variable 600-nucleotide 5' end of the large subunit rRNA gene, suggesting that the two taxa are conspecific (Kurtzman and Robnett, manuscript in preparation).

46. *Saccharomyopsis* Schiöningg

C.P. Kurtzman and M.Th. Smith

Diagnosis of the genus

Abundant development of true mycelium, often with blastoconidia. Budding cells are present and may be formed on a broad or a narrow base. Arthroconidia are produced by some species. Hyphal septa are usually multiperforate, but may be limited to a single central pore.

Asci are usually attached to hyphae and produce 1–4, or rarely 8, ascospores. Ascospores may be hat-shaped, reniform with terminal appendages, spheroidal or ellipsoidal, and may have one or more ledges; surfaces may be smooth or roughened.

Some species are fermentative. Nitrate is not assimilated. Coenzyme Q-8 is the predominant ubiquinone. Diazonium blue B reaction is negative.

Type species

Saccharomyopsis capsularis Schiöningg

Species accepted

1. *Saccharomyopsis capsularis* Schiöningg (1903)
2. *Saccharomyopsis crataegensis* Kurtzman & Wickerham (1973)
3. *Saccharomyopsis fermentans* (C.-F. Lee, F.-L. Lee, Hsu & Phaff) Kurtzman & Robnett (1995)
4. *Saccharomyopsis fibuligera* (Lindner) Klöcker (1924)
5. *Saccharomyopsis javanensis* (Klöcker) Kurtzman & Robnett (1995)
6. *Saccharomyopsis malanga* (Dwidjoseputro) Kurtzman, Vesonder & Smiley (1974)
7. *Saccharomyopsis schoenii* (Nadson & Krasil'nikov) Kurtzman & Robnett (1995)
8. *Saccharomyopsis selenospora* (Nadson & Krasil'nikov) Kurtzman & Robnett (1995)
9. *Saccharomyopsis synnaedendra* D.B. Scott & van der Walt (1971)
10. *Saccharomyopsis vini* (Kreger-van Rij) van der Walt & D.B. Scott (1971)

Systematic discussion of the species

46.1. *Saccharomycopsis capsularis* Schiöningg (1903)

Synonyms:

Endomyces capsularis (Schiöningg) Guilliermond (1909)

Williopsis capsularis (Schiöningg) Zender (1925b)

Endomyces capsularis (Schiöningg) Dekker (Stelling-Dekker 1931)

Prosaccharomyces capsularis (Schiöningg) Novák & Zsolt (1961)

Growth on 5% malt extract agar: After 3 days at 25°C, budding cells are spheroidal, ellipsoidal or elongate, (3.0–11.1) × (7.0–15.8) μm, and single or in pairs. Growth is dull, tannish-white and butyrous to mycelial.

Growth on the surface of assimilation media: Pellicles are formed by some isolates.

Dalmou plate culture on morphology agar: After 7 days at 25°C, growth under the coverglass shows abundant, but sparingly branched true hyphae and infrequent pseudohyphae. Aerobic growth is tannish-white, dull, and mycelial with surface striations. Colonies are low convex with smooth to broadly lobed margins. A mildly acidic odor is present.

Formation of ascospores: Asci may form terminally on the tips of hyphae or they may be intercalary following conversion of a hyphal cell to an ascus (Fig. 160). Each ascus produces two to eight spheroidal ascospores that usually have a subequatorial ring. Asci become deliquescent at maturity. Kreger-van Rij (1970b) reported that single-ascospore isolates produce ascosporegenous colonies indicating the species to be homothallic.

Ascospores were observed on YM and Difco yeast morphology agars after 5–10 days at 25°C.

Fermentation:

Glucose	+	Lactose	-
Galactose	-	Raffinose	-
Sucrose	-	Trehalose	-
Maltose	+/w		

Fig. 160. *S. capsularis*, CBS 2519. Asci with ascospores. Asci may arise from hyphae or hyphal cells may be converted to asci. On YM agar, after 12 days, 25°C. Bar = 5 μm.

Assimilation:

Saccharate	–	Growth at 37°C	–
10% NaCl/5% glucose	+/w		

Co-Q: 8, CBS 5063 (Yamada et al. 1976b).

Mol% G + C: 43.4, CBS 5063 (T_m : Nakase and Komagata 1971g).

Origin of the strains studied: CBS 2519 (NRRL Y-17639) originally from H. Schnegg, Germany, substrate unknown; CBS 5063 (NRRL Y-7486), Harden's strain 127 originally from the National Collection of Type Cultures (UK), but received by CBS from the University of Hiroshima; CBS 5638 (NRRL Y-7487), from pollen of *Xylocopa caffra*, South Africa, J.P. van der Walt.

Type strain: CBS 2519, designated as neotype by Lodder and Kreger-van Rij (1952).

46.2. *Saccharomycopsis crataegensis* Kurtzman & Wickerham (1973)**Synonym:**

Endomycopsella crataegensis (Kurtzman & Wickerham) von Arx (van der Walt and von Arx 1980)

Growth on 5% malt extract agar: After 3 days at 25°C, budding cells are ellipsoidal to elongate and frequently tapered on one end. The cells measure (2.0–3.0) × (4.0–9.5) μm, and often occur singly. Growth is dull and sometimes powdery, tannish-white and butyrous to mycelial.

Growth on the surface of assimilation media: Heavy pellicles are formed.

Dalmau plate culture on morphology agar: After 7 days at 25°C, growth under the coverglass shows abundant true hyphae with blastoconidia. Pseudohyphae are less frequent. Aerobic growth is grayish-white, dull, powdery and mycelial. Single colonies are low convex with entire to broadly lobed margins. A strong, fragrant odor is produced.

Formation of ascospores: This species is heterothallic and all known strains have been isolated as haploid mating types. Conjugation begins within 12 h following mixing of complementary mating types and ascospores may be observed as early as 24 h after pairing. Asci are ellipsoidal and either borne directly on hyphae or supported by short stalks. Occasionally, chains of two to four asci may be formed. Asci form two ascopores and about half of the asci eventually deliquesce. Ascospores are elongated, usually slightly flattened, have a roughened surface, and a median longitudinal ledge (Fig. 161).

Ascospores were observed on YM and 5% malt extract agars after 1–7 days at 25°C.

Fermentation:

Glucose	w/–	Lactose	–
Galactose	–	Raffinose	–
Sucrose	–	Trehalose	–

10% NaCl/5% glucose	–		

Co-Q: Not determined.

Mol% G + C: 39.1, CBS 6447 (BD: Kurtzman, unpublished).

Fig. 161. *S. crataegensis*, CBS 6447 × CBS 6448. Ascus with ascospores. On YM agar, after 2 weeks, 25°C. Bar = 5 μm.

Origin of the strains studied: NRRL YB-192, Concord grapes (*Vitis labrusca*), Peoria, Illinois; NRRL Y-5902 (CBS 6447), NRRL Y-5903, NRRL Y-5904 (CBS 6448), NRRL Y-5910, from fallen hawthorne (*Crataegus* sp.) fruits, Peoria, Illinois.

Complementary mating types: NRRL YB-192, NRRL Y-5902, mating type *a*; NRRL Y-5903, NRRL Y-5904, NRRL Y-5910, mating type *α*.

Type strain: CBS 6447, from fallen hawthorne fruits.

Comments: *S. crataegensis* and *S. vini* have similar habitats and co-occur on the fruits of grapes. Shepherd et al. (1987) and Bolen et al. (1992) reported some strains of *S. crataegensis* to contain linear DNA plasmids and/or double-stranded RNA plasmid-like molecules.

46.3. *Saccharomycopsis fermentans* (C.-F. Lee, F.-L. Lee, Hsu & Phaff) Kurtzman & Robnett (1995)

Synonym:

Arthroascus fermentans C.-F. Lee, F.-L. Lee, Hsu & Phaff (1994a)

Growth on 5% malt extract agar: After 3 days at 25°C, the cells are spheroidal, ellipsoidal or elongate, (2.5–5.0)×(5.0–17.3)µm, and often tapered. The cells are mostly single. Budding may be on either a narrow or rather broad base. Growth is somewhat butyrous and tannish-white in color.

Growth on the surface of assimilation media: Pellicles are not formed.

Dalmou plate culture on morphology agar: After 7 days at 25°C, growth under the coverglass shows abundant, moderately branched true hyphae, but with few blastoconidia. Pseudohyphae are infrequent. Aerobic growth is tannish-white, dull, and low with fine striations. Margins are finely lobed with a narrow band of subaerial hyphae. A faint odor of esters is present.

Formation of ascospores: Asci are spindle-shaped and form directly from single cells or following conjugation between two independent cells. Asci become deliquescent at maturity. Each ascus forms two to four ascospores that are oblate-ovoidal and with a narrow equatorial ridge (Fig. 162). Scanning electron microscopy suggests some roughening of spore surfaces (Lee et al. 1994a). Heat treatment of ascosporegenous cultures indicates the species to be homothallic (Lee et al. 1994a).

Ascospores were observed on 5% malt extract, YM, and GPY agars after 3–7 days at 25°C.

Fermentation:

Glucose	+	Lactose	–
Galactose	–	Raffinose	–
Sucrose	–	Trehalose	–
Maltose	–		

Fig. 162. *S. fermentans*, CBS 7830. Asci with ascospores. After 1 week on 5% malt extract agar, 25°C. Bar = 5µm.

Assimilation:

Glucose	+	<i>N</i> -Acetyl-D-glucosamine	–
Galactose	–	Methanol	–
L-Sorbose	v	Ethanol	+
Sucrose	–	Glycerol	+
Maltose	–	Erythritol	–
Cellobiose	–	Ribitol	–
Trehalose	s	Galactitol	–
Lactose	–	D-Mannitol	–
Melibiose	–	D-Glucitol	–
Raffinose	–	α-Methyl-D-glucoside	–
Melezitose	–	Salicin	–
Inulin	–	D-Gluconate	–
Soluble starch	–	DL-Lactate	–
D-Xylose	–	Succinate	v
L-Arabinose	–	Citrate	–
D-Arabinose	–	Inositol	–
D-Ribose	–	Hexadecane	–
L-Rhamnose	–	Nitrate	–
D-Glucosamine	–	Vitamin-free	–

Additional assimilation tests and other growth characteristics:

2-Keto-D-gluconate	–	Starch formation	–
5-Keto-D-gluconate	–	Gelatin liquefaction	–
Saccharate	–	Growth at 37°C	–
10% NaCl/5% glucose	–		

Co-Q: 8, CBS 7830, 2 additional strains (Lee et al. 1994a).

Mol% G+C: 36.5–37.5, CBS 7830, CBS 8731, CBS 8732 (HPLC: Lee et al. 1994a).

Origin of the strains studied: CBS 7830 (CCRC 22530, NRRL Y-17710), soil from a papaya orchard, Taiwan; CBS 7831, CBS 7832, soil from carambola orchards, Taiwan.

Type strain: CBS 7830.

Comments: In the original description, *S. fermentans* was assigned to the genus *Arthroascus*, but rDNA sequence comparisons showed *Arthroascus* to be a synonym of *Saccharomycopsis* (Kurtzman and Robnett 1995). Comparisons of nDNA complementarity showed ca. 30% relatedness between *A. fermentans* and *A. javanensis*, thus demonstrating the two taxa to be sibling species (Lee et al. 1994a).

46.4. *Saccharomycopsis fibuligera* (Lindner) Klöcker (1924)

Synonyms:

Endomyces fibuliger Lindner (1907)

Endomyces fibuliger (Lindner) Dekker (Stelling-Dekker 1931)

Pichia fibuliger (Lindner) Boidin, Pignal, Lehodey, Vey & Abadie (1964)

Endomyces lindneri Saito (1913)

Saccharomycopsis lindneri (Saito) Klöcker (1924)

Endomyces fibuliger (Lindner) Dekker var. *lindneri* (Saito) Dekker (Stelling-Dekker 1931)

Endomyces hordei Saito (1914)

Saccharomycopsis hordei (Saito) Klöcker (1924)

Endomyces fibuliger (Lindner) Dekker var. *hordei* (Saito) Dekker (Stelling-Dekker 1931)

Candida lactosa Dwidjoseputro & Wolf (1970)

?*Endomyces bubodii* Sakai & Caldo (1985) nom. nud.

Botryosaurus cladosporoides Martínez, González, Abarca & Cabañas (1990)

Growth on 5% malt extract agar: After 3 days at 25°C, budding cells are ovoidal to elongate, (2.2–5.1)×(3.3–12.5) μm, sometimes tapered, and occur singly, or less frequently in pairs. Growth is dull white, sometimes powdery, and mycelial. Some strains are noticeably more mycelial than other strains.

Growth on the surface of assimilation media: Pellicles are formed by some strains.

Dalmáu plate culture on morphology agar: After 7 days at 25°C, growth under the coverglass shows abundant true hyphae with varying numbers of blastoconidia, as well as some pseudohyphae. Aerobic growth is dull and gray-white with a somewhat raised center. Tufts of hyphal outgrowths on the colony surface give a diagnostic roughness that generally allows immediate species identification. A pleasant ester-like odor is produced.

Formation of ascospores: Asci are spheroidal to ovoidal and may be free, having formed from a single vegetative cell, or attached to the ends or sides of hyphae. Occasionally, asci arise on protuberances from two adjacent hyphal cells, but generally asci are un-conjugated. Each ascus forms two to four hat-shaped ascospores that are liberated at maturity (Fig. 163). Kreger-van Rij (1970b) reported that single-spore isolates form ascosporegenous colonies, indicating the species to be homothallic.

Ascospores were observed on YM, 5% malt extract, V8 or potato-dextrose agars after 3–30 days at 25°C.

Fig. 163. *S. fibuligera*, CBS 6266. Asci and ascospores. After 2 days on potato-dextrose agar at 25°C. A curved crystal of 2-D-hydroxy fatty acids is located to the left of the scale bar. Bar=5 μm.

Fermentation:

Co-Q: 8, AJ 4270 (Yamada et al. 1976b).

Mol% G+C: 39.3, AJ 4270 (T_m : Nakase and Komagata 1970b).

Origin of the strains studied: Wheat flour, U.S.A. (6); chalky bread, U.S.A., Europe (4); yeast cake, U.S.A., Asia (4); macaroni, U.S.A. (9); ensiled maize, U.S.A. (2); beer starter, Tibet (3); lao chao, China (11); murcha, Nepal (17); wine koji, Korea (1); thumba, India (1); ragi, Indonesia (17); bubod, Philippines (13); chica, Bolivia (2); unknown (16).

Type strain: CBS 2521 (NRRL Y-2388), from chalky rye bread, Germany.

Comments: *S. fibuligera* is found worldwide in starchy substrates and is the major amylolytic yeast in indigenous food fermentations using rice and cassava (Hesseltine and Kurtzman 1990). Wickerham et al. (1944) were the first to report starch hydrolysis by *S. fibuligera*, and this discovery formed the basis of the Swedish Symba yeast process in which a mixed culture of *S. fibuligera* and *Candida utilis* is used to break down potato processing wastes to produce yeast cells for cattle feed (Jarl 1969).

Cultures of *S. fibuligera* commonly exhibit aggregates of crystals when viewed under the light microscope. Kurtzman et al. (1973b) determined that the crystals are comprised of mixtures of C₁₄–C₁₈ 2-D-hydroxy fatty acids. Similar crystalline mixtures are found in cultures of *Pichia sydowiorum* (Vesonder et al. 1970).

In the current treatment, *Endomycopsis bubodii* is given as a possible synonym of *S. fibuligera*. Cultures of *E. bubodii* are unavailable, but the description of this species (Sakai and Caldo 1985) suggests that it may be conspecific with *S. fibuligera*.

46.5. *Saccharomycopsis javanensis* (Klöcker) Kurtzman & Robnett (1995)

Synonyms:

Endomyces javanensis Klöcker (1909b)
Schwanniomyces javanensis (Klöcker) Zender (1925b)
Endomycopsis javanensis (Klöcker) Dekker (Stelling-Dekker 1931)
Schizosaccharomyces javanensis (Klöcker) Streiblová (1963)
Arthroascus javanensis (Klöcker) von Arx (1972)

Growth on 5% malt extract agar: After 3 days at 25°C, the cells are elongated and often tapered, (2.5–5.0) × (7.4–25.0) μm, and occur singly or in pairs. Budding is generally on a broad base. Growth is tannish-white and sparingly butyrous.

Growth on the surface of assimilation media: Pellicles are not formed.

Dalmu plate culture on morphology agar: After 7 days at 25°C, growth under the coverglass shows moderately branched true hyphae which are devoid of blastoconidia. Pseudohyphae are not present. Aerobic growth is somewhat butyrous, white, semi-glistening, and low convex with a depressed center. Margins are finely lobed. A faint acidic odor is present.

Fig. 164. *S. javanensis*, CBS 2555. Asci with ascospores. After 2 days on 5% malt extract agar at 25°C. Bar = 5 μm.

Formation of ascospores: Ascus formation is generally preceded by conjugation which may occur between independent cells or between adjacent cells following dissolution of the cross wall (Kreger-van Rij and Veenhuis 1976a). One to four ascospores form in each ascus, and asci often become spindle-shaped (Fig. 164). The ascospores, which are released at maturity, are often warty and either spheroidal or subspheroidal with an equatorial or subequatorial ledge.

Ascospore germination was observed on 5% malt extract, V8 and YM agars after 3–7 days at 25°C.

Fermentation: absent.

Assimilation:

Glucose	+	<i>N</i> -Acetyl-D-glucosamine	+
Galactose	–	Methanol	–
L-Sorbose	+	Ethanol	+

Co-Q: 8, CBS 2555 (Yamada et al. 1976b).

Mol% G + C: 31.5, 31.0, CBS 2555 (T_m : Nakase and Komagata 1971g, Smith et al. 1990a).

Origin of the strains studied: CBS 2555 (NRRL Y-1483), from Guilierrmond and attributed to be Klöcker's original strain from soil, Java.

Type strain: CBS 2555.

46.6. *Saccharomycopsis malanga* (Dwidjoseputro) Kurtzman, Vesonder & Smiley (1974)

Synonym:

Hansenula malanga Dwidjoseputro (Dwidjoseputro and Wolf 1970)

Growth on 5% malt extract agar: After 3 days at 25°C, budding cells are mostly single, and spheroidal, (3.2–6.0) μm, or ellipsoidal to elongate, (3.0–6.0) × (8.0–13.0) μm, with many of the elongated cells somewhat tapered. Growth is dull, tannish-white, and often has a somewhat wet appearance.

Growth on the surface of assimilation media: Pellicles are formed by some strains.

Dalmu plate culture on morphology agar: After 7 days at 25°C, growth under the coverglass shows abundant, but sparingly branched true hyphae as well as pseudohyphae. Aerobic growth is dull tannish-white, and often appears somewhat wet. Colonies are low convex, striated, and margins are lobed and fringed with hyphae. A faintly acidic odor is present.

Formation of ascospores: Asci are spheroidal and may be free, but are usually borne laterally or terminally on hyphae, and may be single or in clusters of up to ten. Ascospores are hat-shaped (Fig. 165). Usually two are formed in each ascus and they are released at maturity. Single-spore isolates gave ascospore germination

colonies indicating that either the species is homothallic or that the spores are diploid.

Ascosporeulation was observed on YM and 5% malt extract agars after 3–7 days at 25°C.

Fig. 165. *S. malanga*, CBS 6531. Asci with ascospores. Note angular cluster of 3-D-hydroxypalmitic acid crystals, lower right. After 3 days on YM agar at 25°C. Bar = 5 µm.

Co-Q: Not determined.

Mol% G + C: Not determined.

Origin of the strains studied: Ragi, Indonesia (2); Chinese yeast ball (chiu-yüeh), the commercial starter

used for making lao-chao, a fermented rice product, Taiwan (7).

Type strain: CBS 6267 (NRRL Y-7175), the type strain of *Hansenula malanga*, isolated from ragi-tape, Indonesia, by Dwidjoseputro and Wolf (1970).

Comments: *S. malanga* was initially described as a species of *Hansenula* by Dwidjoseputro (Dwidjoseputro and Wolf 1970) because it was believed that this species assimilated nitrate as a sole source of nitrogen. *S. malanga* and *S. fibuligera* are common to starchy fermented foods, but the two species are readily separated by assimilation tests (Table 38) and from culture odor. *S. fibuligera* has a strong fruity odor whereas *S. malanga* has a faint acidic smell.

Cultures of *S. malanga* are usually characterized by the presence of crystals. Kurtzman et al. (1974) identified 3-D-hydroxypalmitic acid as a major component of these crystals.

46.7. *Saccharomycopsis schoenii* (Nadson & Krasil'nikov) Kurtzman & Robnett (1995)

Synonyms:

- Endomyces schoenii* Nadson & Krasil'nikov (1932)
Arthroascus schoenii (Nadson & Krasil'nikov) Bab'eva, Vustin, Naumov & Vinovarova (1985)
Pichia nonfermentans Nakase (1971b)

Growth on 5% malt extract agar: After 3 days at 25°C, the cells are mostly elongated, (2.5–5.0) × (5.0–24.7) µm, and may be curved or with irregular constrictions. Some cells show short, hair-like extensions. Cells occur singly and in pairs. Budding is on a broad base. Growth is tannish-white and somewhat butyrous.

Growth on the surface of assimilation media: Pellicles are not formed.

Dalmu plate culture on morphology agar: After 7 days at 25°C, growth under the coverglass shows moderately branched true hyphae without blastoconidia. Pseudohyphae are not present. Aerobic growth is tannish-white, faintly glistening with fine striations, somewhat butyrous, and oppressed except for a slightly raised center. Margins are finely lobed. A faint acidic odor is present.

Formation of ascospores: Ascus formation is preceded by conjugation between independent cells or between adjacent hyphal cells. Asci are usually spindle-shaped and deliquescent. One to four ascospores are formed in each ascus, and the spores are spheroidal or subspheroidal with a smooth surface and an equatorial or subequatorial ledge (Fig. 166).

Ascospores were observed on 5% malt extract, V8, YM and rice agars after 3–7 days at 25°C.

Fig. 166. *S. schoenii*, CBS 2556. Asci with ascospores. After 4 days on 5% malt extract at 25°C. Bar = 5 µm.

Fermentation: absent.

Co-Q: 8, CBS 7223 (Lee et al. 1994a).

Mol% G+C: 34.1, CBS 6423 (T_m : Nakase 1971b); 31.4–35.5, CBS 7223, 4 additional strains (T_m : Smith et al. 1990a).

Origin of the strains studied: CBS 7223 (VKM 1073, NRRL Y-17595) exudate of oak (*Quercus* sp.), de Hoog from VKM; CBS 2556 (NRRL Y-2389), slime flux of oak (*Quercus* sp.), Phaff; CBS 6423 (IFO 1579), soybean protein factory, Nakase, type strain of *P. nonfermentans*; CBS 6449, rotten tree trunk, van der Walt; CBS 7048, slime flux of oak (*Quercus* sp.), Bab'eva; CBS 7425, sour rot of grapes, Shann.

Type strain: CBS 7223.

Comments: In 1954, Kursanov noted the similarity of *Endomyces schoenii* with *Arthroascus javanensis*. Bab'eva et al. (1985) and Naumov et al. (1985b) concluded on the basis of genetic studies that *E. schoenii*

should be assigned to *Arthroascus*, and that it is distinct from *A. javanensis*, thereby resulting in the reclassification of *E. schoenii* as *Arthroascus schoenii* (Bab'eva et al. 1985). The validity of this new combination was substantiated by Smith et al. (1990a) who showed low nDNA relatedness between *A. javanensis* and *A. schoenii*. In further comparisons, Smith et al. (1990a) showed high nDNA relatedness between *A. schoenii* and *Pichia nonfermentans*, a species earlier considered a synonym of *A. javanensis* by von Arx et al. (1977) on the basis of phenotypic similarity. Lee et al. (1994a) described a third species of *Arthroascus*, *A. fermentans*, and demonstrated that it had low nDNA relatedness with *A. javanensis* and *A. schoenii*. Kurtzman and Robnett (1994a, 1995) showed from rRNA/rDNA sequence comparisons that species of *Arthroascus* were closely related to members of *Saccharomycopsis* and proposed the transfer of *Arthroascus* species to *Saccharomycopsis*. This transfer is discussed further under Comments on the genus.

46.8. *Saccharomycopsis selenospora* (Nadson & Krasil'nikov) Kurtzman & Robnett (1995)

Synonyms:

Guilliermondella selenospora Nadson & Krasil'nikov (1928)

Endomyces selenospora (Nadson & Krasil'nikov) Dekker (Stelling-Dekker 1931)

Growth on 5% malt extract agar: After 3 days at 25°C, the cells are ovoidal to long ellipsoidal, (2.0–5.0) × (5.0–15.0) µm, and occur singly or in pairs. Budding may be on either a narrow or a somewhat broad base. Thin, short cellular extensions often occur giving cells a knobby appearance. Growth is dull and roughened.

Growth on the surface of assimilation media: Pellicles are not formed.

Dalmau plate culture on morphology agar: After 7 days at 25°C, growth under the coverglass shows abundant, moderately branched true hyphae with few blastoconidia. Pseudohyphae are infrequent. Aerobic growth is dull, white and mycelial with deep striations that have a segmented appearance. Margins are finely lobed with a narrow band of subaerial mycelium. An acidic, ester-like odor is present.

Formation of ascospores: Asci are somewhat spindle-shaped and either form at hyphal tips or they can be intercalary. Occasionally, asci form between adjacent hyphae giving the impression of having arisen following conjugation. Ascospores are spheroidal, ovoidal or reniform and those of some strains have terminal appendages that are extensions of the cell wall (Kreger-van Rij and van der Walt 1963) (Fig. 167). Four spores are usually formed in each ascus and asci deliquesce at maturity. Kreger-van Rij (1970b) reported that single-spore isolates are ascosporegenous indicating the species to be homothallic.

Ascospores were observed on YM agar after 4–7 days at 25°C.

Fig. 167. *S. selenospora*, CBS 2563. An ascus with ascospores. After 10 days on YM agar at 25°C. Bar = 5 µm. Inset: Free ascospores showing terminal extensions of the spore wall. Bar = 1 µm.

Co-Q: 8, CBS 2562 (Yamada et al. 1976b).

Mol% G + C: 30.2, S.A. Meyer (unpublished).

Origin of the strains studied: CBS 2562 (NRRL Y-1357) was originally from Guillaiermond, but the source of isolation is unknown; CBS 2563 (NRRL Y-17724) was isolated from tanning fluid in France and originally supplied by J. Boidin.

Type strain: CBS 2562.

46.9. *Saccharomycopsis synnaedendra* D.B. Scott & van der Walt (van der Walt and D.B. Scott 1971d)

Synonyms:

Botryoascus synnaedendus (D.B. Scott & van der Walt) von Arx (1972)

Pichia microspora Batra (1971)

Growth on 5% malt extract agar: After 3 days at 25°C, the cells are infrequently spheroidal, but usually ellipsoidal to elongate, (2.0–4.0) × (3.0–5.0) µm, often tapered, and occur singly, in pairs, or in small clusters. Growth is tannish-white and mycelial.

Growth on the surface of assimilation media: Some strains form pellicles.

Dalmau plate culture on morphology agar: After 7 days at 25°C, growth under the coverglass shows abundant, well-branched true hyphae that are devoid of blastoconidia. Pseudohyphae are rare and often only a few cells in length. Aerobic growth is dull, tannish-white, convoluted and mycelial. Margins are finely lobed. A faint acidic odor is present.

Formation of ascospores: Asci may be free or form terminally on the tips of hyphae, either singly or in chains of two or three, or hyphal cells may develop into asci. Asci are unconjugated, but conjugations between hyphae as well as between yeast cells are often seen. Each ascus contains two to four hat-shaped ascospores that are liberated at maturity (Fig. 168). It is not known whether the species is homothallic or heterothallic, but germinating ascospores often conjugate with each other raising the possibility of heterothallism.

Ascospores were observed on 5% malt extract and potato-dextrose agars after 3–7 days at 25°C.

Fermentation: absent.

Assimilation:

Co-Q: 8, CBS 6161 (Yamada et al. 1976b).

Mol% G + C: 42.0, (S.A. Meyer, unpublished data).

Origin of the strains studied: CBS 6161 (NRRL Y-7466) tunnel of *Platypus externedentatus*, South Africa, J.P. van der Walt; CBS 6393 (NRRL Y-7404), type strain of *Pichia microspora*, from *Crossotarsus wollastoni* in *Dipterocarpus indicus*, India, L.R. Batra.

Type strain: CBS 6161.

Comments: In contrast to the original description of *S. synnaedendra* by Scott and van der Walt (in van der Walt and Scott 1971d), von Arx (1972) reported the absence of budding yeast cells in cultures of this species. Because members of the genus *Saccharomycopsis* typically form budding cells, von Arx (1972) described the genus *Botryoascus* to accommodate *S. synnaedendra*. Upon examining cultures of *S. synnaedendra*, Kreger-van Rij (1984f) detected budding cells and rejected the genus *Botryoascus*. Kurtzman and Robnett (1994a, 1995) compared rRNA/rDNA sequences from all known species of hyphal yeasts and found *S. synnaedendra*, as well as the other *Saccharomycopsis* species accepted in the present treatment, to be members of a single clade. Consequently, these data show that *Botryoascus* is not phylogenetically separate from *Saccharomycopsis*.

46.10. *Saccharomycopsis vini* (Kreger-van Rij) van der Walt & D.B. Scott (1971d)**Synonyms:**

Endomycopsis vini Kreger-van Rij (1964a)

Endomycopsella vini (Kreger-van Rij) von Arx (van der Walt and von Arx 1980)

Growth on 5% malt extract agar: After 3 days at 25°C, budding cells are ovoidal to elongate and often tapered. Budding cells measure (1.9–4.0) × (3.8–14.1) μ m,

and occur singly, in pairs, and in small clusters. Growth is dull, tannish-white, and butyrous to mycelial.

Growth on the surface of assimilation media: Pellicles are formed on the surfaces of some media.

Dalmat plate culture on morphology agar: After 7 days at 25°C, growth under the coverglass shows abundant moderately branched true hyphae with occasional blastoconidia. Pseudohyphae are infrequent. Aerobic growth is tannish-white and dull with a white, powdery periphery of hyphae. Margins are broadly lobate. A faint, fruity odor is present.

Formation of ascospores: Asci are spheroidal to ellipsoidal and are commonly borne on short sterigma on the tips and sides of hyphal cells. Conjugation often occurs between cells before ascus formation. Asci are persistent and contain one to four spheroidal spores that have an equatorial ledge as well as a subequatorial ledge (Fig. 169). Wart-like protuberances on spore surfaces can be seen by SEM (Kurtzman and Wickerham 1973). Single-ascospore isolates give ascosporegenous colonies indicating the species to be homothallic.

Ascospore formation was observed on YM, 5% malt extract, and yeast morphology agars after 5–7 days at 25°C.

Type strain: CBS 4110, from a grape, Chile.

Comments on the genus

The history of the genus *Saccharomyces* is perhaps the most convoluted of any of the ascomycetous yeast genera. Many of the species currently accepted in *Saccharomyces* were originally assigned to *Endomyces* Reess, a genus characterized by formation of true hyphae. Yeast phases of some of the species result from budding (blastoconidia), whereas those of the other species are from arthroconidium formation (fission). Stelling-Dekker (1931) used this morphological distinction to subdivide *Endomyces* and placed the budding species in the newly described genus *Endomyces* Dekker while reserving *Endomyces* for those species that form only arthroconidia. A number of other mycelial species, such as *Pichia bisporea*, *P. burtonii*, *Ambrosiozyma monospora* and *A. platypodis*, were later assigned to *Endomyces* by various authors.

In 1971, van der Walt and Scott (1971d) pointed out that *Endomyces* Dekker was illegitimate and reinstated *Saccharomyces* Schöning in its original context (i.e., presence of budding cells, true septate mycelium, and ascospores with double membranes) for placement of certain of the *Endomyces* species. Shortly thereafter, van der Walt (1972) described the genus *Ambrosiozyma* for mycelial species with dolipore-like septa. Von Arx (1972) promptly emended species assignments in the genus by describing *Hormoascus* for nitrate-assimilating species of *Ambrosiozyma*. Later, van der Walt and von Arx (1985) emended *Hormoascus* to include both nitrate-assimilating and non-assimilating species. *Botryoascus* was described for *Saccharomyces synnaedendra*, a species von Arx (1972) believed not to produce budding yeast cells, and *Arthroascus* was described for *Endomyces (Endomyces) javanensis* which forms spheroidal ascospores and buds on a broad base (von Arx 1972). Later, van der Walt and von Arx (1980) transferred

Saccharomyces lipolytica to the genus *Yarrowia*, and *S. vini* and *S. crataegensis* to *Endomycesella*, a genus known only from the illustrations of Boedijn (1960). *Saccharomyces fibuligera* was returned to *Endomyces* in a paper aptly titled "The adventures of the yeast genus *Endomyces* Dekker" (von Arx and Yarrow 1984).

The delimitation of *Endomyces* from *Dipodascus* and from *Saccharomyces* and its synonyms has been controversial for a number of reasons. The phylogenetic significance of blastoconidium and arthroconidium formation has been interpreted many ways, as has the significance of ascospore morphology and the ultrastructure of hyphal septa. For example, von Arx and van der Walt (1987) aligned genera of the Endomycetales primarily on the basis of ascospore shape and their possible relatedness to members of the euascomycetes. Additionally, the characteristics of *Endomyces decipiens*, the type species of the Order Endomycetales, are known only from the drawings of Brefeld (von Arx 1972, von Arx and Yarrow 1984) and subject to wide interpretation. In an effort to preserve the nomenclatural stability of the Endomycetales, Redhead and Malloch (1977) designated as neotype a specimen identified as *Endomyces decipiens* that was found on *Agaricus melleus*.

Kurtzman and Robnett (1994a, 1995) approached the taxonomic dilemma of the Endomycetales from a molecular phylogenetic perspective. Partial sequences of rRNA/rDNA were compared from the type species of all cultivatable yeast genera as well as from all known species of the mycelial yeasts. These data demonstrated that the yeasts and yeastlike taxa form a clade separate from *Schizosaccharomyces*, *Taphrina/Protomyces*, and the euascomycetes. The rDNA analyses also showed that a strain identified as *Endomyces decipiens* aligned with the yeast clade, but a strain identified as *Endomyces scopularum* proved to be a euascomycete, thus raising doubts about the phylogenetic affinities of the Order Endomycetales and providing a reason for use of the Order Saccharomycetales for those taxa traditionally assigned to the Endomycetales.

The preceding phylogenetic analysis demonstrated that species accepted in the present treatment of *Saccharomyces* form a distinct clade that is separate from other mycelial genera (Fig. 170) as well as from such species as *Pichia burtonii*, *P. scolytii*, *P. bisporea* and *P. wickerhamii* (C.P. Kurtzman and C.J. Robnett, manuscript in preparation). Members of *Saccharomyces* show considerable species-specific variation in the shape of their ascospores, which may be hat-shaped (galeate) or spheroidal to elongate, and with or without equatorial ledges or short polar appendages. Asci are generally spheroidal to ellipsoidal and either free or attached to hyphae. Species previously assigned to *Arthroascus* and *Guilliermondella* are morphologically distinguished from one another by ascospore shape and from the remainder of the species in *Saccharomyces* by the appearance of their asci, which are often transformed hyphal cells

Fig. 170. A phylogenetic tree derived from maximum parsimony analysis depicting the mycelial ascomycetous yeasts, yeastlike fungi, and various reference species (Kurtzman and Robnett 1995). The phylogram was calculated from nucleotide divergence in the 5' end of the large subunit rRNA gene (positions 63–680). Branch lengths are proportional to nucleotide differences, and the numbers given on branches are the percentage of frequencies with which a given branch appeared in 100 bootstrap replications. Branches with frequencies of less than 50% were collapsed.

that become spindle-shaped as the ascospores are formed (Kreger-van Rij 1984c,e). Hyphal septa of all species assigned to *Saccharomycopsis* are multiperforate with the exception of *S. javanensis*, which has septa with a single central micropore. Consequently, phylogenetic analysis of rDNA nucleotide sequences shows that ascospore shape, and to a lesser extent, septum ultrastructure, are not genus-specific characters.

47. *Saturnispora* Liu & Kurtzman¹

C.P. Kurtzman

Diagnosis of the genus

Asexual reproduction is by multilateral budding on a narrow base. Cells are spheroidal, ovoidal or somewhat elongate. True hyphae are not formed but pseudohyphae may occur. Certain of the species form pellicles on the surface of liquid media.

Asci may be unconjugated or show conjugation between a parent cell and its bud or between independent cells. Asci may be either persistent or deliquescent and form 1–4 or, rarely, 5–8 spheroidal ascospores which are ornamented with an equatorial ledge.

Glucose is fermented. Neither nitrate nor D-xylose is assimilated. Diazonium blue B reaction is negative.

Type species

Saturnispora dispora (Dekker) Liu & Kurtzman

Species accepted

1. *Saturnispora ahearnii* Kurtzman (1991)
2. *Saturnispora dispora* (Dekker) Liu & Kurtzman (1991)

<i>S. zaruensis</i>	+	+	–	–	1–2	+

^a Formation of a pellicle on the surface of liquid growth media.

Systematic discussion of the species**47.1. *Saturnispora ahearnii* Kurtzman (1991b)**

Growth on 5% malt extract agar: After 3 days at 25°C, the cells are spheroidal, ellipsoidal or somewhat elongate, (4.0–7.0)×(4.2–12.0)µm, and occur singly or occasionally in pairs.

Growth on the surface of assimilation media: Thin, climbing pellicles are formed.

Dalmeu plate culture on morphology agar: After 7 days at 25°C, colonies are low convex, tannish-white in color with a smooth to faintly striated, semi-glistening

surface and a butyrous texture. Colony margins are smooth to slightly scalloped. Hyphae or pseudohyphae are not formed.

Formation of ascospores: Asci are either unconjugated or show conjugation between a cell and its bud. The asci form 1–4 or, rarely, 5–8 spheroidal ascospores that have a thin equatorial ledge. Asci are deliquescent and release their spores soon after formation. Isolation of single ascospores demonstrated this species to be homothallic (Kurtzman 1991b).

Ascospores form abundantly within 2–3 days at 25°C on 5% malt extract and YM agars.

¹ The original spelling of the genus name *Saturnospora* has been treated as an orthographic error.

Co-Q: Not determined.**Mol% G + C:** 34.9, CBS 6121 (BD: Kurtzman 1991a).

Origin of the strain studied: CBS 6121 (NRRL Y-7555) is the only known strain of *S. ahearnii* and was isolated from muddy water in the rhizosphere of oyster grass (*Spartina alterniflora* Loisel) growing in the salt marshes of Barataria Bay in southeastern Louisiana, U.S.A.

Type strain: CBS 6121 (NRRL Y-7555), received from D.G. Ahearn, U.S.A.

Comments: *S. ahearnii* is an interesting species because of its close relatedness to *S. satoi*. *S. ahearnii* initially appeared to be a strain of *S. satoi* that failed to assimilate trehalose. Comparisons of nuclear DNA complementarity showed the two taxa to have 30% relatedness (Kurtzman 1991b), thus placing them in the category of genetic sibling species that have only recently diverged (Kurtzman 1987b). All known strains of *S. satoi* are from Japan, but speculation on whether or not the genetic separation of these two species can be attributed to allopathy is premature until additional strains of both species are isolated and there is a better understanding of their geographical ranges.

47.2. *Saturnispora dispora* (Dekker) Liu & Kurtzman (1991)**Synonyms:***Saccharomyces disporus* Beijerinck (1908) nom. nud.*Debaryomyces disporus* Dekker (Stelling-Dekker 1931)*Zymodebaryomyces disporus* (Dekker) Novák & Zsolt (1961)*Pichia dispora* (Dekker) Kreger-van Rij (1970c)? *Pichia krusei* Tsuchiya, Fukazawa, Shinoda & Imai (1967) nom. nud.

Growth on 5% malt extract agar: After 3 days at 25°C, the cells are spheroidal to ovoidal, (2.5–5.5) × (2.5–6.5) μ m, and occur singly and in pairs. Growth is butyrous and tannish-white in color.

Growth on the surface of assimilation media: Rings of growth may occur, but pellicles are not formed.

Dalmau plate culture on morphology agar: After 7 days at 25°C, growth under the coverglass shows neither hyphae nor pseudohyphae but only an occasional outgrowth of elongated cells. Aerobic growth is tannish-white, butyrous, smooth, glistening, and with an occasionally lobed margin.

Formation of ascospores: Asci may be unconjugated or, more frequently, they result from conjugation between a parent cell and a bud or from the pairing of independent cells. Each ascus contains one or two spheroidal spores that exhibit an incomplete equatorial ledge which may be barely perceptible under the light microscope (Fig. 171). Asci are persistent.

Ascospores were observed on 5% malt extract and YM agars after 10–20 days at 25°C.

Co-Q: 7 (Yamada et al. 1973a).**Mol% G + C:** 37.6, CBS 794 (T_m : Nakase 1972a); 38.0, CBS 794, NRRL Y-7656 (BD: Kurtzman 1991a).

Fig. 171. *S. dispersa*, CBS 794. Ascus with ascospores, after 15 days on YM agar, 25°C. Bar = 5 µm.

Origin of the strains studied: CBS 794 (NRRL Y-1447), Beijerinck's strain from the exudate of an oak (*Quercus* sp.); NRRL Y-7656 (LKB 801), a strain of unknown origin from K. Kodama, Japan.

Type strain: CBS 794 (NRRL Y-1447), Beijerinck's strain.

Comments: Kreger-van Rij (1970c) transferred this species from *Saccharomyces* to *Pichia* because of the presence of a ledge on the ascospores, but noted that in the transmission electron microscope, the ledge appeared not to be circumfluent. Using the scanning electron microscope, Kurtzman and Smiley (1974) confirmed the thin ledge to traverse only about half of the ascospore circumference. This is in contrast to the other species in the genus which have ascospores with circumfluent ledges. The taxon described as *P. krusei* is considered to be a synonym of *S. dispersa*, but this needs to be verified from comparisons of DNA relatedness. Separation of *S. dispersa* and *S. zaruensis* is discussed under the latter species.

47.3. *Saturnispora saitoi* (K. Kodama, Kyono & S. Kodama) Liu & Kurtzman (1991)

Synonym:

Pichia saitoi K. Kodama, Kyono & S. Kodama (1962)

Growth on 5% malt extract agar: After 3 days at 25°C, the cells are ovoidal, (2.3–4.5) × (2.8–7.5) µm, and occur singly and in pairs. Growth is butyrous and tannish-yellow in color.

Growth on the surface of assimilation media: Climbing pellicles are present.

Dalmau plate culture on morphology agar: After 7 days at 25°C, growth under the coverglass may show pseudohyphae but not true hyphae. Aerobic growth is light tan, smooth, glistening, butyrous and with a lobate margin.

Formation of ascospores: Asci are generally unconjugated but occasional conjugations occur between a cell and its bud. Two to four saturn-shaped spores are

produced in each ascus, but the ledge on the spores is sometimes difficult to discern under the light microscope (Fig. 172). The spores are released soon after formation. This species appears to be homothallic. Single-spore isolates from four-spored asci of the type strain gave approximately two-thirds sporogenous colonies and one-third asporogenous colonies. Mixtures of asporogenous cultures showed neither conjugations nor spores. Single-spore isolations from three additional four-spored strains gave only sporogenous cultures (Kurtzman, unpublished data).

Ascospores were observed on YM- and 5% malt extract agars after 2–7 days at 25°C.

Co-Q: 7 (Yamada et al. 1973a).

Mol% G+C: 32.2–33.4, four strains (T_m : Nakase 1972a); 33.0–34.1, CBS 4910, NRRL Y-7820, NRRL Y-7821 (BD: Kurtzman 1991a).

Origin of the strains studied: CBS 4910 (NRRL Y-6671), from exudate of hornbeam (*Carpinus* sp.); NRRL Y-7655, NRRL Y-7820 through NRRL Y-7826, from K. Kodama, Japan.

Type strain: CBS 4910 (NRRL Y-6671), from exudate of *Carpinus* sp.

Comments: The close relatedness between *S. saitoi* and *S. ahearnii* is discussed under the Comments section of the latter species. There are few phenotypic differences upon which to separate species of *Saturnispora*. Nakase (1972a) reported that some strains of *S. saitoi* assimilate ribitol, thus precluding separation of this species from *S. dispersa* and *S. zaruensis* by growth differences on standard carbon assimilation tests. However, strains of *S. saitoi* form pellicles on liquid media and have deliquescent asci, characters not shared by isolates of *S. dispersa* and *S. zaruensis*.

47.4. *Saturnispora zaruensis* (Nakase & Komagata) Liu & Kurtzman (1991)

Synonyms:

Pichia zaruensis Nakase & Komagata (1966)

Candida agrestis S. Goto & Oguri (1983)

Growth on 5% malt extract agar: After 3 days at 25°C, the cells are spheroidal to ovoidal, (2.3–5.6) × (2.5–6.6) μm, and occur singly and in pairs. Growth is butyrous and tannish-white in color.

Growth on the surface of assimilation media: Pellicles are not formed, but thin rings of surface growth may occur.

Dalmau plate culture on morphology agar: After 7 days at 25°C, growth under the coverglass shows neither hyphae nor pseudohyphae. Aerobic growth is tannish-white, butyrous, smooth, glistening, and with margins that are occasionally lobed.

Formation of ascospores: Asci may be unconjugated or show conjugation between a parent cell and a bud or between independent cells. Asci contain one or usually two saturnoid spores. Asci are persistent.

Ascospores were formed on YM and 5% malt extract agars after 10–15 days at 25°C.

Co-Q: 7 (Yamada et al. 1973a).

Mol% G+C: 39.5, 39.6, CBS 5799, NRRL Y-7009 (BD: Kurtzman 1991a).

Origin of the strains studied: CBS 5799 (NRRL Y-7008) from exudate of an oak (*Quercus serrata* complex), Japan; NRRL Y-7009 (AJ 4143) from soil, Japan.

Type strain: CBS 5799 (NRRL Y-7008), from exudate of *Quercus serrata*.

Comments: Because there appear to be no differences in growth reactions or cellular morphology, *S. zaruensis* has been considered a synonym of *S. dispersa* (Kreger-van Rij 1970c, Kurtzman 1984d). However, comparisons of nuclear DNA relatedness revealed the two taxa to be separate species (Kurtzman 1991a). Kurtzman (1991a) examined the banding patterns generated by SDS-PAGE electrophoresis of unpurified cellular proteins from all four *Saturnispora* species and noted that this relatively rapid method allowed separation of *S. dispersa* and *S. zaruensis*. Additionally, as seen under the scanning electron microscope, ascospores of *S. zaruensis* have a heavy circumfluent ledge, whereas the equatorial ledge on ascospores of *S. dispersa* is incomplete (Kurtzman and Smiley 1974, unpublished data).

Comments on the genus

The genus *Saturnispora* was described by Liu and Kurtzman (1991) for certain saturn-spored species that had been maintained in *Pichia* (Kreger-van Rij 1970c, Kurtzman 1984d). The relationships among the saturn-spored yeasts are discussed in the chapter on the genus *Williopsis*.

48. *Schizosaccharomyces* Lindner

Ann Vaughan-Martini and Alessandro Martini

Diagnosis of the genus

Cells are globose to cylindroidal and reproduce by fission. In some species true septate hyphae develop and break into arthrospores.

Asci are usually produced by somatic conjugation of vegetative cells. Ascospores may be liberated at an early stage. Ascospores are globose or short ellipsoidal, seldom cylindroidal.

Sugars are fermented. Nitrate is not assimilated. Positive starch test in Wickerham's liquid medium. Urea is hydrolyzed. Diazonium blue B reaction is negative.

Type species

Schizosaccharomyces pombe Lindner

Species accepted

1. *Schizosaccharomyces japonicus* Yukawa & Maki (1931)
2. *Schizosaccharomyces octosporus* Beijerinck (1894)
3. *Schizosaccharomyces pombe* Lindner (1893)

Key to species

See Table 40.

Systematic discussion of the species

48.1. *Schizosaccharomyces japonicus* Yukawa & Maki (1931)

Synonyms:

Schizosaccharomyces versatilis Wickerham & Duprat (1945)
nom. nud.

Schizosaccharomyces japonicus Yukawa & Maki var. *versatilis*
(Wickerham & Duprat) Slooff (1970)

Octosporomyces japonicus (Yukawa & Maki) Kudryavtsev (1960)
Hasegawaea japonica (Yukawa & Maki) Y. Yamada & Banno (1987a)
Hasegawaea japonica (Yukawa & Maki) Y. Yamada & Banno var.
versatilis (Wickerham & Duprat) Y. Yamada & Banno (1987b)

Growth in 5% malt extract: After 3 days at 25°C, the cells are globose, subglobose, ellipsoidal or occasionally cylindroidal, (5.0–9.0) × (6.0–22.0) μm, single, in pairs or in small groups. Ascospores may be present. A sediment is present at 3 days and after one month at 20°C as well.

Growth on 5% malt agar: After one month at 20°C, the streak culture is grayish to light brown, glistening, and slightly raised in the center with irregular striations; the margin is fringed with hyphae.

Growth on the surface of assimilation media: Pellicles are not formed.

Dalmay plate culture on morphology agar: After 5 days at 25°C, true septate hyphae and arthrospores are formed. Conjugating cells as well as ascospores may be present.

Formation of ascospores: Conjugation of cells usually precedes the formation of asci which contain six to eight, sometimes fewer, globose to ellipsoidal ascospores. The asci are evanescent, and released ascospores may remain together in chains or clumps. Mature ascospores of some

Fig. 173. *S. japonicus*, CBS 354. True mycelium, vegetative and conjugating cells and 8-spored asci after 3 days. Potato agar, 25°C. Bar = 10 µm.

strains may be reniform to allantoid and give an amyloid reaction with Lugol's iodine. Conjugation may also occur between ascospores (Fig. 173). When observed by SEM, the ascospores present a smooth surface (Mikata and Banno 1987).

Sporulation was observed on malt-, potato- and corn meal agars after 7 days at 25°C.

Co-Q: not detected (Yamada et al. 1973b).

Mol% G+C: 32.3–36.3, CBS 103, CBS 354, DBVPG 6573 (T_m : Vaughan-Martini, unpublished data)

Linoleic acid: present (Kock and van der Walt 1986).

Origin of the strains studied: DBVPG 6274 (CBS 354) from strawberry wine; DBVPG 6351 (CBS 103), type strain of *S. japonicus* var. *versatilis*; DBVPG 6371 (CBS 5679) from tree exudate; DBVPG 6416 (CBS 102) from grape juice.

Type strain: CBS 354 (DBVPG 6274), isolated from strawberry wine by Yukawa and Maki (1931).

Comments: The high DNA relatedness between strains representing the two varieties of *S. japonicus* demonstrated that there is little reason to separate the species into the varieties *japonicus* and *versatilis* (Vaughan-Martini 1991). This separation was originally based upon a slight difference in the shape and iodine reaction of mature ascospores from some strains (Slooff 1970b, Yarrow 1984b). Johannsen (1981) and Sipiczki et al. (1982) found high percentages of mating between strains of *S. japonicus* var. *japonicus* and *S. japonicus* var. *versatilis*, indicating conspecificity. A study of electrophoretic mobility of selected enzymes of four strains representing the two varieties showed identical profiles (Yamada et al. 1987a).

48.2. *Schizosaccharomyces octosporus* Beijerinck (1894)

Synonyms:

Octosporomyces octosporus (Beijerinck) Kudryavtsev (1960)

Schizosaccharomyces slooffiae Kumbhojkar (1972)

Growth in 5% malt extract: After 3 days at 25°C, the cells are subglobose, (4.4–10.0) µm, to cylindroidal, (4.5–7.0) × (9.0–22.0) µm, single, in pairs or small groups. A sediment is present at 3 days and after one month at 20°C as well.

Growth on 5% malt agar: After one month at 20°C, the streak culture is gray to grayish-brown, dull, raised irregularly and striated; the margin is entire, sinuous or lobate.

Growth on the surface of assimilation media: Pellicles are not formed.

Dalmau plate culture on morphology agar: After 5 days at 25°C, hyphae were not observed. Ascospores may be present.

Formation of ascospores: Conjugation of cells usually precedes the formation of asci containing six to eight, or fewer, ascospores that are globose to short ellipsoidal. Conjugation may also occur between ascospores (Fig. 174). When observed by SEM ascospore surfaces appear papillate (Mikata and Banno 1987).

Sporulation was observed on malt-, potato- and corn meal agars after 7–9 days at 25°C.

- Schizosaccharomyces pombe* Lindner var. *malidevorans* (Rankine & Fornachon) Sipiczki, Kucsera, Ulaszewski & Zsolt (1982)
- Schizosaccharomyces pombe* Lindner var. *acidodevoratus* (Tschalenko) Dittrich (1964)

Growth in 5% malt extract: After 3 days at 25°C,

the cells are globose, ellipsoidal or cylindroidal, (3.0–5.0) × (5.0–15.0–24.0) μ m, single, in pairs or small groups. After one month at 20°C, a sediment is present and sometimes a thin ring.

Growth on 5% malt agar: After one month at 20°C, the streak culture is brownish, dull or glistening, slightly raised, striated, and the margin is entire or sinuous.

Growth on the surface of assimilation media: Pellicles are not formed.

Dalmau plate culture on morphology agar: After 5 days at 25°C, a few short chains of cells may be observed. Ascospores may be present.

Formation of ascospores: Conjugation of vegetative cells precedes the formation of evanescent asci containing two to four globose to ellipsoidal ascospores. The ascospores may cohere in small groups upon release (Figs. 175, 176). Haploid heterothallic strains may be encountered. When observed by SEM, the ascospore surface is warty (Mikata and Banno 1987).

Sporulation was observed on malt-, potato- and corn meal agars after 5–6 days at 25°C.

Co-Q: 10 (Yamada et al. 1973b).

Mol% G+C: 42, 1 strain (T_m : Rost and Venner 1964); 35.1–37.5, CBS 356, CBS 357, CBS 1042, CBS 1061, CBS 5557 (T_m : Vaughan-Martini, unpublished data).

Linoleic acid: not present (Kock and van der Walt 1986).

Fig. 175. *S. pombe*, CBS 356. Vegetative cells after 2 days on YEPG agar, 25°C. Bar = 10 µm.

Fig. 176. *S. pombe*, CBS 5557. Conjugating cells and 4-spored asci after 6 days on YEPG agar, 25°C. Bar = 10 µm.

Origin of the strains studied: DBVPG 6277 (CBS 356) from arak mash; DBVPG 6280 (CBS 357) from cane sugar molasses; DBVPG 6373 (CBS 352) from arak mash; DBVPG 6374 (CBS 358); DBVPG 6418 (CBS 374) from molasses; DBVPG 6448 (CBS 5680) from apples; DBVPG 6450 (CBS 1063) from cane sugar molasses.

Complementary mating types: CBS 358 and CBS 1057.

Type strain: CBS 356 (DBVPG 6277), received from the Král collection in 1922, and designated as the type by Lodder and Kreger-van Rij (1952).

Comments: The distinction between *S. pombe* and *S. malidevorans* was not justified (Vaughan-Martini 1991) after DNA reassociation studies revealed that the type strains share 98% of their genomes. Conspicuity was proposed by Sipiczki et al. (1982) who found mating in all crosses between strains of the two taxa, as well as recombination between their mitochondrial genomes, and similar respiratory chains, as revealed by low temperature cytochrome spectra. Identical electrophoretic enzyme mobilities were found by Yamada et al. (1987a) for all strains of the group.

Comments on the genus

Low relatedness as seen from DNA reassociation studies

confirmed the separation of the genus *Schizosaccharomyces* into three species: *S. japonicus*, *S. octosporus*, and *S. pombe* (Vaughan-Martini 1991). This was also demonstrated from hybridization studies (Johannsen 1981, Sipiczki et al. 1982) where interspecific mating was consistently absent.

Although a close relationship between 8- and 4-spored species was postulated by Kossikov and Medvedeva (1977), who reported mating between *S. pombe* and *S. japonicus*, complete documentation is lacking as to the identity and stability of this hybrid. Sipiczki (1979) also obtained a limited number of prototrophic hybrids by protoplast fusion between recognized strains of the species *S. pombe* and *S. octosporus*. It has been postulated, however, that fusion products do not necessarily reflect conspecificity, but rather are the result of a limited genetic exchange still to be clearly defined (Spencer et al. 1985, Vaughan-Martini 1991). In contrast, Sipiczki et al. (1982) found that *S. japonicus* and related strains had similar low-temperature cytochrome spectra, which were quite different from those of *S. pombe* and *S. octosporus*.

Over the years, different authors have called for the separation of *Schizosaccharomyces* into two or even three genera based on studies using various techniques such as composition of coenzyme Q (Yamada et al. 1973b), low-temperature cytochrome spectra (Sipiczki et al. 1982), fatty acid profiles (Kock and van der Walt 1986), and ascospore surface morphology as seen by SEM (Mikata and Banno 1987). As a result of these studies, Yamada and Banno (1987a) proposed the creation of the genus *Hasegawaea* for the species *S. japonicus*, the reinstatement of the genus *Octosporomyces* for the species *S. octosporus*, and the maintenance of *Schizosaccharomyces* for *S. pombe*.

Kurtzman & Robnett (1991), in a study of ribosomal RNA, found that strains comprising *S. japonicus* were somewhat divergent from the other two species of the genus. However, these authors felt that the distances were not sufficiently great to justify the division of the genus *Schizosaccharomyces* as proposed by Yamada and Banno (1987a).

49. *Sporopachydermia* Rodrigues de Miranda

M.A. Lachance and H.J. Phaff

Diagnosis of the genus

Asexual reproduction is by multilateral budding on a narrow base. Cells are ovoid, ellipsoidal or elongate, occasionally curved. Pseudomycelium and true mycelium are not formed. Cultures growing on agar media have a strong, unpleasant odor.

Conjugation may or may not precede ascus formation. The ascospores are spheroidal, subglobose, ellipsoidal, or bacilliform. One to four ascospores are formed per ascus. The spores usually have a thick coat of refractile material. They are liberated from the ascus at maturity, and are kept together by the refractile material.

Glucose fermentation is absent or very weak. Nitrate is not assimilated. Inositol as sole carbon source is assimilated. Coenzyme Q-9 is formed. Diazonium blue B reaction can be negative or positive.

Type species

Systematic discussion of the species

49.1. *Sporopachydermia cereana* Rodrigues de Miranda (1978)

Synonym:

Cryptococcus cereanus Phaff, M.W. Miller, Miranda, Heed & Starmer (1974)

Growth on YM agar: After 3 days at 25°C, the cells are ellipsoidal to elongate, (2–4) × (4–14) μm, single, in pairs or in small groups. In some strains, a high proportion of the cells is curved. Growth is butyrous, white to cream-colored, and glistening.

Growth in glucose–yeast extract broth: A sediment and a scant pellicle are formed after 2 weeks at 25°C.

Dalmau plate culture on corn meal agar: A few

chains of cells may form under the coverslip after 2 weeks at 17°C.

Formation of ascospores: Asci arise directly from vegetative cells. Asci contain one to four spheroidal to ellipsoidal ascospores with a very thick smooth wall (Fig. 177). The spores are liberated from the ascus at maturity and tend to agglutinate.

Sporulation is scant and rare. Malt extract (1%) and McClary's acetate agar are suitable media. Sporulation is enhanced by transferring cultures from malt extract to acetate medium. Strain CBS 6644 sporulates relatively well after one week on malt extract at 25°C followed by three weeks on acetate at 17°C.

Fermentation: absent.

Fig. 177. *S. cereana*, CBS 6644. Vegetative cells and ascus on McClary's acetate agar. Bar = 5 μ m.

Assimilation:

Glucose	+	<i>N</i> -Acetyl-D-glucosamine	-
Galactose	-	Methanol	-
L-Sorbose	+	Ethanol	+
Sucrose	-	Glycerol	+
Maltose	-	Erythritol	+
Cellobiose	v	Ribitol	+
Trehalose	v	Galactitol	-
Lactose	-	D-Mannitol	+
Melibiose	-	D-Glucitol	+
Raffinose	-	α -Methyl-D-glucoside	-
Melezitose	-	Salicin	+
Inulin	-	D-Gluconate	-
Soluble starch	-	DL-Lactate	v
D-Xylose	+	Succinate	w/-
L-Arabinose	v	Citrate	-
D-Arabinose	-	Inositol	+

Cadaverine	+	1-Butanol	v
L-Lysine	+	Acetone	-
Ethylamine-HCl	+	Tannic acid	-
50% Glucose	-	DBB	-
Gelatin liquefaction	-	Growth at 37°C	+

Co-Q: 9 (Y. Yamada, personal communication).

Mol% G+C: 49.6, CBS 6644 (BD: Phaff et al. 1974).

Origin of the strains studied: UCD-FST 72-313 (CBS 6644), from stem rot of giant saguaro cactus (*Carnegiea gigantea* (Englemann) Britton & Rose), Arizona, U.S.A., is among the many strains isolated from various species of columnar cacti belonging to the subtribe Pachycereinae. Numerous strains are from stem rots of columnar cacti in the subtribe Stenocereinae (e.g., UCD-FST 76-214C, Baja California, Mexico), from cladode rots of prickly pear cacti (*Opuntia* L. spp., e.g., UWO(PS)87-2411.2, Hawaii, U.S.A.), and from necrotic somatic tissue of other cacti (e.g., UCD-FST 76-406C, Sonora, Mexico).

Type strain: CBS 6644, isolated from necrotic somatic tissue of giant saguaro cactus (*Carnegiea gigantea*), Arizona, U.S.A.

Comments: Discrepancies between the above and the information given by Phaff et al. (1974), Rodrigues de Miranda (1978, 1984b), or Lachance (1982a) may be to some extent indicative of the heterogeneous nature of *S. cereana*. Variation occurs between strains in the assimilation of several carbon compounds. We were unable to confirm the weak assimilation of nitrite reported by Rodrigues de Miranda (1984b) for any strain. The problem of variation is complicated by the fact that some, but not all isolates exhibit a characteristic curved cell appearance. This extensive physiological, morphological, and genetic variation does not pattern itself into any evident correlations.

Variation is even more pronounced in yeasts that have been designated in the literature (Lachance et al. 1988, Starmer et al. 1990) as members of the "*S. cereana* complex" because of uncertainties concerning the exact species boundaries of *S. cereana*. Our preliminary results indicate that the complex may represent up to four species, including *S. cereana* sensu stricto. Only strains confirmed as authentic members of the species by DNA reassociation with the type strain were used as a basis for the data reported here. The assimilation of erythritol and the lack of growth on tannic acid (0.5% in Yeast Nitrogen Base, with or without added glucose) are consistent throughout the complex, but variation exists in most other characters.

Representatives of the "*S. cereana* complex" were present in 30% of approximately 1700 samples of necrotic somatic tissue of cacti examined so far by Starmer and coworkers (1990), making it the second (after *Pichia cactophila*) most abundant cactophilic yeast. The conspicuous absence of *S. cereana* from cactus fruit samples has been attributed to the abundance, in cactus fruit, of yeasts capable of producing killer toxins to which certain strains of *S. cereana* are sensitive (Starmer et al. 1987). Moreover, a negative correlation exists between the presence of *S. cereana* in individual samples of prickly pear somatic tissue and the occurrence in each sample of strong killer strains of *Pichia kluyveri*.

49.2. *Sporopachydermia lactativora* Rodrigues de Miranda (1978)

Synonym:

Cryptococcus lactativorus Fell & Phaff (1967)

Growth on YM agar: After 3 days at 25°C, the cells are ellipsoidal to elongate, (2–4) × (4–6) μ m, single, in pairs or in small groups. Growth is butyrous, white to cream-colored, and glistening.

Growth in glucose–yeast extract broth: A sediment is formed after 2 weeks at 25°C.

Dalmu plate culture on corn meal agar: Pseudomycelium or true mycelium are not formed after one month at 17°C.

Fig. 178. *S. lactativora*, CBS 6989. Vegetative cells and ascus on McClary's acetate agar. Bar = 5 μ m.

Formation of ascospores: Asci arise from the conjugation of cells of opposite mating types, or in diploid strains, directly from vegetative cells. They contain one to four spheroidal ascospores with a very thick smooth wall and an oil droplet inside (Fig. 178). The spores are liberated from the ascus at maturity and tend to agglutinate.

Sporulation is generally scant in mixtures of compatible cells. It is enhanced by transferring cultures showing signs of sexuality to fresh sporulation media. The diploid strain CBS 6989 sporulates abundantly on 1% malt extract and on McClary's acetate agar after 3–5 days at 25°C.

Fermentation: absent.

Assimilation:

Glucose	+	<i>N</i> -Acetyl-D-glucosamine	–
Galactose	–	Methanol	–
L-Sorbose	+	Ethanol	+
Sucrose	–	Glycerol	+
Maltose	–	Erythritol	–
Cellobiose	–	Ribitol	+
Trehalose	–	Galactitol	–
Lactose	–	D-Mannitol	v
Melibiose	–	D-Glucitol	v
Raffinose	–	α -Methyl-D-glucoside	–
Melezitose	–	Salicin	–
Inulin	–	D-Gluconate	–
Soluble starch	–	D,L-Lactate	+
D-Xylose	+	Succinate	+
L-Arabinose	–	Citrate	–
D-Arabinose	–	Inositol	+
D-Ribose	v	Hexadecane	–
L-Rhamnose	–	Nitrate	–
D-Glucosamine	–	Vitamin-free	–

Additional assimilation tests and other growth characteristics:

2-Keto-D-gluconate	–	Cycloheximide 100 mg/l	+
Cadaverine	–	1-Butanol	+
L-Lysine	+	Acetone	+
Ethylamine·HCl	+	Tannic acid	+
50% Glucose	–	DBB	–
Gelatin liquefaction	–	Growth at 37°C	+

A positive DBB reaction can be obtained in some cases (see Comments on the genus).

Co-Q: 9 (Y. Yamada, personal communication).

Mol% G+C: 46.1–46.3, the latter for CBS 5771, type strain of *Cryptococcus lactativorus*, the former for CBS 5772 (BD: Phaff et al. 1974).

Origin of the strains studied: CBS 5771 and CBS 5772, in two distinct samples of sea water near the Antarctic Peninsula, Fell, U.S.A.; CBS 6058, waste lagoon of asphalt plant, Georgia; CBS 6192, from the mouth of a patient, Finland; CBS 6989, diploid strain selected from a mixture of strains CBS 5771, CBS 5772, and CBS 6192, Rodrigues de Miranda.

Complementary mating types: CBS 6912 and CBS 5771.

Type strain: CBS 6192, from the mouth of a patient; CBS 5771, from Antarctic sea water, is the isotype.

Comments: Rodrigues de Miranda (1984b) designated strain CBS 6989, a diploid selected from a mixture of strains CBS 5771, CBS 5772, and CBS 6192, as the type culture. However, in the original description (Rodrigues de Miranda 1978), strain CBS 6192 had been chosen as the holotype, with CBS 5771 as the isotype. In accordance with Article 7.3, Note 1 of the International Code of Botanical Nomenclature (Greuter et al. 1988), the earlier designation must prevail.

Natural isolates of *S. lactativora* are haploid with their mating compatibility apparently controlled by two alleles of a single locus. Strain CBS 6912 is arbitrarily designated as h^+ , equivalent to a , following Rodrigues de Miranda's (1978, 1984b) convention, and strains CBS 5771, CBS 5772, and CBS 6058 are of mating type h^- (equivalent to α).

Minor discrepancies exist between our nutritional data and those given by Rodrigues de Miranda (1978, 1984b). When tested by replica plating on agar media, all four strains studied failed to utilize L-arabinose. Strains CBS 6192 and CBS 6989 grew slowly on D-xylose and rapidly on mannitol and glucitol, whereas the other three gave clearly negative responses on these tests. At variance with the responses in Barnett et al. (1983) was our observation, in all strains, of growth on ribitol as carbon source and lack of growth on cadaverine as nitrogen source.

The infrequent isolation of *S. lactativora* precludes the formulation of extensive hypotheses about its ecology, although the species appears to be cosmopolitan in its distribution. Because of its high maximum temperature of growth in contrast to the sea water temperature from which some strains were isolated (ca. 0°C), Fell and Phaff (1967) suggested that its occurrence in sea water could have come from feces of several species of large birds that are common in Antarctica.

49.3. *Sporopachydermia quercuum* Lachance (1982a)

Growth on YM agar: After 3 days at 25°C, the cells are ellipsoidal to elongate, frequently curved, (2–3) × (4–8) μ m, single, in pairs or in small groups. Growth is butyrous, white to cream-colored, and glistening.

Growth in glucose–yeast extract broth: A sediment and a very spotty ring are formed after one month at 25°C.

Dalmou plate culture on corn meal agar: A few chains of cells may be formed under the coverslip after 2 weeks at 17°C.

Formation of ascospores: Asci arise directly from vegetative cells or following conjugation between cells within the same culture (Fig. 179). Asci may bear protuberances indicative of bud-parent cell conjugation. Asci contain one to four ovoid, ellipsoid to bacilliform ascospores with a very thick smooth wall. The spores are liberated from the ascus at maturity and tend to agglutinate.

Sporulation is scant on McClary's acetate agar, and is enhanced by transferring cultures exhibiting protuberance formation or conjugation to fresh sporulation medium and incubating at 17°C. All strains are sporogenous, strain CBS 8070 being one of the most vigorous.

Fermentation:

Glucose	s/w	Lactose	–
Galactose	–	Raffinose	–
Sucrose	–	Trehalose	–
Maltose	–		

Assimilation:

Glucose	+	<i>N</i> -Acetyl-D-glucosamine	–
Galactose	–	Methanol	–
L-Sorbose	+	Ethanol	+
Sucrose	–	Glycerol	+
Maltose	–	Erythritol	–
Cellobiose	–	Ribitol	–
Trehalose	–	Galactitol	–
Lactose	–	D-Mannitol	–
Melibiose	–	D-Glucitol	–
Raffinose	–	α -Methyl-D-glucoside	–
Melezitose	–	Salicin	–
Inulin	–	D-Gluconate	–
Soluble starch	–	DL-Lactate	w
D-Xylose	+	Succinate	v
L-Arabinose	–	Citrate	–
D-Arabinose	–	Inositol	+
D-Ribose	–	Hexadecane	–
L-Rhamnose	–	Nitrate	–
D-Glucosamine	–	Vitamin-free	–

Additional assimilation tests and other growth characteristics:

2-Keto-D-gluconate	–	Cycloheximide 100 mg/l	+
Cadaverine	+	1-Butanol	+
L-Lysine	+	Acetone	+
Ethylamine-HCl	+	Tannic acid	+
50% Glucose	–	DBB	–
Gelatin liquefaction	–	Growth at 37°C	–

A positive DBB reaction can be obtained in some cases (see Comments on the genus).

Co-Q: 9 (Y. Yamada, personal communication).

Mol% G + C: 37.8, CBS 8070 (BD: Phaff, unpublished data).

Origin of the strains studied: UWO(PS)80-118 (CBS 8070, ATCC 56629), UWO(PS)80-141 (ATCC 56630) and other strains were collected from slimy exudates of red oaks (*Quercus rubra* L.), Ontario, Canada.

Type strain: CBS 8070, from red oak (*Quercus rubra* L.).

Fig. 179. *S. quercuum*, CBS 8070. Vegetative cells on YM agar. Ascus on McClary's acetate agar (from Lachance 1982a). Bar = 5 μ m.

Comments: *S. quercuum* was described (Lachance 1982a) to accommodate isolates from red oak (*Quercus rubra* L.) exudates, whose characteristics differed only slightly from those of *S. lactativora*. The predominance of curved cells and the difference in maximum growth temperature were taken as sufficient grounds for the description of a separate species. This is confirmed by the nearly 8% difference in nDNA base composition with the other two accepted species.

Cultures of *S. quercuum* appear to be mixtures of haploid and diploid cells. Because of the scant sporulation and the tendency of liberated spores to agglutinate, no attempt has been made to determine whether self-fertility is due to homothallism.

A difference exists between the maximum growth temperatures reported by different laboratories (Lachance 1982a, Barnett et al. 1983). As this difference is important for the identification of *S. quercuum*, it is worth mentioning that the measurements reported here were performed on replica plates with both synthetic (YNB–glucose) and complex (YM) agar media. The maximum determined in this way was $34.5 \pm 0.5^\circ\text{C}$. A higher value ($36 \pm 0.5^\circ\text{C}$) was obtained on media dispensed in tubes and incubated in a heating block (J.E. Kaden and M.A. Lachance, unpublished results). Barnett et al. (1983), using liquid media, reported good growth at 37°C and no growth at 42°C .

Comments on the genus

Rodrigues de Miranda (1978) described the genus *Sporopachydermia* based on the observation of the formation of thick-walled ascospores in two species of *Cryptococcus* known not to be basidiomycetous anamorphs (Phaff et al. 1974). Although neither the chemistry nor the evolutionary significance of the spore sheath are understood, such a feature brings together species that represent an evolutionarily coherent assemblage. Ribosomal RNA sequence comparisons (Yamada et al. 1992a) confirmed this view, showing that *Sporopachydermia* is monophyletic with respect to various other Q-9 genera. Phenetic analysis of the physiological responses of all yeasts given in Barnett

et al. (1983) shows that the combination of nutritional abilities found in the genus is unique among yeasts with demonstrated ascomycetous life cycles, substantiating the hypothesis that the genus is monophyletic within ascomycetes. A superficial physiological resemblance exists, however, with the asexual species *Trigonopsis variabilis*, *Candida pararugosa*, and *Candida sorbophila*. The nDNA base compositions of members of these taxa fall well within the range exhibited by *Sporopachydermia* species.

The slow but positive diazonium blue B reaction reported in *S. quercuum* (Lachance 1982b) occurs also in *S. lactativora*, but not in *S. cereana*. A purple reaction is observed after two minutes on colonies grown on casein hydrolysis agar medium. Colonies grown on YM agar and subjected to a 50°C treatment, as recommended by Hagler and Ahearn (1981), gave a yellow reaction (M.A. Lachance, unpublished results). Although surprising, these results are not unparalleled. Summerbell (1985) observed normal (purple) diazonium blue B reactions

in several filamentous fungi of ascomycetous affinity, if they were first subjected to an alkali treatment. Yellow reactions occurred in a few basidiomycetous species without alkali treatment. Simmons and Ahearn (1987) examined closely the cell wall structure and the diazonium blue B reaction of *S. quercuum*, and concluded that the yeast is typically ascomycetous for both traits. They suggested that the positive reaction reported by Lachance (1982b) was most likely the result of impurities present in the chemical. While the complete significance of all these observations remains to be clarified, the sharing of such an unusual property by two *Sporopachydermia* species acts as additional evidence of their close relatedness.

Sporopachydermia appears to be ecologically similar to *Clavispora* and *Pichia*, in that these genera contain some species that act as generalists, and others as specialists. The little that is known about *S. lactativora* suggests that it is a generalist. *S. cereana* and *S. quercuum* appear to be specialists, although the small number of isolates of the latter species limits speculation at this time.

50. *Stephanoascus* M.Th. Smith, van der Walt & E. Johannsen

M.Th. Smith and G.S. de Hoog

Diagnosis of the genus

Colonies are restricted, dry, and snow-white. Asexual reproduction is either by multilateral budding (anamorph genus *Candida*) or by short chains of sympodial conidia on true hyphae (anamorph genus *Blastobotrys*).

Gametangia are formed on hyphae after fusion of two intercalary cells or lateral outgrowths. Asci are globose with firm, thick walls and contain 2–4 ascospores. Asci bear a sterile apical cell. Ascospores are oblate to hat- or helmet-shaped. Septa with micropores are present.

Sugars may be fermented. Nitrate may be assimilated. Diazonium blue B reaction is negative.

Type species

Stephanoascus ciferrii M.Th. Smith, van der Walt & E. Johannsen

Species accepted

1. *Stephanoascus ciferrii* M.Th. Smith, van der Walt & E. Johannsen (1976)
2. *Stephanoascus farinosus* de Hoog, Rantio-Lehtimäki & M.Th. Smith (1985)
3. *Stephanoascus smithiae* Giménez-Jurado (1994)

Key to species

See Table 42.

1. a Apical cell on ascus is hemispherical; growth at 37°C *Stephanoascus ciferrii*: p. 400
 b Apical cell on ascus is clavate; growth absent at 37°C → 2
- 2(1). a Growth with inositol *Stephanoascus smithiae*: p. 402
 b Growth absent with inositol *Stephanoascus farinosus*: p. 401

Table 42
Key characters of species in the genus *Stephanoascus*

Species	Glucose fermentation	Assimilation		Growth at 37°C	Apical cell	Mating system
		Succinate	Inositol			
<i>Stephanoascus ciferrii</i>	–	+	+	+	hemispherical	heterothallic
<i>S. farinosus</i>	w	–	–	–	clavate	homothallic
<i>S. smithiae</i>	–	+	+	–	clavate	heterothallic

Systematic discussion of the species

50.1. *Stephanoascus ciferrii* M.Th. Smith, van der Walt & E. Johannsen (1976)

Synonyms:

Candida ciferrii Kreger-van Rij (1965)

Sporothrix catenata de Hoog & Constantinescu (1981)

Candida mucifera Kocková-Kratochvilová & Sláviková (1988)

Growth on 4% malt extract/0.5% yeast extract agar:

After 10 days at 20–22°C, colonies are 4 mm in diameter, dry, white, and somewhat raised. Budding cells are absent or present, multilateral, and often in short chains. True hyphae are absent or present, 2–3 µm wide, and form a

compact mycelium. Conidia are sympodially produced in dense, swollen clusters; they are terminal or intercalary just below hyphal septa, with marked, sharp denticles bearing conidia. Conidia are formed singly or in short chains about (1.5–3.0) × (3.5–5.5) µm; lower conidia are somewhat larger.

Formation of ascospores: Gametangia are formed by conjugation of opposite hyphal cells; the conjugation bridge forms a lateral outgrowth which develops into an ascus. Asci are globose, with firm, thick, persistent walls, and are crowned by a hemispherical sterile cell. Asci

contain 2–4 obovate to hat-shaped ascospores measuring (3–5) × (5–8) μm (Fig. 180). The species is heterothallic.

Mating tests are conducted on V8 agar at 28°C.

Fermentation: absent.

Fig. 180. *S. ciferrii*, CBS 5295 × 6699. Asci with ascospores (top). Asci are on the conjugation bridge formed from conjugation of hyphae of opposite mating partners. V8, 28°C, 10 days. Anamorph (bottom) (CBS 215.79) producing short, branched chains of conidia from swollen, denticulate heads; clusters of multilateral budding cells. MEYA, 22°C, 10 days.

Assimilation:

Additional assimilation tests and other growth characteristics:

Arbutin v Growth at 37°C +
Co-Q: 9, CBS 5295, CBS 6699 and 4 additional strains (Yamada and Smith 1985).

Mol% G + C: 46.2–47.0, CBS 6699 (T_m : Giménez-Jurado et al. 1994).

Origin of the strains studied: CBS 4856 (ATCC 22873), type strain of *Candida ciferrii*, from a cow, Netherlands; CBS 7409, type strain of *Candida mucifera*, from liver of a toad, Brazil; CBS 215.79, type strain of *Sporothrix catenata*, from calf skin, Romania; from fence post (1); from pig (1); from bovine placenta (1); from soil (1).

Complementary mating types: CBS 5645 (*a*), 6699 (*a*), 7409 (*a*), 4856 (*α*), 5165 (*α*), 5166 (*α*), 5295 (*α*).

Isotype strains: CBS 6699 and CBS 5295.

Comments: The species is often associated with animals and occasionally found in humans, mainly involved in otitis (Furman and Ahearn 1983). It is slightly thermophilic. The type strain of *Candida mucifera* from toad liver in Brazil was found to be mating type *a*, and produces ascospores with the tester strain CBS 5295.

Some strains are strongly hyphal and produce conidia from characteristically inflated, denticulate heads. This anamorph has been described as *Sporothrix catenata*.

50.2. *Stephanoascus farinosus* de Hoog, Rantio-Lehtimäki & M.Th. Smith (1985)

Synonyms:

?*Sporothrix fungorum* de Hoog & de Vries (1973)

Blastobotrys farinosus de Hoog, Rantio-Lehtimäki & M.Th. Smith (1985)

?*Blastobotrys gigas* de Hoog, Rantio-Lehtimäki & M.Th. Smith (1985)

Growth on 4% malt extract/0.5% yeast extract agar: After 10 days at 20–22°C, colonies are 5 mm in diameter, white, and farinose with flat, glassy margins. Expanding hyphae are straight and somewhat stiff, 1.8–2.5 μm wide, forming terminal and intercalary groups of

primary conidia, (3–5)×(5–7)µm, each bearing several globose secondary conidia, 2–3µm in diameter.

Formation of ascospores: Asci are formed from fused gametangia laterally on hyphae. They are globose, 7–9µm in diameter, with persistent, firm walls, and are crowned with a cylindrical to clavate top cell. Asci contain 2–4 ascospores that are broadly ellipsoidal, 2.0–2.5µm, with an irregular gelatinous basal brim, the widest diameter about 4µm (Fig. 181). The species is homothallic.

Asci are formed on MEYA at 15°C.

Additional assimilation tests and other growth characteristics:

Arbutin	v	Growth at 37°C	–
Co-Q: 9, IGC 4592		(Giménez-Jurado et al. 1994).	
Mol% G + C: 48.5–49.9, IGC 4592		(<i>T_m</i> : Giménez-Jurado et al. 1994).	

Origin of the strains studied: CBS 140.71, from the carpophore of *Hirneola auricula-judae*, Gams, Netherlands; CBS 421.78, type strain of *Blastobotrys gigas*, from a frozen mummy, Bodenhoff, Greenland; CBS 259.70, type strain of *Sporothrix fungorum*, from carpophore of *Fomes fomentarius*, Gams, Germany; from carpophore of *Corticium* (1); from carpophore of *Hirneola* (1); from Sphaeriales (1).

Type strain: CBS 140.71.

Comments: The species is homothallic. Traquair et al. (1988a) reported *S. farinosus* teleomorphs in strains which de Hoog et al. (1985) found to be different in morphology and physiology. However, characters are notoriously variable, as demonstrated by physiological differences between two strains of *Sporothrix fungorum* (de Hoog et al. 1985).

Fig. 181. *S. farinosus*, CBS 140.71. Asci with ascospores (top). Asci are on the conjugation bridge formed from adjacent cells of a single hypha. MEYA, 15°C, 10 days. Anamorph (bottom) with conidia in compact clusters, formed on small denticles. MEYA, 20°C, 10 days.

The species is somewhat psychrophilic, with asci developing at 18°C. It is found on dead carpophores of fungi, be they basidio- or ascomycetous. *Blastobotrys gigas* was isolated from a mummy in ice (Bodenhoff et al. 1979); it differs markedly from the remaining anamorphs by having large conidioferous denticles. De Hoog et al. (1985), though with hesitation, introduced separate names for the groups within this taxonomic complex. DNA/DNA reassociations are needed to determine species borderlines and to evaluate currently used taxonomic criteria in these hyphal yeasts.

50.3. *Stephanoascus smithiae* Giménez-Jurado (Giménez-Jurado et al. 1994)

Synonym:

Candida edax van der Walt & Nel (1968)

Growth on 2% glucose/0.5% yeast extract/1% peptone agar: After 7 days at 20–22°C, colonies are white to cream-colored, compact, and somewhat raised at the center. Budding cells are scarce, multilateral and measure (1–2)×(2–12)µm. True hyphae are present, with conidia produced from denticle-like structures, either terminal or intercalary (Fig. 182). Conidia measure about (1.5–4.0)×(2.0–3.0)µm.

Fig. 182. *S. smithiae*, CBS 7522.1. Anamorph with conidia formed on denticulate heads. MEYA, 10°C, 10 days.

Formation of ascospores: Gametangia are formed by conjugation of opposite hyphal cells, the conjugation bridge forms a lateral outgrowth which develops into an ascus. Asci are globose, with firm, thick, persistent walls, (5.0–8.0) × (3.0–5.0) μm, and are crowned with a sterile clavate cell. Asci contain one hemispherical or helmet-shaped ascospore which has a thick basal brim (Fig. 183). The species is heterothallic.

Mating tests are conducted on malt extract agar at 25°C.

Fermentation: absent.

Fig. 183. *S. smithiae*, CBS 7522.1 × 7522.2. Asci with ascospores on oatmeal agar, 1 week, 25°C. Bar = 5 μm.

Co-Q: 9, CBS 7522.1, 7522.2 (Giménez-Jurado et al. 1994).

Mol% G+C: 47.0–47.4, CBS 7522.1, 7522.2 (T_m : Giménez-Jurado et al. 1994).

Origin of the strains studied: CBS 5657 (ATCC 18414, IFO 10273, NRRL Y-17083), type strain of *Candida edax*, from an insect tunnel, South Africa, van der Walt; CBS 6461, from soil, Japan, Furukawa; CBS 7522.1 (IGC 4646) and 7522.2 (IGC 4647), isotype strains of *Stephanoascus smithiae*, from soil, Brazil.

Complementary mating types: CBS 7522.1 and CBS 7522.2.

Isotype strains: CBS 7522.1 (mt *a*) and CBS 7522.2 (mt *α*).

Comments: A full description of the species was given by Giménez-Jurado et al. (1994), including results of an extended series of assimilation tests. The species was shown to have one central micropore in the hyphal septa. Its identity as a new species was proven by low DNA/DNA homology values with the remaining *Stephanoascus* species.

Comments on the genus

Stephanoascus species are variable in the morphology of their anamorphs and in their physiology. They may be hyphal, with characteristic, sympodial conidiogenous apparatus, or entirely yeastlike.

Currently three species are accepted. The authentic strains of *S. flocculosus* Traquair et al. (1988b) and *S. rugulosus* Traquair et al. (1988b) proved to be *Pseudozyma* anamorphs of smut fungi (Boekhout 1995).

51. *Torulaspota* Lindner

C.P. Kurtzman

Diagnosis of the genus

Asexual reproduction is by multilateral budding on a narrow base. Cells are spheroidal to ellipsoidal. Pseudohyphae may be present but true hyphae are not formed.

Asci are persistent and may be unconjugated or show conjugation between a cell and its bud or between independent cells. Cells with tapered protuberances resembling conjugation tubes may also be present. Asci contain 1–4 spheroidal ascospores that are either roughened or smooth.

Sugars are fermented. Nitrate is not assimilated. Pellicles are absent or weakly formed. Coenzyme Q-6 is produced. Diazonium blue B reaction is negative.

Type species

Torulaspota delbrueckii (Lindner) Lindner

Schwanniomyces hominis Batista, Vieira & Coêlho (1959b)

Debaryomyces dekkeri Mrak, Phaff, Vaughn & Hansen ex Kudryavtsev (1960)

Zymodebaryomyces dekkeri (Mrak, Phaff, Vaughn & Hansen ex Kudryavtsev) Novák & Zsolt (1961)

Saccharomyces inconspicuus van der Walt (1965a)

Torulaspota inconspicua (van der Walt) van der Walt & E. Johannsen (1975a)

Saccharomyces vafæi van der Walt (1965a)

Torulaspota vafæi (van der Walt) van der Walt & E. Johannsen (1975a)

Torulaspota benedictæ Capriotti (1969)

Saccharomyces saitoanus van der Walt (1970c)

Saccharomyces mikroellipsodes Osterwalder var. *osmophilus* van der Walt (1970c)

Saccharomyces florenzani Balloni, Materassi & Margheri (1971)

Torulopsis taboadae Ulloa & Herrera (1978)

Growth on 5% malt extract agar: After 3 days at 25°C, the cells are spheroidal to ellipsoidal, (2.1–5.6)×(3.0–6.6)µm, and single or occasionally in pairs. Growth is butyrous, dull-glistening and tannish-white in color.

Growth on the surface of assimilation media: Pellicles are not formed.

Dalmiau plate culture on morphology agar: After 7 days at 25°C, growth under the coverglass may show a few chains of somewhat elongated cells, but there are no pseudohyphae or true hyphae. Aerobic growth is white to tannish-white, smooth, moderately glistening, and butyrous. Colonies are low convex with a depressed center and a smooth margin. A faint acidic odor is present.

Formation of ascospores: Asci are persistent and often conjugated. Conjugation may be between a cell and its bud or between independent cells. In addition, cells with tapered protuberances that resemble conjugation tubes are often present. Asci form one to four spheroidal ascospores that often appear faintly roughened under the light microscope (Fig. 184).

Ascospores were observed on YM, 5% malt extract,

Fig. 184. *T. delbrueckii*, CBS 4865. Asci with ascospores, after 3 weeks on RG agar at 15°C. Bar=5 µm.

corn meal, McClary's acetate and RG agars after 5–30 days at 15 or 25°C.

Co-Q: 6, CBS 1146, and numerous other strains (Yamada et al. 1976b).

Mol% G+C: 42.7–43.9, CBS 1146, and numerous other strains, (T_m : Nakase and Komagata 1971e); 43.4–43.9 (BD: Price et al. 1978).

Origin of the strains studied: Cucumber brine, North Carolina, U.S.A. (5); fermented sausages, U.S.A. (2); food processing plant, U.S.A. (1); ragi, Indonesia (2); sugar mill (1); sorghum brandy (1); type strain of *Torulopsis taboadae*, wine, Mexico; pickled herring, U.S.A. (1); grape juice (1); spoiled beer (1); insect frass, U.S.A. (2); soil, U.S.A. (2), Ghana (1); slime flux, oak (*Quercus* sp.), U.S.A. (1); rotted tree stumps, eastern U.S.A. (3); unknown (4).

Type strain: CBS 1146 (NRRL Y-866), neotype designated by van der Walt (1970d).

Comments: Strains of *T. delbrueckii* show considerable variation in their abilities to ferment and to assimilate carbon compounds, which has contributed to the uncertain circumscription of this species and has resulted in the description of numerous taxa that are now regarded to be synonyms. Price et al. (1978) determined the extent of nDNA complementarity among many of the described species of *Torulaspota* and demonstrated that such long recognized species as *T. rosei*, *T. fermentati*, and *T. vafæi* are conspecific with *T. delbrueckii*. However, not all of the taxa listed as synonyms have been subjected to nDNA comparisons.

51.2. *Torulaspora globosa* (Klöcker) van der Walt & E. Johannsen (1975a)

Synonyms:

Debaryomyces globosus Klöcker (1909a)

Zymodebaryomyces globosus (Klöcker) Novák & Zsolt (1961)

Saccharomyces kloeckerianus van der Walt (1971)

Growth on 5% malt extract agar: After 3 days at 25°C, the cells are spheroidal to ovoidal, (3.2–6.6) × (3.3–6.6) μm, and single or in pairs. Growth is butyrous, dull-glistening, and tannish-white in color.

Growth on the surface of assimilation media: Pellicles are not formed.

Dalmou plate culture on morphology agar: After 7 days at 25°C, growth under the coverglass shows neither pseudohyphae nor true hyphae. Aerobic growth is white to tannish-white, smooth, moderately glistening, and butyrous. Colonies are low convex with a depressed center and an entire to lobed margin. A faintly acidic odor is present.

Formation of ascospores: Asci are persistent and usually form following conjugation between individual cells, or less often between a cell and its bud. Cells bearing protuberances are often present. Asci form one or two spheroidal ascospores that often appear faintly roughened when viewed with the light microscope (Fig. 185). Yarrow (1984c) reported the presence of mating types.

Ascospores were observed on YM and RG agars after 5–10 days at either 15 or 25°C.

Mol% G + C: 47.5, CBS 764; 47.0, CBS 5380 (BD: Price et al. 1978).

Origin of the strains studied: Soil, West Indies (1), New Guinea (1), unknown (2).

Complementary mating types: CBS 5500 and CBS 5503.

Type strain: CBS 764 (NRRL Y-12650), from soil, West Indies.

Fig. 185. *T. globosa*, CBS 5380. Conjugated ascus with ascospores, after 7 days on RG agar at 25°C. Bar = 5 μm.

51.3. *Torulaspora pretoriensis* (van der Walt & Tscheuschner) van der Walt & E. Johannsen (1975a)

Synonyms:

Saccharomyces pretoriensis van der Walt & Tscheuschner (1956c)

Torulaspora francisca Capriotti (1958a)

Debaryomyces francisca (Capriotti) K. Kodama, Kyono, Naganishi & Takahara (1964b)

Growth on 5% malt extract agar: After 3 days at 25°C, the cells are spheroidal to short ellipsoidal, (2.5–5.1) × (3.0–6.6) μm, and single or in pairs. Growth is butyrous, dull-glistening, and tannish-white in color.

Growth on the surface of assimilation media: Pellicles are not formed.

Dalmou plate culture on morphology agar: After 7 days at 25°C, growth under the coverglass shows infrequent, poorly differentiated pseudohyphae, but no true hyphae. Aerobic growth is white to tannish-white, smooth, moderately glistening, and butyrous. Colonies are low convex with a depressed center and an entire to lobed margin. A faintly acidic odor is present.

Formation of ascospores: Asci are persistent and usually form following conjugation between a cell and its bud. Each ascus forms one to four spheroidal ascospores that may be roughened or smooth (Fig. 186).

Fig. 186. *T. pretoriensis*, CBS 2926. Conjugated asci with ascospores, after 3 months on YM agar at 5°C. Bar = 5 µm.

Ascospores were observed on YM agar, often following refrigeration (ca. 5°C) for one to several months.

Origin of the strains studied: CBS 2187 (NRRL Y-17251), from soil, South Africa; CBS 2926 (NRRL Y-17532), type strain of *Torulaspora franciscae*, from soil, Spain.

Type strain: CBS 2187.

Comments on the genus

As shown by the long lists of synonyms for some species, use of phenotypic characters to separate the genera *Torulaspora*, *Saccharomyces*, *Zygosaccharomyces* and *Debaryomyces* has given uncertain results. In the 1970 edition of *The Yeasts, A Taxonomic Study*, *Debaryomyces* was maintained, but species of *Torulaspora* and *Zygosaccharomyces* were assigned to *Saccharomyces*. In 1975, van der Walt and Johannsen revived *Torulaspora* and enlarged it with the transfer of all *Debaryomyces* species and further included species of *Pichia* with spheroidal ascospores. With the 1984 edition of *The Yeasts*, all four genera were again recognized. Distinguishing characters included the following:

Debaryomyces – Cells are predominately haploid with ascosporeulation usually preceded by conjugation between independent cells or between a cell and its bud; ascospores are roughened; fermentation is absent or usually not vigorous; coenzyme Q-9.

Saccharomyces – Cells of some species are predominantly diploid, others are haploid; conjugation may not immediately precede ascosporeulation; ascospores are smooth; fermentation is vigorous; coenzyme Q-6.

Torulaspora – Cells are predominantly haploid with ascosporeulation usually preceded by conjugation between independent cells or between a cell and its bud; ascospores are usually roughened; fermentation is vigorous; coenzyme Q-6.

Zygosaccharomyces – Cells are predominantly haploid with ascosporeulation usually preceded by conjugation between independent cells, often with each conjugant producing ascospores; ascospores are smooth; fermentation is vigorous; coenzyme Q-6.

Examination of ascospores by transmission electron microscopy (Kawakami 1958, Kodama et al. 1964a–c, Kreger-van Rij 1969c, Kreger-van Rij and Veenhuis 1976b) and scanning electron microscopy (Kurtzman et al. 1972, 1975) demonstrated some differences in the patterns of wall ornamentation among rough-spored species, but did not provide a clear separation of genera. Furthermore, one strain of *Torulaspora pretoriensis* had rough ascospores whereas spores of the type strain were smooth. Strains of the other two species of *Torulaspora* always formed roughened ascospores.

Biochemical comparisons, such as the formation of intracellular β-glucosidases (Fiol 1973) and nitrate reductase (Fiol and Billon-Grand 1977), did not clearly resolve genera. The type of coenzyme Q synthesized provided some correlation with genus circumscriptions (Yamada et al. 1976b). Species of *Debaryomyces* have Q-9, whereas *Saccharomyces*, *Torulaspora* and *Zygosaccharomyces* are characterized by Q-6.

Ribosomal RNA/rDNA sequence comparisons have had the most significant impact on resolving intra- and interspecific relationships among the four genera

(Kurtzman and Robnett 1991, Yamada et al. 1991b, James et al. 1994b, 1996, 1997). From what is presently known, *Debaryomyces* is phylogenetically separate from the other three genera. *Torulaspota* species arise from within *Zygosaccharomyces*, suggesting *Torulaspota* to be an artificial taxon. Although there appears to be poor separation between *Saccharomyces* and *Zygosaccharomyces* (James et al. 1997, Kurtzman and Robnett, unpublished data), the present four genera have been retained until further analyses can be made.

52. *Wickerhamia* Soneda

H.J. Phaff and M.W. Miller

Diagnosis of the genus

Cells are ovoidal to elongate or apiculate, single, in pairs or very short chains, reproducing mainly by bipolar budding on a relatively broad base.

Asci are formed without prior conjugation. Ascospores are cap-shaped; the crown deflects to one side of a sinuous brim, giving the appearance of a sporting cap; usually only one or two spores form per ascus but occasionally there may be many (up to 16 have been reported); the asci rupture when the spores are mature.

Sugars are fermented; nitrate is not assimilated; biotin is the only vitamin required for growth. In liquid media a sediment and a ring are formed. Diazonium blue B reaction is negative.

Type species

Wickerhamia fluorescens Soneda

Species accepted

1. *Wickerhamia fluorescens* Soneda (1960)

Systematic discussion of the species

52.1. *Wickerhamia fluorescens* Soneda (1960)

Anamorph: *Kloeckera fluorescens* Soneda

Synonym:

Kloeckera fluorescens Soneda (1959)

Growth in 5% malt extract: After two or three days at 25°C, cells are apiculate with blunt ends, ovoidal, elongate (sometimes sausage-shaped or slightly curved), or in the shape of bowling pins, (4–7) × (8–15–22) μm. They occur singly, in pairs, and occasionally in groups of three; reproduction is by bipolar budding on a broad base (Fig. 187); a sediment and a thin ring begin to form. After 3–4 weeks there are a sediment, ring and sometimes a few islets, but no pellicle.

Growth on 10% malt agar: After 3–4 weeks the streak culture is gray to slightly yellowish, smooth, semiglossy, texture pasty, cross section low convex to flat, margin entire. The medium may become yellowish due to excretion of riboflavin, which shows strong fluorescence under ultraviolet light.

Dalmau plate culture on potato agar: Pseudomycelium is not formed.

Formation of ascospores: Spores are formed without immediately preceding conjugation of vegetative cells. The ascospores resemble a sporting cap; the crown is deflected to one side of a sinuous brim, and they contain a single, conspicuous refractile lipid globule (Fig. 188).

In our study only one and rarely two spores per ascus have been observed, although Soneda (1960) reported up to 16 per ascus. Upon maturity, asci rupture along an equatorial plane, releasing the spores.

Sporulation is best on corn meal agar, oatmeal agar, or potato agar at 25°C, after 3 to 5 days.

Co-Q: 9, IFO 1116 (CBS 4565) (Yamada et al. 1976a).

Mol% G + C: 37.6, one strain (T_m : Nakase and Komagata 1971g).

Origin of the strain studied: CBS 4565, isolated by Soneda (1959) from dung of a wild squirrel in Japan.

Type strain: CBS 4565 (IFO 1116).

Comments on the genus

Mitotic division of the rather large nucleus of *W. fluorescens* under phase contrast and in stained preparations has been followed in detail by Matile et al. (1969). Meiosis and ascospore delimitation were studied by Rooney and Moens (1973a,b) with the use of electron microscopy of ultrathin sections. The nuclear behavior is similar to that occurring in *Saccharomyces cerevisiae* in that the nuclear envelope remains intact during the two meiotic divisions and a four-lobed nucleus is formed. One of the four nuclear lobes has a complex spindle-pole body, which is the site from where the prospore wall develops that eventually surrounds the ascospore nucleus and associated cytoplasm. With few exceptions (two-spored asci) the three remaining nuclei degenerate. The outer membrane of the prospore wall forms a fold, or brim, on the outside of the spore, ultimately resulting in an asymmetric cap-shaped spore. Because in the above-cited work and in our own laboratory multispored asci were never observed, it is possible that Soneda's (1960) observation of multispored asci was based on viewing clumps or aggregates of numerous liberated spores.

53. *Wickerhamiella van der Walt*

C.P. Kurtzman

Diagnosis of the genus

Asexual reproduction is by multilateral budding on either a narrow or a broad base, and the cells range from spheroidal to ellipsoidal. Neither hyphae nor pseudohyphae are produced. Pellicles are not formed on liquid media.

Asci are conjugated and usually form a single, roughened, asymmetrical elongated ascospore. Asci become deliquescent at the terminus, and following ascospore release, become somewhat corrugated in appearance.

Sugars are not fermented. Nitrate is assimilated. Diazonium blue B reaction is negative.

Type species

Wickerhamiella domercqiae van der Walt

Species accepted

1. *Wickerhamiella domercqiae* van der Walt (1973)

Systematic discussion of the species

53.1. *Wickerhamiella domercqiae* van der Walt (van der Walt and Liebenberg 1973a)

Anamorph: *Candida domercqiae* (van der Walt & van Kerken) S.A. Meyer & Yarrow

Synonyms:

Torulopsis domercqiae (as *T. domercqii*) van der Walt & van Kerken (1960)

Candida domercqiae (van der Walt & van Kerken) S.A. Meyer & Yarrow (Yarrow and Meyer 1978)

Torulopsis saccharum Shehata (1960) nom. nud.

Growth on 5% malt extract agar: After 3 days at 25°C, the cells are spheroidal to ellipsoidal, (1.2–3.5) × (1.4–3.5) μm, and single, in pairs or in small clusters. CBS 4351 has quite small cells that tend to be at

the lower end of the size range given, whereas CBS 4733 has noticeably larger cells. Growth is butyrous and light tannish-white in color.

Growth on the surface of assimilation media: Pellicles are not formed.

Dalmau plate culture on morphology agar: After 7 days at 25°C, neither hyphae nor pseudohyphae are seen under the coverglass. Aerobic growth is tannish-white, glistening and butyrous. Colonies are somewhat raised but with a depressed center, and have smooth to finely lobed margins.

Formation of ascospores: Asci are conjugated and each produces a single elongated spore which is released at maturity (Fig. 189). Because of the small size of cells and spores, van der Walt and Liebenberg (1973a) examined the process of ascospore formation by transmission electron microscopy. They demonstrated that asci arise from conjugation between independent cells rather than from parent cell–bud conjugation. The elongated ascospores were shown to be somewhat roughened and irregular in shape. Following dissolution of a terminal portion of the ascus wall, van der Walt and Liebenberg (1973a) stated that the spores are ejected. Empty asci often have a corrugated appearance. Heat treatment of sporulating cultures gave only sporogenous colonies, thus indicating the species to be homothallic.

Ascospores were observed in PDA cultures of CBS 4733 after two weeks at 15°C. Sporulation was not detected in CBS 4351, the type strain.

Fermentation: absent.

Fig. 189. *W. domercqiae*, CBS 4733. Vegetative cells and an ascus with a single ascospore (arrow), after two weeks on PDA, 15°C. A cluster of four free ascospores is located on the left of the photomicrograph. Bar=5 μm. Inset. An enlarged view of an ascus with an ascospore. Bar=1 μm.

Co-Q: Not determined.

Mol% G + C: 48.6, CBS 4351 (BD, T_m : Stenderup et al. 1972).

Origin of the strains studied: NRRL Y-6692 (CBS 4351), type strain of *Torulopsis domercqiae*, from a wine vat, South Africa; NRRL Y-6698 (CBS 4733), type strain of *Torulopsis saccharum*, effluent from a sugar cane factory.

Type strain: CBS 4351, isolated by van der Walt and van Kerken from the surface of a wine vat, South Africa.

Comments on the genus

Wickerhamiella has been isolated only rarely and forms vegetative cells that are among the smallest known for yeasts. The genus is also unique by virtue of its ascospores which have an elongated, irregular shape with a roughened surface.

54. *Williopsis* Zender

C.P. Kurtzman

Diagnosis of the genus

Asexual reproduction is by multilateral budding on a narrow base. Cells are spheroidal, ovoidal or occasionally elongate. True hyphae are not produced, but pseudohyphae may form. Pellicles are formed on the surface of liquid media by some species.

Asci may be unconjugated or there may be conjugation between a cell and its bud or between independent cells. Asci, which may be either persistent or deliquescent, form 1–4 saturnoid ascospores.

Glucose is fermented. D-xylose is assimilated. Diazonium blue B reaction is negative.

Type species

Williopsis saturnus (Klöcker) Zender

Species accepted

1. *Williopsis californica* (Lodder) von Arx (1977)
2. *Williopsis mucosa* (Wickerham & Kurtzman) Kurtzman (1991)

^a Abbreviations: Glu, glucose; Su, sucrose; Raf, raffinose; Gal, galactose; L Sor, L-sorbose; Mal, maltose; Cel, cellobiose; Mel, melezitose; L Rham, L-rhamnose; NO₃, nitrate.

^b Growth in vitamin-free medium.

^c Separation of *W. saturnus* var. *saturnus* and *W. saturnus* var. *suaveolens* is based on the following assimilation reactions on maltose and L-rhamnose: var. *saturnus*, maltose -/L-rhamnose + or maltose +/L-rhamnose v; var. *suaveolens*, maltose -/L-rhamnose -.

7 days at 25°C, growth under the coverglass shows neither pseudohyphae nor true hyphae. Aerobic growth is white to grayish-white, moderately glistening, and butyrous. Colony margins are finely lobed.

Formation of ascospores: Conjugation occurs between cells and their buds, between independent cells, or rarely asci are unconjugated. Asci contain one to four elongated saturn-shaped ascospores which become moderately refractile upon release from their deliquescent asci (Fig. 190). Single-ascospore isolates from four-spored asci form sporogenous colonies, thus suggesting the species to be homothallic.

Ascospores were observed on 5% malt extract agar after 2 weeks at 25°C.

Fig. 190. *W. californica*, CBS 5760. Asci with ascospores, after 4 days on 5% malt extract agar at 25°C. Bar = 5 µm.

Co-Q: 7 (Yamada et al. 1973a).

Mol% G + C: 43.9, 44.1, two strains (*T_m*: Nakase and Komagata 1971b); 42.6–43.3, type and four additional strains (BD: Kurtzman 1991a).

Origin of the strains studied: This species has a worldwide distribution: soil, Australia (2), Belgium (1), Canada (1), India (1), New Zealand (4), U.S.A. (13); streams and lakes, U.S.A. (2); frass from the momi fir

(*Abies firma* Sieb & Zucc.), Japan (1), European beech (*Fagus sylvaticus* L.), Sweden (1), mountain ash (*Sorbus americana* L.), U.S.A. (1), elm (*Ulmus* sp.), U.S.A. (1); flux of the koa acacia (*Acacia koa* Gray), U.S.A. (1); shrimp, U.S.A. (1); bear (*Ursus actos yesoensis*) dung, Japan (2); ox dung, France (1); unknown (2).

Type strain: CBS 252 (NRRL Y-17395), isolated by F.M. Muller in California, U.S.A., from an enrichment culture of *Azotobacter*. The original description of the species was based on this strain. CBS 5760 (NRRL Y-1680), isolated from soil, Murray Bridge, South Australia, was considered by Wickerham (1951) as the most typical strain of the species and came to be regarded by some as the type strain.

Comments: The taxa designated *Hansenula dimennae*, *Pichia saturnospora* and *Endomycopsis fukushimae* were reported by Kurtzman (1991a) to show 94–100% nuclear DNA relatedness with *W. californica* and, therefore, represent synonyms of this latter species. *H. dimennae* had been separated from *W. californica* because of its failure to assimilate sucrose.

54.2. *Williopsis mucosa* (Wickerham & Kurtzman) Kurtzman (1991a)

Synonyms:

Pichia mucosa Wickerham & Kurtzman (1971)

Waltiozyma mucosa (Wickerham & Kurtzman) Muller & Kock (1986)

Growth on 5% malt extract agar: After 3 days at 25°C, the cells are spheroidal to mostly ellipsoidal, (2.5–5.1)×(4.5–8.0)µm, and occur singly or in pairs. Growth is tannish-white in color and mucoid.

Growth on the surface of assimilation media: Dry climbing pellicles are formed.

Dalmau plate culture on morphology agar: After 7 days at 25°C, growth under the coverglass shows pseudohyphae to be common and highly branched. True hyphae are not present. Aerobic growth is raised, highly glistening, mucoid, gray-white in color and with an entire margin.

Formation of ascospores: Asci are unconjugated and persistent and each contains one or two spores. The spores are spheroidal to occasionally slightly ellipsoidal and have a thick equatorial ring. Colonies from single-ascospore isolates are sporogenous, but since four-spored asci were not available for testing, it is not certain that this species is homothallic.

Ascospores were observed on 5% malt extract- and YM agars after 1 week at 25°C.

Origin of the strains studied: Soil, South Africa (1), U.S.A. (1).

Type strain: CBS 6341 (NRRL YB-1344), from soil, Illinois, U.S.A.

Comments: As discussed under Comments on the genus, *W. mucosa* was transferred to *Williopsis* from *Pichia* because of the overall similarity of its rRNA nucleotide sequences to other members of the genus (Liu and Kurtzman 1991). *W. mucosa* is unique among the saturn-spored yeasts because it produces substantial amounts of an extracellular polysaccharide. The polysaccharide is neutral and the only sugar present is D-mannose (Seymour et al. 1976).

W. mucosa was assigned to the newly described genus *Waltiozyma* by Muller and Kock (1986) on the basis of apparent uniqueness in cellular fatty acid composition and because it was believed to produce coenzyme Q-6 (Billon-Grand 1985), in contrast to Q-7 that is produced by other *Williopsis* spp., as well as by *Saturnispora* spp. Y. Yamada (personal communication) reexamined *W. mucosa* and reported that both known strains are characterized by coenzyme Q-7.

54.3. *Williopsis pratensis* Bab'eva & Reshetova (1979)

Synonym:

Komagataea pratensis (Bab'eva & Reshetova) Y. Yamada, Matsuda, Maeda, Sakakibara & Mikata (1994b)

Growth on 5% malt extract agar: After 3 days at 25°C, the cells are spheroidal to short ellipsoidal, (2.8–6.0)×(3.0–7.3)µm, and single, in pairs, or in small clusters. Growth is butyrous and tannish-white in color.

Growth on the surface of assimilation media: Pellicles are not formed but thin films and rings may occur.

Dalmau plate culture on morphology agar: After 7 days at 25°C, growth under the coverglass shows neither pseudohyphae nor true hyphae. Aerobic growth is white, dull-glistening, finely striated and butyrous. Colony margins are irregular.

Formation of ascospores: Ascospores were not observed in the present study. Bab'eva and Reshetova (1979) reported the formation of unconjugated, persistent asci having one or two spheroidal spores with ledges.

Mol% G+C: 39.9, CBS 7079 (BD: Kurtzman 1991a).

Origin of the strains studied: Soil from a meadow, Russia (2).

Type strain: CBS 7079 (NRRL Y-12696), from meadow soil, Russia.

54.4. *Williopsis salicorniae* Hinzelin, Kurtzman & M.Th. Smith (1991)

Growth on 5% malt extract agar: After 3 days at 25°C, the cells are spheroidal to ellipsoidal, (3.0–6.5)×(3.0–8.0)µm, and single, in pairs, or in small clusters. Growth is butyrous and tannish-white in color.

Growth on the surface of assimilation media: Pellicles are not formed.

Dalmau plate culture on morphology agar: After

7 days at 25°C, growth under the coverglass shows neither pseudohyphae nor true hyphae, but “tree-like” outgrowths of undifferentiated cells occur infrequently. Aerobic growth is tannish-white, dull-glistening, and butyrous. Colony margins are irregular.

Formation of ascospores: Asci are unconjugated, persistent, and form one to four globose to subglobose spores having a thin equatorial ledge.

Ascospores were observed on 5% malt extract agar after 3–4 weeks at 25°C.

Fermentation:

Glucose	+	Lactose	–
Galactose	–	Raffinose	–
Sucrose	–	Trehalose	–
Maltose	–		

Assimilation:

Additional assimilation tests and other growth characteristics:

2-Keto-D-gluconate	–	Starch formation	–
5-Keto-D-gluconate	–	Gelatin liquefaction	–
Saccharate	–	Growth at 37°C	–
10% NaCl/5% glucose	–		

Co-Q: Not determined.

Mol% G+C: 36.7, CBS 8071 (BD: Hinzelin et al. 1991).

Origin of the strain studied: Brackish water, France.

Type strain: CBS 8071 (NRRL Y-12834), isolated from the brackish water of a salt spring near Château-Salins, France.

54.5. *Williopsis saturnus* (Klöcker) Zender (1925b)

This species has five varieties:

***Williopsis saturnus* (Klöcker) Zender var. *saturnus* (1991)**

Synonyms:

Saccharomyces saturnus Klöcker (1902)

Willia saturnus (Klöcker) Hansen (1904)

Hansenula saturnus (Klöcker) H. & P. Sydow (1919)

Hansenula beijerinckii van der Walt (1957)

Williopsis beijerinckii (van der Walt) Naumov & Vustin (Naumov et al. 1981)

Hansenula coprophila Soneda (1959)

Williopsis saturnus* var. *mrakii* (Wickerham) Kurtzman (1991a)*Synonyms:***Hansenula mrakii* Wickerham (1951)*Williopsis mrakii* (Wickerham) Naumov & Vustin (Naumov et al. 1981)***Williopsis saturnus* var. *sargentensis* (Wickerham & Kurtzman) Kurtzman (1991a)****Synonyms:***Pichia sargentensis* Wickerham & Kurtzman (1971)*Williopsis sargentensis* (Wickerham & Kurtzman) Naumov (1987a)***Williopsis saturnus* var. *suaveolens* (Klöcker) Kurtzman (1991a)****Synonyms:***Pichia suaveolens* Klöcker (1912a)*Hansenula suaveolens* (Klöcker) Dekker (Stelling-Dekker 1931)*Williopsis suaveolens* (Klöcker) Naumov, Vustin & Bab'eva (Naumov et al. 1985a)***Williopsis saturnus* var. *subsufficiens* (Wickerham) Kurtzman (1991a)****Synonyms:***Hansenula saturnus* (Klöcker) H. & P. Sydow var. *subsufficiens* Wickerham (1969b)*Williopsis subsufficiens* (Wickerham) Vustin, Naumov & Bab'eva (Vustin et al. 1982)

Growth on 5% malt extract agar: After 3 days at 25°C, the cells are spheroidal, ellipsoidal, or occasionally elongate, (2.5–5.2) × (3.5–8.5) μm, and occur singly, in pairs, or small clusters. Growth is butyrous and tannish-white in color.

Growth on the surface of assimilation media: Pellicles vary from thin and smooth to thick and folded, and may reach a height of 20 mm above the surface of the medium.

Dalmau plate culture on morphology agar: After 7 days at 25°C, growth under the coverglass shows only occasional primitive pseudohyphae. True hyphae are not produced. Aerobic growth is tannish-white, smooth, dull, and butyrous. Colony margins may be entire or finely lobed.

Formation of ascospores: Asci are generally unjugated but occasionally conjugation between independent cells is observed. One to four saturn-shaped ascospores are formed per ascus (Fig. 191). The thickness of the rings on the spores varies, and spores from one strain may even lack rings (Wickerham 1970a). Asci are persistent. Single-spore isolates form sporogenous colonies indicating the species to be homothallic.

Ascospores were observed on 5% malt extract agar and on YM agar after 2 weeks at 25°C.

Fermentation:

Glucose	+	Lactose	–
Galactose	–	Raffinose	+/-w
Sucrose	+	Trehalose	–

Co-Q: 7, varieties *saturnus*, *subsufficiens*, *mrakii* (Yamada et al. 1973a).

Mol% G+C: variety *saturnus*, 42.4–43.7, three strains (T_m), 44.3–44.6, five strains (BD); variety *mrakii*, 42.0, one strain (T_m), 44.3, two strains (BD); variety *sargentensis*, 44.1, one strain (BD); variety *suaveolens*, 44.5, 44.7, two strains (BD); variety *subsufficiens*, 42.9, 43.2, two strains (T_m), 43.5, 43.7, two strains (BD) (T_m : Nakase and Komagata 1971b; BD: Kurtzman 1991a).

Supplementary description of *W. saturnus* varieties:

Variety *mrakii*: sucrose is neither fermented nor assimilated.

Variety *sargentensis*: sucrose is neither fermented nor assimilated, nitrate is not assimilated, an exogenous supply of vitamins is required for growth.

Variety *suaveolens*: neither maltose nor L-rhamnose are assimilated, whereas for the variety *saturnus*, one or both of these sugars are assimilated.

Variety *subsufficiens*: sucrose is fermented and assimilated but an exogenous supply of vitamins is required for growth.

Origin of the strains belonging to the variety *saturnus*: The taxon has been isolated worldwide from the following: soil, Egypt (1), Liberia (6), New Zealand (1), South Africa (2), U.S.A. (21); streams, lakes, bogs, U.S.A. (10); leaf litter, Japan (1), U.S.A. (1); tree frass, U.S.A. (3); vegetables, Japan (1); elephant dung, Japan (1); unknown (7).

Type strain: CBS 254 (NRRL Y-17396), believed to be Klöcker's original isolate from soil, Himalayas, and obtained through Winge. Wickerham (1951) considered CBS 5761 (NRRL Y-1304) to be a typical strain, and this inadvertently came to be regarded as the type strain.

Origin of the strains belonging to the variety *mrakii*: Soil, India (1), New Guinea (1); swamp water, Wyoming, U.S.A. (1); water from a hot spring, California, U.S.A. (1).

Type strain: CBS 1707 (NRRL Y-1364), isolated from soil in New Guinea.

Origin of the strain belonging to the variety *sargentensis*: Outlet of a small lake at Camp Sargent near Peterborough, New Hampshire, U.S.A.

Type strain: CBS 6342 (NRRL YB-4139).

Origin of the strains belonging to the variety *suaveolens*: Soil, Canada (1), Denmark (1), New Zealand (2), U.S.A. (3); ponds and streams, U.S.A. (6); unknown (2).

Type strain: CBS 255 (NRRL Y-17391), Klöcker's culture from soil, Denmark.

Origin of the strains belonging to the variety *subsufficiens*: Soil, Liberia (2), Illinois, U.S.A. (1).

Type strain: CBS 5763 (NRRL YB-1657), from soil, Liberia.

Comments: *W. saturnus* and the four taxa designated as its varieties in this treatment have had a long and varied taxonomic history. Wickerham (1969a) attempted to address the issue of species delimitation in the *W. saturnus* complex by measuring the fertility of intertaxon pairings. Hybrids were obtained between the following pairs: *Hansenula californica* and *H. dimennae*; *H. mrakii* and *H. beijerinckii*; *H. saturnus* var. *saturnus* and *H. beijerinckii*; and *H. saturnus* var. *subsufficiens* and *H. beijerinckii*. Hybrids showed reduced sporulation and a greater proportion of poorly formed ascospores, but the analysis was complicated by the finding that hybrids failed to form in certain intraspecific pairings.

Naumov and colleagues (Naumov et al. 1985a, Naumov 1987a) extended Wickerham's genetic studies by using auxotrophic mutants, which allowed hybridizations to be followed more accurately, and by analysis of any resulting single-spore isolates. Crosses of the species pairs *W. saturnus* var. *saturnus* × *W. beijerinckii*, *W. saturnus* var. *saturnus* × *W. mrakii* and *W. beijerinckii* × *W. mrakii* yielded hybrids producing ascospores with only 0–4% viability,

leading to the interpretation that all four taxa represent biologically separate sibling species (Naumov 1987a). However, in earlier work, Naumov et al. (1985a) suggested that *W. (Zygowilliopsis) californica* and its suspected synonyms *Endomycopsis fukushimae* and *Pichia saturnospora* were conspecific on the basis of crosses that yielded progeny viabilities much like those found among the *W. saturnus* complex.

Kurtzman (1991a) addressed the taxonomy of the *W. saturnus* complex from the perspective of nuclear DNA relatedness. DNA complementarity ranged from 36–72%. Thus, as with the foregoing genetic crosses, the extent of DNA relatedness approaches that of separate species in some cases, but is nonetheless, greater than previously seen among many closely related sibling species (Kurtzman 1987b). Because of the uncertainties expressed about genetic isolation among the strains, all taxa showing intermediate DNA relatedness have been defined as varieties of *W. saturnus*. This approach also serves to emphasize their close genetic relatedness in a way not possible if some of the taxa are designated as separate species. Consistent with this treatment is the similarity of rRNA nucleotide sequences exhibited by members of the group (Liu and Kurtzman 1991).

W. saturnus var. *sargentensis* was earlier classified as *Pichia sargentensis* (Wickerham and Kurtzman 1971). The relatively high DNA relatedness (68%) detected between this taxon and *W. saturnus* var. *mrakii* (Kurtzman 1991a) further argues that ability to assimilate nitrate as a sole source of nitrogen offers little taxonomic resolution, an observation in keeping with other work (Kurtzman 1984a).

Comments on the genus

The genus *Williopsis*, as defined by Zender (1925b), was based mainly on the formation of saturn-shaped ascospores by the species assigned to it rather than on ability to assimilate nitrate as a sole source of nitrogen as later became the basis for separating *Hansenula* and *Pichia* (Stelling-Dekker 1931). More recent taxonomic treatments have discarded use of *Williopsis* (Wickerham 1951, Lodder and Kreger-van Rij 1952, Lodder 1970, Kreger-van Rij 1984a) in favor of assigning nitrate-assimilating species to *Hansenula* and placing in *Pichia* those species that do not assimilate nitrate. Von Arx et al. (1977) revived the use of *Williopsis* but seem to have restricted species assignment to those saturn-spored taxa that were formerly placed in *Hansenula*.

Naumov (1987a) has argued for retention of *W. californica* in *Zygowilliopsis* as proposed earlier when the genus was described by Kudryavtsev (1960). Wickerham (1951) examined the species now assigned to *Williopsis* and pointed out that all form some haploid cells, thus negating the distinction between haploid and diploid species, the primary criterion for separation of *Zygowilliopsis* and *Williopsis*.

Kurtzman (1991a) measured the extent of nuclear DNA complementarity among saturn-spored taxa assigned to *Williopsis* and *Pichia* thus defining species. Because the resolution of this methodology extends only to definition of closely related sibling species (Kurtzman 1987b), Liu and Kurtzman (1991) estimated species relationships from rRNA divergence. Results from these comparisons were rather surprising. The saturn-spored *Pichia* spp. formed a close cluster that was well-separated from *Williopsis*, but all five *Williopsis* spp. were rather widely separated from one another. Because of their genetic isolation, the four *Pichia* spp. were assigned to the newly described genus *Saturnispora* (Liu and Kurtzman 1991). The apparent great phylogenetic distance between species of *Williopsis* raised several possibilities: the taxa represented five monotypic sibling genera, rates of nucleotide substitution were abnormally high causing the genetic distance to appear greater than it is, or that there are numerous taxa

missing from the clade. In view of the uncertainty, Liu and Kurtzman (1991) considered the five species to be members of *Williopsis*.

Kurtzman and Robnett (unpublished data) reexamined the phylogeny of *Williopsis* by including the species in rRNA sequence analyses of *Pichia*. The genus *Pichia* separated into six major clades with *Williopsis* species distributed among several of them. These data demonstrated *Williopsis* and *Pichia* to be polyphyletic and therefore artificial genera. Additional work is required before the species can be reassigned to genera that are phylogenetically circumscribed.

At present, *Williopsis* and *Saturnispora* can be separated on standard growth tests because all species assigned to *Williopsis* assimilate D-xylose whereas *Saturnispora* species do not. D-xylose assimilation is regarded as a fortuitous phenotypic marker and not of phylogenetic significance.

55. *Yarrowia* van der Walt & von Arx

C.P. Kurtzman

Diagnosis of the genus

Asexual reproduction is by multilateral budding on a narrow base. Arthroconidia may occasionally be formed as well. Budded cells are spheroidal, ellipsoidal, or often elongate. True hyphae and pseudohyphae are formed; true hyphae have septa with a single central micropore.

Asci are unconjugated and generally arise from diploid hyphae. The asci, which slowly deliquesce, form 1–4 ascospores that may be spheroidal, hat-shaped, hemispheroidal, or somewhat angular.

Sugars are not fermented. Nitrate is not assimilated. Lipases, proteases, and urease are produced. Coenzyme Q-9 is formed. Diazonium blue B reaction is negative.

Candida petrophilum Takeda, Iguchi, Tsuzuki & Nakano (1972)

nom. nud.

Candida pseudolipolytica Blagodatskaya & Kocková-Kratochvilová (1973)

Saccharomycopsis pseudolipolytica Blagodatskaya (1979)

Growth on 5% malt extract agar: After 3 days at 25°C, the cells are spheroidal, ellipsoidal to elongate, (3.0–5.0) × (3.3–15.0) μm, and single, in pairs or small clusters. Growth is butyrous to mycelial and tannish-white in color.

Growth on the surface of assimilation media:

Pellicles are formed and may be thin or rather thick.

Dalmou plate culture on morphology agar: After

7 days at 25°C, growth under the coverglass shows pseudohyphae, and true hyphae are usually present as well. The septa of true hyphae have a single central pore that lacks tapered edges (Kreger-van Rij and Veenhuis 1973). Aerobic growth is white to tannish-white and smooth-glistening to dull and convoluted. Colony margins may be entire or lobed.

Formation of ascospores: This species is heterothallic. Asci are unconjugated and may form from natural diploids or from diploids resulting from conjugation of complementary mating types. Asci are usually produced on hyphal cells but infrequently an ascus will arise on a single blastoconidium. Asci may be either stalked or sessile, and they become deliquescent as they mature. Generally, one to four ascospores are formed in each ascus (Fig. 192). Ascospore shape is quite variable and is determined in part by the mating types paired. Ascospores from NRRL YB-

Fig. 192. *Y. lipolytica*, CBS 6124.1 × CBS 6124.2. Asci with ascospores, after 1 week at 25°C, on YM agar. Bar = 5 μm.

423-3×NRRL YB-423-12 are spheroidal, hat-shaped, or irregular, and may be roughened, whereas ascospores from NRRL YB-421×NRRL YB-423-12 are hemispheroidal and somewhat saucer-like.

Ascospores were observed on YM agar after 3–7 days at 25°C. Herman (1971b) reported increased fertility and ascospore germination when complementary mating types were paired on RG medium.

Fermentation: absent.

(CBS 6124.1) and NRRL YB-423-12 (CBS 6124.2), single-ascospore isolates from NRRL YB-423.

Type strain: CBS 6124 (NRRL YB-423), an ascosporegenous strain isolated by Wickerham from corn fiber tailings, Illinois, U.S.A.

Comments on the genus

Wickerham et al. (1970a,b) discovered the teleomorph of *Candida lipolytica*, which they described as *Endomycopsis lipolytica*. However, van der Walt and Scott (1971b) pointed out that *Endomycopsis* was an obligate synonym of *Saccharomycopsis* Schiöningg, but they placed only some of the species in other genera. Later, Yarrow (1972) transferred *E. lipolytica* to the genus *Saccharomycopsis*. Relative to other members of *Saccharomycopsis*, *S. lipolytica* appeared unique because of the shape of its ascospores and the presence of coenzyme Q-9. Based on these criteria, van der Walt and von Arx (1980) described the genus *Yarrowia* for placement of *S. lipolytica*.

Through comparisons of 18S rRNA sequences, Barns et al. (1991) demonstrated *Y. lipolytica* to be phylogenetically distant from selected members of *Candida* and several teleomorphic ascomycetous yeast genera. Kurtzman and Robnett (1994a, 1995) showed from partial rRNA/rDNA sequence analyses that *Y. lipolytica* is only distantly related to most other known ascomycetous yeasts and that its nearest neighbor appears to be *Wickerhamiella domercqiae*.

Y. lipolytica has several physiological properties of industrial significance. The species is well-known for production of proteases, lipase, and utilization of *n*-paraffins (Peters and Nelson 1948, Tsugawa et al. 1969). This last property focused interest on *Y. lipolytica* as a potential source of yeast protein from hydrocarbons, a popular idea in an era of low cost petroleum. The discovery in the late 1960's that high yields of citric acid were produced by *Y. lipolytica* (Yamada 1977) signaled a dramatic change in the fermentation industry, because the yields of this industrially important acidulant were about twice that obtained from *Aspergillus niger*; the industry mainstay since the early 1900's.

56. *Zygoascus* M.Th. Smith

M.Th. Smith

Diagnosis of the genus

Asexual reproduction is by multilateral budding, and formation of pseudomycelium and true hyphae with blastoconidia. Hyphal septa have micropores.

Asci are formed after fusion of opposing hyphal cells and are obovate to spheroidal, persistent and contain 1–4 hemispheroidal to galeate ascospores.

Sugars are fermented. Nitrate is not assimilated. Diazonium blue B reaction is negative.

Type species

Zygoascus hellenicus M.Th. Smith

Species accepted

1. *Zygoascus hellenicus* M.Th. Smith (1986)

Systematic discussion of the species

56.1. *Zygoascus hellenicus* M.Th. Smith (1986)

Anamorph: *Candida hellenica* (Verona & Picci) D.S. King & S.-C. Jong

Synonyms:

Trichosporon hellenicum Verona & Picci (1958)

Candida hellenica (Verona & Picci) D.S. King & S.-C. Jong (1977)

Candida steatolytica Yarrow (1969)

Candida inositophila Nakase (1975)

Pichia hangzhouana Lu & M.X. Li (1989)

Growth on glucose–yeast extract–peptone water:

After 3 days at 25°C, the cells are ovoidal, long ovoidal, sausage-shaped, or elongate to cylindroidal, (2.0–5.0) × (4.5–15.5) µm. Pseudomycelium with long branches and mycelial cells (up to 30 µm in length) may also be present. A sediment and ring with islets or a thick wrinkled pellicle are formed.

Growth on glucose–yeast extract–peptone agar:

After one month at 25°C, the streak culture is white or cream-colored, shiny or dull, soft or slightly membranous, and smooth or delicately wrinkled. A mycelial border is present.

Dalmau plate culture on corn meal agar: Both pseudomycelium and true hyphae are abundantly formed. Pseudohyphal cells slender and often curved. Ovoidal blastoconidia are present.

Formation of ascospores: The species is heterothallic. Asci, which may be single or in clusters, form either directly from conjugation of opposite hyphal cells, where the conjugation bridge forms one or more lateral outgrowths which develop into asci, or from apical cells which arise after sequential buddings of the lateral outgrowths. Asci are obovoidal to spheroidal and persistent. One to four hemispheroidal to hat-shaped ascospores are formed (Fig. 193).

Ascospores were observed on 5% Difco malt agar within 7–21 days at 25°C.

Complementary mating types: CBS 5839 and CBS 6736.

Type strain: Holotype as dried sporulating specimen of CBS 5839×CBS 6736. Living strains CBS 5839 and CBS 6736.

Comments on the genus

The genus *Zygoascus* is characterized by the production of budding cells, pseudohyphae, septate hyphae and asci with 1–4 hemispheroidal to galeate ascospores which have a distinct electron-dense base (Smith 1986). In this respect, *Zygoascus* resembles eight yeast genera as classified by von Arx (1981) in the Endomycetaceae and Saccharomycetaceae. However, *Zygoascus* can be distinguished from these genera either by morphological differences of the septa and the asci or by differences in biochemical properties (Table 45). Kurtzman and Robnett (unpublished data) found *Pichia hangzhouana* and *Z. hellenicus* to have identical nucleotide sequences in the 5' end of the large subunit rDNA, indicating that the two taxa are conspecific.

57. *Zygosaccharomyces* Barker

C.P. Kurtzman

Diagnosis of the genus

Vegetative reproduction is by multilateral budding. Cells are spheroidal, ellipsoidal or elongate. Pseudohyphae may be present but true hyphae are not formed.

Asci are persistent and may be unconjugated or show conjugation between a cell and its bud; most frequently, asci form following conjugation between independent cells, often with both cells producing ascospores. Ascospores are smooth, spheroidal to ellipsoidal, with 1–4 per ascus.

Glucose is fermented. Nitrate is not assimilated. Pellicles are not formed on liquid media. Coenzyme Q-6 is produced. Diazonium blue B reaction is negative.

Type species

Zygosaccharomyces barkeri Saccardo & Sydow

An original culture no longer exists, but *Z. barkeri*, the type species of *Zygosaccharomyces*, may be a synonym of *Z. rouxii*.

Species accepted

1. *Zygosaccharomyces bailii* (Lindner) Guilliermond (1912)
2. *Zygosaccharomyces bisporus* H. Naganishi (1917)

Systematic discussion of the species

57.1. *Zygosaccharomyces bailii* (Lindner) Guilliermond (1912)

Synonyms:

- Saccharomyces bailii* Lindner (1895)
Zygosaccharomyces mandshuricus Saito (1914)
Zygosaccharomyces nishiwakii Guilliermond (1930)
Zygosaccharomyces naniwaensis Otani (1931)
Zygosaccharomyces sake Suminoe (Naganishi 1941)
Saccharomycodes mestrus Marcilla & Feduchy (1943)

Zygosaccharomyces acidifaciens Nickerson (1943)

Saccharomyces acidifaciens (Nickerson) Lodder & Kreger-van Rij (1952)

Saccharomyces elegans Lodder & Kreger-van Rij (1952)

Saccharomyces elegans Lodder & Kreger-van Rij var. *intermedia* Verona & Zardetto de Toledo (1959b) nom. nud.

Growth on 5% malt extract agar: After 3 days at 25°C, the cells are spheroidal to ellipsoidal, (3.1–7.0)×(3.6–11.8) μ m, and single or in pairs. Growth is butyrous and tannish-white in color.

Table 46
Key characters of species in the genus *Zygosaccharomyces*

Species	Assimilation			Growth				
	Tre	Mel	α -MG	0.1% Cycloheximide	W/o inositol	GTYE/1% acetic acid	16%NaCl/ 5%glucose	37°C

<i>Z. mrakii</i>	–	+	–	+	+	–	–	–
<i>Z. rouxii</i>	×	–	–	–	+	–	+	v

^a Abbreviations: Tre, trehalose; Mel, melibiose; α -MG, α -methyl-D-glucoside; GTYE/1% acetic acid, glucose-tryptone-yeast extract agar with 1% acetic acid; 16%NaCl/5%glucose, 16%NaCl/5%glucose in yeast nitrogen base.

Growth on the surface of assimilation media: Pellicles are not formed.

Dalmau plate culture on morphology agar: After 7 days at 25°C, growth under the coverglass often shows pseudohyphal outgrowths, but the pseudohyphae usually show little branching and the cells are seldom elongated. True hyphae are not formed. Aerobic growth is tannish-white, dull-glistening with a smooth to finely convoluted surface, butyrous, and with margins that are entire to finely lobed. A faint, acidic odor is present.

Formation of ascospores: Asci are persistent and generally conjugated with each conjugant forming one or two smooth, globose to ovoidal ascospores (Fig. 194). The species appears homothallic.

Ascospores were observed on YM and 5% malt extract agars after 3–30 days at 25°C.

Fig. 194. *Z. bailii*, CBS 1097. Conjugated ascus with ascospores, after 3 weeks on 5% malt extract agar at 25°C. Bar = 5 μ m.

¹ Growth on GTYE agar with 1% acetic acid (see Table 46).

Co-Q: 6, CBS 680 and 2 additional strains (Yamada et al. 1976b).

Mol% G + C: 40.5, CBS 680 (T_m : Nakase and Komagata 1971e); 43.8–45.5, CBS 680 and 10 additional strains (BD: Kurtzman 1990c).

Origin of the strains studied: CBS 680 (NRRL

Y-2227), Inst. of Brewing, Tokyo; apple juice, Netherlands (1); spoiled salad dressing, U.S.A. (9).

Type strain: CBS 680.

Comments: *Z. bailii* has a worldwide distribution and is often isolated from spoiled acidified condiments. Kurtzman et al. (1971) showed that much of the yeast spoilage of mayonnaise and salad dressing was due to *Z. bailii*.

Z. bailii is of potential industrial interest. Nickerson (1943), Nickerson and Carroll (1945) and Spencer and Sallans (1956) reported some strains to produce large amounts of L-arabitol, glycerol, erythritol and mannitol.

57.2. *Zygosaccharomyces bisporus* H. Naganishi (1917)

Synonym:

Saccharomyces bisporus (H. Naganishi) Lodder & Kreger-van Rij (1952) [nec *Zygosaccharomyces bisporus* Anderson (1917)]

Growth on 5% malt extract agar: After 3 days at 25°C, the cells are spheroidal to ellipsoidal, (2.3–5.2) × (2.4–10.1) μm, and single or in pairs. Growth is butyrous and tannish-white in color.

Growth on the surface of assimilation media: Pellicles are not formed.

Dalmou plate culture on morphology agar: After 7 days at 25°C, growth under the coverglass may occasionally show a few short chains of ellipsoidal cells, but neither well-developed pseudohyphae nor true hyphae are formed. Aerobic growth is butyrous, white to tannish-white, dull-glistening, with a smooth surface, and with margins that are entire or lobed. A faint, acidic odor is present.

Formation of ascospores: Asci are persistent and often conjugated, with each conjugant forming one or two smooth, globose to ovoidal ascospores (Fig. 195). The species appears homothallic.

Ascospores were observed on YM and 5% malt extract agars after 5–30 days at 25°C.

Fig. 195. *Z. bisporus*, NRRL Y-7253. Conjugated asci with ascospores after 20 days on 5% malt extract agar at 25°C. Bar = 5 μm.

Fermentation:

Glucose	+	Lactose	–
Galactose	–	Raffinose	–
Sucrose	–	Trehalose	–
Maltose	–		

Assimilation:

Glucose	+	<i>N</i> -Acetyl-D-glucosamine	–
Galactose	v	Methanol	–
L-Sorbose	+	Ethanol	+
Sucrose	–	Glycerol	+

¹ Growth on GTYE agar with 1% acetic acid (see Table 46).

Co-Q: 6, CBS 702 and 1 additional strain (Yamada et al. 1976b).

Mol% G+C: 44.1, 43.7, CBS 702, IFO 0723 (*T_m*: Nakase and Komagata 1971e); 44.0, CBS 702 (BD: Price et al. 1978); 45.0–45.6, CBS 702 and 2 additional strains (BD: Kurtzman 1990c).

Origin of the strains studied: CBS 702 (NRRL Y-12626), from K. Saito; CBS 1082, from tea-beer fungus, Java; NRRL Y-7253, from spoiled salad dressing, U.S.A.

Type strain: CBS 702.

Comments: *Z. bisporus* is often isolated from spoiled, acidic foods. Painting and Kirsop (1984) and Toh-e et al. (1982, 1984) discovered DNA plasmids in *Z. bailii*, *Z. bisporus* and *Z. rouxii*.

57.3. *Zygosaccharomyces cidri* (Legakis) Yarrow (von Arx et al. 1977)

Synonyms:

Saccharomyces cidri Legakis (1961)

Torulasporea cidri (Legakis) van der Walt & E. Johannsen (1975a)

Growth on 5% malt extract agar: After 3 days at 25°C, the cells are spheroidal to ellipsoidal, or occasionally cylindrical, (2.3–5.9) × (3.0–6.2) μm, and single or in pairs. Growth is butyrous and tannish-white in color.

Growth on the surface of assimilation media: Pellicles are not formed.

Dalmau plate culture on morphology agar: After 7 days at 25°C, growth under the coverglass may occasionally show short chains of ellipsoidal cells, but neither well-developed pseudohyphae nor true hyphae are formed. Aerobic growth is butyrous, tannish-white, dull to glistening with a smooth surface, and with entire to finely lobed margins. A faint, acidic odor is present.

Formation of ascospores: Asci are persistent and generally conjugated, with each conjugant forming one, two, or three smooth, globose to ovoidal ascospores. (Fig. 196). The species appears homothallic.

Ascospores were observed on YM and 5% malt extract agars after 2–4 weeks at 25°C.

Fig. 196. *Z. cidri*, CBS 4575. Conjugated ascus with ascospores after 4 weeks on 5% malt extract agar at 25°C. Bar = 5 µm.

Mol% G+C: 42.6, CBS 4575 (BD: Price et al. 1978); 43.9, 43.3, CBS 4575, CBS 2950 (BD: Kurtzman 1990c).

Origin of the strains studies: CBS 4575 (NRRL Y-12634) and CBS 2950 (NRRL Y-12635), both from cider.

Type strain: CBS 4575.

57.4. *Zygosaccharomyces fermentati* H. Naganishi (1928)

Synonyms:

[non *Zygosaccharomyces fermentati* (Saito) Krumbholz (1933)]

Debaryomyces mandshuricus H. Naganishi (1924)

Zymodebaryomyces mandshuricus (H. Naganishi) Novák & Zsolt (1961)

Torulaspora manchurica (H. Naganishi) van der Walt & E. Johannsen (1975a)

Saccharomyces montanus Phaff, M.W. Miller & Shifrine (1956)

Saccharomyces malacitensis Santa Maria (1960) nom. nud.

Saccharomyces nilssoni (Capriotti) Santa Maria var. *malacitensis* Santa Maria (1963b)

Saccharomyces amurcae van der Walt (1970c)

Torulaspora amurcae (van der Walt) van der Walt & E. Johannsen (1975a)

Saccharomyces albasitensis Santa Maria (1978)

Saccharomyces astigiensis Santa Maria (1978)

Growth on 5% malt extract agar: After 3 days at 25°C, the cells are spheroidal to cylindrical, (2.0–7.1) × (3.0–8.1) µm, and occur singly, in pairs or in small clusters. Growth is butyrous and tannish-white.

Growth on the surface of assimilation media: Pellicles are not formed.

Dalmau plate culture on morphology agar: After 7 days at 25°C, growth under the coverglass may show simple, branched pseudohyphae, but true hyphae are not present. Aerobic growth is butyrous, tannish-white, and with a smooth, glistening surface. Colony margins are entire to irregularly lobed. A faint, acidic, ester-like odor is present.

Formation of ascospores: Asci are persistent and may be unconjugated or show conjugation between independent cells. Asci form one to four spheroidal to ovoidal ascospores that appear smooth (Fig. 197). The species is probably homothallic.

Ascospores were observed on YM, corn meal and 5% malt extract agars after 2–4 weeks at 25°C.

Fermentation:

Glucose	+	Lactose	–
Galactose	+	Raffinose	v

Y-12620), type strain of *Saccharomyces nilssoni* var. *malicitensis*, alpechin, Spain.

Type strain: CBS 707.

Comments: Kurtzman (1990c) determined the extent of nDNA relatedness between strains of *Z. fermentati* and found the species to be comprised of two populations each having high intragroup complementarity (95%) but diminished intergroup relatedness (70–77%). The first group included the type strain as well as CBS 6544 and CBS 6711. The second group was comprised of the type strains of *Saccharomyces montanus* (CBS 4506), *S. astigiensis* (CBS 7004), *S. albasitensis* (CBS 7005) and *S. nilssoni* var. *malicitensis* (CBS 4686). The divergent population has been maintained within *Z. fermentati*, but genetic crosses might show members of this group to be a sibling species of *Z. fermentati*.

57.5. *Zygosaccharomyces florentinus* Castelli ex Kudryavtsev (1960)

Synonyms:

Saccharomyces florentinus (Castelli ex Kudryavtsev) Lodder & Kreger-van Rij (1952)

Torulaspota florentina (Castelli ex Kudryavtsev) van der Walt & E. Johansen (1975a)

Zygosaccharomyces eupagyucus Sacchetti ex Kudryavtsev (1960)

Saccharomyces eupagyucus (Sacchetti ex Kudryavtsev) van der Walt (1970d)

Torulaspota eupagycia (Sacchetti ex Kudryavtsev) van der Walt & E. Johansen (1975a)

Growth on 5% malt extract agar: After 3 days at 25°C, the cells are spheroidal to ovoidal, (2.1–7.0) × (2.5–7.1) µm, and occur singly, in pairs, or occasionally in small clusters. Growth is butyrous and white to tannish-white in color.

Growth on the surface of assimilation media: Pellicles are not formed.

Dalmat plate culture on morphology agar: After 7 days at 25°C, growth under the coverglass shows occasional outgrowths of relatively simple, moderately branched pseudohyphae. True hyphae are not formed. Aerobic growth is butyrous, tannish-white, glistening, and with a smooth to finely striated surface. Margins are finely lobed. A faint, ester-like odor is present.

Formation of ascospores: Asci are persistent and generally form following conjugation between individual cells, but occasional asci may be unconjugated or show conjugation between a cell and its bud. One to four smooth, spheroidal to subspheroidal ascospores form in each ascus. The species appears to be homothallic.

Ascospores were observed on YM, corn meal, and 5% malt extract agars after 1–4 weeks at 25°C.

Fermentation:

Glucose	+	Lactose	-
Galactose	+	Raffinose	+
Sucrose	+	Trehalose	+
Maltose	+		

Assimilation:

Glucose	+	<i>N</i> -Acetyl-D-glucosamine	–

¹ Growth on GTYE agar with 1% acetic acid (see Table 46).

Co-Q: 6, AJ 4100 (Yamada et al. 1976b).

Mol% G+C: 42.4, CBS 746 and CBS 748 (BD: Price et al. 1978); 43.1, 42.8, CBS 746 and CBS 6081 (BD: Kurtzman 1990c).

Origin of the strains studied: CBS 746 (NRRL Y-1560), from grape must, Italy; CBS 748 (NRRL Y-1558), type strain of *Z. eupagycus*, orange drink, Italy; CBS 6081 (NRRL Y-12642), mountain laurel (*Rhododendron* sp.), Japan.

Type strain: CBS 746.

Comments: Price et al. (1978) showed 100% nDNA relatedness between the type strains of *Z. florentinus* and *Z. eupagycus*, thus demonstrating the conspecificity of the two taxa.

57.6. *Zygosaccharomyces mellis* Fabian & Quinet (1928)**Synonyms:**

Saccharomyces mellis (Fabian & Quinet) Lodder & Kreger-van Rij (1952)

Saccharomyces bisporus (H. Naganishi) Lodder & Kreger-van Rij var. *mellis* (Fabian & Quinet) van der Walt (1970d)

Zygosaccharomyces mellis-acidi von Richter (1912)

Zygosaccharomyces nadsonii Guillaermond (1918)

Zygosaccharomyces nussbaumeri Lochhead & Heron (1929)

Zygosaccharomyces amoeboides Kroemer & Krumbholz (Krumbholz 1931)

Zygosaccharomyces polymorphus Kroemer & Krumbholz f. *stellata* Krumbholz (1931)

Saccharomyces rouxii Boutroux var. *polymorphus* (Kroemer & Krumbholz) Lodder & Kreger-van Rij (1952)

Zygosaccharomyces perspicillatus Sacchetti (1932c)

Zygosaccharomyces ravennatis Sacchetti (1932c)

Kluyveromyces osmophilus Kreger-van Rij (1966a)

Growth on 5% malt extract agar: After 3 days at 25°C, the cells are spheroidal to ellipsoidal, or infrequently

cylindroidal, (2.5–2.9) × (3.0–6.2) μ m, and occur singly, in pairs, and in small clusters. Growth is butyrous and white to tannish-white in color.

Growth on the surface of assimilation media: Pellicles are not formed.

Dalmau plate culture on morphology agar: After 7 days at 25°C, growth under the coverglass shows occasional branched chains of elongated cells, but neither well-developed pseudohyphae nor true hyphae occur. Aerobic growth is butyrous, white, with surfaces that are smooth or irregular, and either dull or glistening. Margins are finely or irregularly lobed. A faint, acidic, ester-like odor is present.

Formation of ascospores: Ascospores were not observed in the present study.

Fermentation:

Glucose	+	Lactose	–
Galactose	–	Raffinose	–
Sucrose	w/–	Trehalose	–
Maltose	+w		

Assimilation:

Glucose	+	<i>N</i> -Acetyl-D-glucosamine	–
Galactose	–	Methanol	–
L-Sorbose	–	Ethanol	–
Sucrose	–	Glycerol	+
Maltose	v	Erythritol	–

¹ Growth on GTYE agar with 1% acetic acid (see Table 46).

Co-Q: 6, AJ 5262, AJ 5263 (Yamada et al. 1976b).

Mol% G+C: 41.2–41.8, CBS 736 and 6 additional strains (BD: Kurtzman 1990c).

Origin of the strains studied: CBS 736 (NRRL Y-12628), from honey; NRRL Y-56, NRRL Y-58, unknown sources, Tanner Collection, U.S.A.; NRRL Y-1024, honey?, Lochhead strain D-1; NRRL Y-1601 (CBS 684), honey, von Richter, Germany?; NRRL Y-17113, NRRL Y-17114, alpechín, Spain.

Type strain: CBS 736.

Comments: *Z. mellis* previously has been considered a variety of *Z. bisporus* (van der Walt 1970d) and as a synonym of *Z. rouxii* (Yarrow 1984d). Because of the difficulty in identifying strains of *Zygosaccharomyces* using phenotypic tests, Kurtzman (1990c) examined relationships among members of the genus from extent of nDNA complementarity. The study revealed that *Z. mellis* is a distinct species. Additionally, two of the strains (NRRL Y-56 and NRRL Y-1601) showed ca. 75% relatedness with the type strain but 97% relatedness with each other. These two isolates are presently regarded as divergent strains of *Z. mellis*, rather than as members of a sibling species.

Separation of *Z. mellis* and *Z. rouxii* is difficult using standard growth tests. *Z. rouxii* is slightly more tolerant of sodium chloride than is *Z. mellis*, thus allowing their separation on a medium containing 16% NaCl with 5% glucose (Kurtzman 1990c). Because the difference in sodium chloride tolerance between the two species is rather slight, reference strains need to be included for comparison.

57.7. *Zygosaccharomyces microellipsoides* (Osterwalder) Yarrow (von Arx et al. 1977)

Synonyms:

Saccharomyces microellipsoides (as *S. microellipsoides*) Osterwalder (1924a)

Torulasporea microellipsoides (Osterwalder) van der Walt & E. Johannsen (1975a)

Growth on 5% malt extract agar: After 3 days at 25°C, the cells are spheroidal to ellipsoidal, (1.8–6.9) × (2.1–7.1) μm, and occur singly, in pairs, and in small clusters. Growth is butyrous and white to tannish-white in color.

Growth on the surface of assimilation media: Pellicles are not formed.

Dalmau plate culture on morphology agar: After 7 days at 25°C, growth under the coverglass shows infrequent branched chains of elongated cells, but neither well-developed pseudohyphae nor true hyphae occur. Aerobic growth is butyrous, tannish-white, dull glistening, and with a finely lobed margin. A faint, acidic, ester-like odor is present.

Formation of ascospores: Asci are persistent and generally form following conjugation between independent cells. The asci form one to four smooth, spheroidal ascospores. The species is probably homothallic.

Ascospores were observed on YM agar after 2–4 weeks at 25°C.

Fermentation:

Glucose	+	Lactose	–
Galactose	+	Raffinose	+
Sucrose	+	Trehalose	–
Maltose	–		

Assimilation:

Glucose	+	<i>N</i> -Acetyl-D-glucosamine	–

¹ Growth on GYE agar with 1% acetic acid (see Table 46).

Co-Q: 6, AJ 4091, AJ 5292 (Yamada et al. 1976b).

Mol% G + C: 39.5, 39.3, AJ 4091, AJ 5292 (*T_m*: Nakase and Komagata 1971e); 40.3, CBS 427 (BD: Price et al. 1978); 41.2, 41.5, CBS 427, CBS 6142 (BD: Kurtzman 1990c).

Origin of the strains studied: CBS 427 (NRRL Y-1549), apple juice, Germany; CBS 2734 (NRRL Y-17057), berries of black currants (*Ribes nigrum*), Denmark; CBS 6142 (NRRL Y-17058), CBS 6143 (NRRL Y-17059), tea-beer, Finland; CBS 6641 (NRRL Y-17060), exudate of sandalwood (*Myoporum* sp.), Hawaii, U.S.A.; CBS 6762 (NRRL Y-17061), lemonade, Switzerland.

Type strain: CBS 427.

57.8. *Zygosaccharomyces mrakii* Capriotti (1958c)

Synonyms:

Saccharomyces mrakii (Capriotti) van der Walt (1970c)

Torulasporea mrakii (Capriotti) van der Walt & E. Johannsen (1975a)

Growth on 5% malt extract agar: After 3 days at 25°C, the cells are spheroidal to ellipsoidal, (2.1–7.0) × (3.0–7.5) μm, and single or in pairs. Growth is butyrous and white to tannish-white in color.

Growth on the surface of assimilation media: Pellicles are not formed.

Dalmau plate culture on morphology agar: After 7 days at 25°C, growth under the coverglass may show poorly differentiated pseudohyphae, but true hyphae are absent. Aerobic growth is butyrous, glistening, and tannish-white with some reddish-brown, highly ascosporogenous areas. Margins are entire to irregularly lobed. A faint, acidic odor is present.

Formation of ascospores: Asci are persistent and may be unconjugated or arise following conjugation

between independent cells. Each ascus forms one to four smooth, spheroidal ascospores. The species is probably homothallic.

Ascospores were observed on YM agar after 1–4 weeks at 25°C and on Difco yeast morphology agar after 1 week at 25°C. The latter medium gave highly ascosporegenous cultures.

Fermentation:

Glucose	+	Lactose	–
Galactose	+	Raffinose	+
Sucrose	+	Trehalose	–
Maltose	–		

Assimilation:

Glucose	+	<i>N</i> -Acetyl-D-glucosamine	–

Saccharomyces bailii Lindner var. *osmophilus* van der Walt (1970d)
 ?*Candida placentae* S. Goto (1979b)
Saccharomyces placentae S. Goto (1980)

Growth on 5% malt extract agar: After 3 days at 25°C, the cells are spheroidal to cylindroidal, (3.0–7.8) × (3.5–8.1) μm, and occur singly, in pairs, or occasionally in small clusters. Growth is butyrous and white to tannish-white in color.

Growth on the surface of assimilation media: Pellicles are not formed.

Dalmat plate culture on morphology agar: After 7 days at 25°C, growth under the coverglass may show branched, but poorly differentiated pseudohyphae. True hyphae are not formed. Aerobic growth is butyrous, white to tannish-white, with surfaces smooth and glistening or finely convoluted and dull. Margins are entire or finely lobed. A faint, acidic odor is present.

Formation of ascospores: Asci are persistent and form one to four spheroidal to ovoidal ascospores that may appear smooth or slightly roughened. Ascosporeulation may be preceded by conjugation between two cells or between a cell and its bud. (Fig. 198). Additionally, Wickerham and Burton (1960) reported some strains to represent heterothallic mating types.

Ascospores were observed on YM, Gorodkova and 5% malt extract agars after 3–15 days at either 15° or 25°C.

¹ Growth on GTYE agar with 1% acetic acid (see Table 46).

Co-Q: 6, CBS 732 and 2 additional strains (Yamada et al. 1976b).

Mol% G+C: 40.0, CBS 732 and 2 additional strains (T_m : Nakase and Komagata 1971e); 41.3-42.3, CBS 732 and 6 additional strains (BD: Kurtzman 1990c).

Origin of the strains studied: CBS 732 (NRRL Y-229), from grape must, Italy; CBS 742 (NRRL Y-998), from honey, Canada; NRRL Y-1053, unknown; CBS 4837 (NRRL Y-2547), CBS 4838 (NRRL Y-2548), miso, Japan; CBS 8000 (NRRL Y-12616), type strain of *Saccharomyces placentae*, sweet cream sake, Japan; CBS 4021 (NRRL Y-12622), type strain of *Saccharomyces bailii* var. *osmophilus*, soy mash, Japan; NRRL Y-12691, chocolate syrup, Pennsylvania, U.S.A.

Fig. 198. *Z. rouxii*, CBS 732. Ascus with ascospores, after 2 weeks on 5% malt extract agar at 15°C. Bar = 5 μ m.

Complementary mating types: CBS 4837 and CBS 4838.

Type strain: CBS 732, neotype designated by Lodder and Kreger-van Rij (1952). The type strain of *Zygosaccharomyces gracillus* ssp. *italicus*.

Comments: On the basis of phenotypic similarity, *Candida mogii* was believed to represent the anamorph of *Z. rouxii* (Yarrow 1984d). Comparisons of nDNA relatedness showed that the two taxa are separate species (Kurtzman 1990c).

Comments on the genus

The nine species presently accepted in *Zygosaccharomyces* are genetically distinct from one another on the basis of low nDNA relatedness (Kurtzman 1990c). James et al. (1994b, 1996) examined interspecific relationships among species of *Zygosaccharomyces* from comparisons of 18S rRNA gene sequences as well as from nucleotide diversity in the two internal transcribed spacer regions (ITS1, ITS2). Species of *Torulasporea* were included in the ITS study and shown to arise from within *Zygosaccharomyces*. As discussed under *Torulasporea*, circumscription of *Torulasporea* as well as *Saccharomyces* and *Zygosaccharomyces* is likely to change once additional molecular comparisons are done.

58. *Zygozoma van der Walt & von Arx*

M.Th. Smith

Diagnosis of the genus

Asexual reproduction is by multilateral budding, but occasionally by rudimentary septation with the formation of plasmodesmal canals. Cells are hyaline, encapsulated and spherical to ovoidal. Pseudohyphae and septate hyphae are absent. Colonies are watery, becoming mucoid to glutinous.

Asci are saccate, one-to multispored, lytic, arising either from abstricted enlarging evaginations of single cells, from conjugating cells or direct transformation of cells. Ascospores are allantoid to cymbiform, smooth, and amber-colored, and agglutinate when released.

Sugars are not fermented. Nitrate is not assimilated. Extracellular amyloid material is formed. Diazonium blue B reaction is negative.

Type species

Zygozoma oligophaga van der Walt & von Arx

Species accepted

1. *Zygozoma arxii* van der Walt, M.Th. Smith & Y. Yamada (1989)
2. *Zygozoma oligophaga* van der Walt & von Arx (1987)
3. *Zygozoma smithiae* van der Walt, Wingfield & Y. Yamada (1990)
4. *Zygozoma suomiensis* M.Th. Smith, van der Walt & Y. Yamada (1989)

Systematic discussion of the species

58.1. *Zygozoma arxii* van der Walt, M.Th. Smith & Y. Yamada (van der Walt et al. 1989d)

Growth in malt extract: After 3 days at 25°C, the cells are globose to ellipsoidal, (3.0–7.0) × (2.5–5.5) μm, encapsulated, reproduce by multilateral budding, and occur singly or in pairs. Growth is scant and a slight sediment is formed. After 1 month at room temperature, a slight ring and sediment are present.

Growth on malt agar: After 3 days at 25°, the cells have the same appearance as in malt extract. The streak culture is partly hyaline and viscous, partly butyrous and creamish-gray, smooth, glistening, and with an entire margin. After 4 weeks at room temperature, the culture is butyrous, brownish-cream, smooth, somewhat shiny, slightly raised along the center, and with an entire margin.

Dalmau plate cultures on corn meal agar: After

10 days at 25°C, neither hyphae nor pseudohyphae are formed.

Formation of ascospores: Asci are unattached, conjugated, often dumbbell-shaped, (10.0–15.0, rarely up to 19.0) × (2.0–6.0) μm, one- to multispored, evanescent, and generally arise from the fusion of protuberances formed by two free cells. Automictic asci are less common. Unconjugated, free asci are rarely observed. Ascospores are allantoid to cymbiform, (2.5–4.5) × (1.0–1.5) μm, glabrous amber-colored, and conglutinate when liberated.

Ascus formation was observed on 2% malt agar, V8 agar and 1/10 diluted V8 agar. Sporulation is slow, requiring 2–5 weeks at 15–18°C.

Fermentation: absent.

Type strain: CBS 7333 (ATCC 76360), isolated by J.P. van der Walt.

58.2. *Zygozoma oligophaga* van der Walt & von Arx (van der Walt et al. 1987b)

Growth in malt extract: After 3 days at 25°C, the cells are globose to ellipsoidal, (3.0–7.0) × (2.5–5.5) μm, encapsulated, reproduce by multilateral budding, and occur singly or in pairs. Growth is scant and a slight sediment is formed. After 1 month at room temperature, a slight ring and sediment are present.

Growth on malt agar: After 3 days at 25°C, the cells have the same appearance as in malt extract. The streak culture is partly hyaline to slightly creamish-gray and viscous. After 4 weeks at room temperature, the culture

is butyrous, brownish-cream, smooth, somewhat shiny, slightly raised along the center, with an entire margin.

Dalmat plate cultures on corn meal agar: After 10 days at 25°C, neither pseudohyphae nor septate hyphae are formed. Asci may be present.

Formation of ascospores: Asci are saccate, (9.0–15.0, rarely up to 25.0) × (4.0–7.0, rarely up to 11.0) μm, four- to multispored, evanescent and arise from inflated protuberances produced either by adjacent or non-adjacent aggregated cells. Ascospores are allantoid or cymbiform, (2.5–4.0) × (1.0–1.5) μm, smooth, amber-colored and conglutinate when liberated.

Sporulation is abundant on 2% malt agar and V8 agar after 3–4 days at 25°C.

Fermentation: absent.

Type strain: CBS 7107 (ATCC 76359), isolated by J.P. van der Walt.

58.3. *Zygozoma smithiae* van der Walt, Wingfield & Y. Yamada (1990b)

Growth in malt extract: After 3 days at 25°C, the cells are globose to ellipsoidal, (3.0–7.0) × (2.5–5.5) μm, encapsulated, reproduce by multilateral budding, occasionally on a broad base, and occur singly or in pairs. Growth is scant and a slight sediment is formed. After 1 month at room temperature, a slight ring and sediment are present.

Growth on malt agar: After 3 days at 25°C, the cells have the same appearance as in malt extract. The streak culture is watery to mucoid, hyaline to creamish-opaque, smooth, and shiny with an entire margin. After 4 weeks at room temperature, the culture is butyrous, hyaline to brownish-cream, smooth, somewhat shiny, slightly raised along the center, and with an entire margin.

Dalmiau plate cultures on corn meal agar: After 10 days at 25°C, neither pseudohyphae nor septate hyphae are formed.

Formation of ascospores: Asci are unconjugated, attached, globose allantoid or amoeboid, multispored, (9.0–18.0×3.0–9.0) µm, evanescent, and arise by the direct transformation of presumed diploid, aggregated, vegetative cells. Ascospores are allantoid to cymbiform, (2.5–3.5×1.0–1.5) µm, glabrous, amber-colored, and conglomerate when liberated.

Ascus formation was observed on 2% malt agar after 6 days at room temperature.

Fermentation: absent.

Additional assimilation tests and other growth characteristics:

Starch formation	+	Growth at 30°C	+
0.1% Cycloheximide	+	Growth at 35°C	–

Co-Q: 9 (van der Walt et al. 1990b).

Mol% G+C: 55.7, CBS 7407; 55.3, CBS 7408 (T_m : van der Walt et al. 1990b).

Origin of the strains studied: CBS 7407, CBS 7408, frass of *Crossotarus externedentatus* (ambrosia beetle) in *Macaranga capensis*, South Africa, J.P. van der Walt.

Type strain: CBS 7407 (ATCC 76360), isolated by J.P. van der Walt.

58.4. *Zygozoma suomiensis* M.Th. Smith, van der Walt & Y. Yamada (Smith et al. 1989b)

Growth in malt extract: After 3 days at 25°C, the cells are globose to ellipsoidal, (3.0–7.0)×(2.5–5.5) µm, encapsulated, reproduce by multilateral budding, and

occur singly or in pairs. Growth is scant and a slight sediment is formed. After 1 month at room temperature, a slight ring and sediment are present.

Growth on malt agar: After 3 days at 25°C, the cells have the same appearance as in malt extract. The streak culture is viscous to mucoid, partly hyaline, partly creamish-gray, smooth, glistening, and with an entire margin. After 4 weeks at room temperature, the culture is butyrous, brownish-cream, smooth, somewhat shiny, slightly raised along the center, and with an entire margin.

Dalmiau plate cultures on corn meal agar: After 10 days at 25°C, neither pseudohyphae nor septate hyphae are produced.

Formation of ascospores: Asci arise from abstricted inflated evaginations on single cells or from individual cells in aggregations. Asci are saccate, (5.0–11.0×4.5–7.0) µm, persistent and contain four to numerous (up to 12) ascospores. Ascospores are allantoid to oblong with obtuse ends, (2.0–4.5×1.0–2.0) µm, and glabrous.

Asci are produced after 6 weeks on Difco malt (5%)–agar (3%) at 15°C.

Fermentation: absent.

Type strain: CBS 7251 (ATCC 66456), isolated by E. Tunnela.

Comments on the genus

In 1987, van der Walt et al. (1987b) introduced the genus *Zygozoma* to accommodate yeast strains associated with arboricole *Coleoptera* in Northern Natal. These

strains formed mucoid colonies on solid medium similar to species of *Lipomyces* and *Myxozyma* and produced asci with allantoid ascospores resembling those of the hyphal genus *Dipodascopsis*. Differences in ascospore shape and absence of septate hyphae were considered decisive characteristics to assign these isolates to a new

genus, with the species *Z. oligophaga*. Van der Walt et al. (1991) emended the description of *Zygozoma* following demonstration by transmission electron microscopy of the occurrence of plasmodesmal canals in cells of *Z. oligophaga* and *Z. smithiae*, species that show budding on a broad base.

59. *Aciculoconidium* D.S. King & S.-C. Jong

M.Th. Smith

Diagnosis of the genus

Budding cells are ovoidal or ellipsoidal and single, in short chains or clusters. Mycelium is present and consists of branched septate hyphae with blastoconidia. Terminal needle-shaped conidia that are rounded at the base and pointed at the top are also present.

Ascospores and asexual endospores are not produced.

Sugars are fermented. Nitrate is not assimilated. Diazonium blue B reaction is negative.

Type species

Aciculoconidium aculeatum (Phaff, M.W. Miller & Shifrine) D.S. King & S.-C. Jong

Species accepted

1. *Aciculoconidium aculeatum* (Phaff, M.W. Miller & Shifrine) D.S. King & S.-C. Jong (1976)

Systematic discussion of the species

59.1. *Aciculoconidium aculeatum* (Phaff, M.W. Miller & Shifrine) D.S. King & S.-C. Jong (1976a)

Synonym:

Trichosporon aculeatum Phaff, M.W. Miller & Shifrine (1956)

Growth in glucose–yeast extract–peptone water:

After 3 days at 25°C, budding cells and mycelium are formed. Budding cells are ovoidal or ellipsoidal, (3.5–8.5)×(4.0–15.0) μm, and single, in chains or in small clusters. Mycelium consists of thin as well as broad hyphae that are septate. Needle-shaped cells, which are rounded at the base and pointed at the other end, frequently arise from blastospores from which they easily separate (Fig. 199). An irregular ring and a mycelial sediment are present. After one month at 25°C, mycelial growth occurs throughout.

Growth on glucose–yeast extract–peptone agar:

After one month at 25°C, the streak culture is cream-colored, smooth to slightly wrinkled, glossy to dull, and tough.

Dalmu plate cultures on corn meal agar: Abundant true mycelium with blastospores is formed. Blastospores are borne singly or successively in chains, and apically-

produce needle-shaped cells, (0.5–2.0)×(6.0–21.5) μm, which are rounded at the base and pointed at the other end (Fig. 200), are also present. The mycelium may disarticulate.

Comments on the genus

King and Jong (1976b) examined the process of arthroconidia formation in *Trichosporon*. On the basis of differences in this process they removed *T. aculeatum*

from the genus. Since these authors considered the needle-shaped blastoconidia an important characteristic by which *T. aculeatum* differed from previously described species, the new genus *Aciculoconidium* was introduced to accommodate *T. aculeatum* (King and Jong 1976a).

Some comments on the type strain designated by King and Jong (1976a) have to be made. These authors stated in their publication that two subcultures of the type strain isolated from *Drosophila pinicola* were examined. However, the culture chosen by Phaff et al. (1956) as the type and labelled in the original publication as F-0145A had been isolated from *Drosophila occidentalis* (Phaff, personal communication). To this culture the number CBS 5578 was assigned. The culture ATCC 1550 = NRRL YB-4297 considered by King and Jong as an iso-type strain is a subculture of Phaff's isolate from *Drosophila pinicola* (Kurtzman, personal communication). Since subcultures of the authentic strain still exist, the strain CBS 5578 = ATCC 28680 is the type strain.

60. *Arxula van der Walt, M.Th. Smith & Y. Yamada*

M.Th. Smith

Diagnosis of the genus

Asexual reproduction is by multilateral budding. Pseudohyphae, septate hyphae and arthroconidia are abundantly formed. Hyphae are narrow, not spreading, disarticulating into squat arthroconidia. Blastoconidia may be formed on very short denticles of hyphae. Colonies are restricted, dry, dull, white to cream-colored.

Ascospores are not produced.

Fermentation may be present. Nitrate is assimilated. Cultures are xerotolerant. Extracellular amyloid compounds are not produced. Septa have micropores. Diazonium blue B reaction is negative.

Type species

Arxula terrestris (van der Walt & E. Johannsen) van der Walt, M.Th. Smith & Y. Yamada

Species accepted

1. *Arxula adenivorans* (Middelhoven, Hoogkamer-Te Niet & Kreger-van Rij) van der Walt, M.Th. Smith & Y. Yamada (1990)
2. *Arxula terrestris* (van der Walt & E. Johannsen) van der Walt, M.Th. Smith & Y. Yamada (1990)

Key to species

1. a Melibiose assimilated *A. adenivorans*: p. 441
- b Melibiose not assimilated *A. terrestris*: p. 442

Systematic discussion of the species

60.1. *Arxula adenivorans* (Middelhoven, Hoogkamer-Te Niet & Kreger-van Rij) van der Walt, M.Th. Smith & Y. Yamada (1990c)

Synonym:

Trichosporon adenivorans Middelhoven, Hoogkamer-Te Niet & Kreger-van Rij (1984)

Growth in glucose–yeast extract–peptone water:

After 3 days at 25°C, budding cells are short-ovoidal to long-ovoidal, (2.2–3.6) × (2.4–5.6) μm. Branched, septate hyphae, 2.4 μm in diameter, and arthroconidia are also present. A sediment and a white, dry pellicle are formed.

Growth on glucose–yeast extract–peptone agar:

After one month the streak culture is yellowish-white, partly soft, partly tough and restricted. The edge is fringed with mycelium.

Dalmau plate cultures on potato- and corn meal

agar: True, branched, septate mycelium is abundantly formed. It may disarticulate into arthroconidia. Spheroidal or short-ovoidal blastoconidia occur in chains, sometimes on short denticles on the hyphae, but generally between, not at the septa. Aerial hyphae occur.

Formation of endospores: Asexual, spheroidal to ovoidal, endospores of variable size and number (3–6), are observed on Difco malt agar.

Fermentation:

Glucose	s	Lactose	–
Galactose	s	Raffinose	s
Sucrose	+	Trehalose	s
Maltose	s		

Assimilation:

Glucose	+	<i>N</i> -Acetyl-D-glucosamine	n
Galactose	+	Methanol	–
L-Sorbose	+	Ethanol	+
Sucrose	+	Glycerol	+
Maltose	+	Erythritol	+

60% (w/w) glucose–yeast extract agar	+	Growth at 40°C	+
0.1% Cycloheximide	+		

Co-Q: 9 (van der Walt et al. 1990c).

Mol% G+C: Not determined.

Origin of the strains studied: CBS 7350, ensiled whole-crop chopped maize, Netherlands, W.J. Middelhoven; CBS 7370, soil, CBS 7377, garden soil, South Africa, J.P. van der Walt; CBS 7766, liver and intestines of *Heloderma suspectum*, Sweden, R. Mattson; CBS 8244, type strain of *Trichosporon adenivorans*, soil, Netherlands, W.J. Middelhoven.

Type strain: CBS 8244, isolated by W.J. Middelhoven.

60.2. *Arxula terrestris* (van der Walt & E. Johannsen) van der Walt, M.Th. Smith & Y. Yamada (1990c)

Synonyms:

Trichosporon terrestre van der Walt & E. Johannsen (1975d)

Geotrichum terrestre (van der Walt & E. Johannsen) Weijman (1979b)

Growth in glucose–yeast extract–peptone water:

After 3 days at 25°C, branched, septate mycelium, (2.0–3.5) µm in diameter, arthroconidia and pseudomycelium are abundantly formed. Budding yeast cells are ovoidal, ellipsoidal to cylindrical, (2.5–6.5) × (3.0–11.0) µm, and occur singly, in pairs or small clusters (Fig. 201). A flocculent sediment and incomplete ring are present.

Growth on glucose–yeast extract–peptone agar: After one month at 25°, the streak culture is cream-colored, dry, soft, restricted, raised and delicately wrinkled, with a lobate margin.

Dalmu plate cultures on potato- and corn meal agar: Pseudomycelium, septate hyphae and arthroconidia are abundantly formed. Blastoconidia occur on the hyphae at the septa or in between, and may be single or in short chains. Arthroconidia vary in length, and may be short and spheroidal.

Formation of endospores: Asexual endospores, which are formed by endoplasmic cleavage, were observed in old cultures on YM agar.

Fermentation: absent.

Assimilation:

Glucose	+	<i>N</i> -Acetyl-D-glucosamine	n
Galactose	+	Methanol	–
L-Sorbose	+	Ethanol	+
Sucrose	+	Glycerol	+

60% (w/w) glucose–yeast extract agar	+	Growth at 37°C	+
0.1% Cycloheximide	+	Growth at 40°C	–

C_o-Q: 9 (van der Walt et al. 1990c).

Mol% G + C: Not determined.

Origin of the strains studied: CBS 278.86 (CBS

Fig. 201. *A. terrestris*, CBS 6697. Budding cells, pseudohyphae and septate hyphae. (After van der Walt and Johannsen 1975d.)

6697), grassland soil; CBS 7376, soil, South Africa, J.P. van der Walt.

Type strain: CBS 278.86 (CBS 6697), isolated by J.P. van der Walt.

Comments on the genus

The genus *Arxula* was introduced by van der Walt et al. (1990c) to accommodate two arthroconidial, xerotolerant ascomycetous *Trichosporon* species, *T. terrestre* and *T. adeninovorans* of which the taxonomic position was unsettled. Weijman (1979b) revised the anamorphic arthroconidial genera *Trichosporon* and *Geotrichum* on the basis of whole-cell monosaccharide composition and restricted *Trichosporon* to basidiomycetous, arthroconidial anamorphs, and *Geotrichum* to ascomycetous, arthroconidial anamorphs. Consequently, *T. terrestre* was reclassified as *Geotrichum terrestre*. In 1984, Middelhoven et al. described the ascomycetous species *T. adeninovorans* with its uncommon ability to utilize certain purines (uric acid and adenine) as well as *n*-alkylamines (*n*-butylamine and pentylamine) as sole sources of carbon and nitrogen, a property which is shared with *G. terrestre*. De Hoog et al. (1986), in their revision of *Geotrichum*, excluded *G. terrestre* from this genus on the basis of its scant production of septate hyphae and its extremely yeastlike appearance. On the basis of its nutritional profile, *T. adeninovorans* was not transferred to *Geotrichum* by these authors. Since both species were excluded from *Geotrichum*, van der Walt et al. (1990c) followed the proposal of von Arx et al. (1977), and assigned *T. terrestre* and the related species to a new genus.

Studies on molecular relationships among hyphal ascomycetous yeasts and yeastlike taxa were published by Yamada and Nogawa (1990a) and Kurtzman and Robnett (1995). From the data of both studies it can be concluded that the genus *Arxula* is closely related to the teleomorph genus *Stephanoascus* and might represent anamorphs of this genus.

61. *Blastobotrys* von Klopotek

G.S. de Hoog and M.Th. Smith

Diagnosis of the genus

Colonies are restricted, dry, snow-white, and consist of compacted hyphae; budding cells are absent or present. Conidiophores are suberect, sympodial, and produce conidia in clusters on a rachis or alongside hyphae. Conidia are borne on pedicels or denticles, or are sessile. Primary conidia produce smaller, secondary conidia, either synchronously or sympodially in short, acropetal chains; primary conidia often bear setae. Septa have micropores. Teleomorph genus: *Stephanoascus*.

Sugars are often fermented. Nitrate is not assimilated. Diazonium blue B reaction is negative.

Type species

Blastobotrys nivea von Klopotek

Species accepted

1. *Blastobotrys arbuscula* de Hoog, Rantio-Lehtimäki & M.Th. Smith (1985)
2. *Blastobotrys aristata* Marvanová (1976)

Systematic discussion of the species

61.1. *Blastobotrys arbuscula* de Hoog, Rantio-Lehtimäki & M.Th. Smith (1985)

Growth on 4% malt extract/0.5% yeast extract agar:

After 10 days at 20–22°C, colonies are 1 mm in diameter, butyrous, and cream-colored. Budding cells are abundant and in coherent chains, composing star-shaped pseudomycelial microcolonies. Hyphae are hyaline, straight and stiff, 2.5–3.5 µm wide, and with clusters of minute conidium-bearing denticles at the apex and just below distal septa. Primary conidia are broadly ellipsoidal to subglobose, about 4–6 µm wide, without setae and produce densely crowded, globose secondary conidia, 2.5–3.5 µm diameter, in more or less synchronous order (Fig. 202).

Fermentation:

Glucose	+	Lactose	–
Galactose	+	Raffinose	–
Sucrose	–	Trehalose	+
Maltose	+		

Fig. 202. *B. arbuscula*, CBS 227.83. Conidiophores with primary and secondary conidia and initial growth with multilateral budding. MEYA, 22°C, 10 days.

Assimilation:

Glucose	+	<i>N</i> -Acetyl-D-glucosamine	n
Galactose	+	Methanol	n
L-Sorbose	+	Ethanol	–
Sucrose	–	Glycerol	+
Maltose	+	Erythritol	+
Cellobiose	+	Ribitol	+
Trehalose	+	Galactitol	+
Lactose	–	D-Mannitol	+
Melibiose	–	D-Glucitol	+
Raffinose	–	α-Methyl-D-glucoside	v
Melezitose	–	Salicin	–
Inulin	v	D-Gluconate	n
Soluble starch	+	DL-Lactate	v
D-Xylose	+	Succinate	+
L-Arabinose	+	Citrate	–
D-Arabinose	–	Inositol	–
D-Ribose	+	Hexadecane	n
L-Rhamnose	–	Nitrate	–
D-Glucosamine	+	Vitamin-free	–

Additional assimilation tests and other growth characteristics:

Growth at 37°C: –

Co-Q: Not determined.

Mol% G+C: Not determined.

Origin of the strain studied: CBS 227.83, from house air, Tunnela, Finland.

Type strain: CBS 227.83.

Comments: The species is close to *B. gigas* de Hoog et al. (1985), which was recently reported to have a teleomorph similar to *Stephanoascus farinosus* de Hoog et al. (Traquair et al. 1988a). These taxa may belong to a single, psychrophilic, homothallic species, *S. farinosus*, which would be more variable in its morphological and physiological characters than was originally reported (de Hoog et al. 1985). Genomic studies are needed to clarify this matter.

61.2. *Blastobotrys aristata* Marvanová (1976)

Growth on 4% malt extract/0.5% yeast extract agar:

After 10 days at 20–22°C, colonies are 10 mm in diameter, dry, farinose, snow-white and consist of compact

Fig. 203. *B. aristata*, CBS 521.75. Conidiophore tips with primary conidium initials and primary conidia with secondary conidia and setae. MEYA, 22°C, 10 days.

mycelium; budding cells are often absent. Hyphae are hyaline and 2–3 µm wide. Conidiophores are ascending, up to 100 µm long and bear 1–3 conidia at the apex; each is borne on a 2–4 µm long denticle. Primary conidia are pear-shaped, (3–8) × (4.5–9.0) µm, with 1–2 sterile setae and bear synchronously produced, densely crowded, globose secondary conidia of 1.5–3.5 µm diameter (Fig. 203).

Fermentation:

Glucose	+	Lactose	–
Galactose	v	Raffinose	–
Sucrose	–	Trehalose	+
Maltose	+		

Assimilation:

Glucose	+	<i>N</i> -Acetyl-D-glucosamine	n
Galactose	+	Methanol	n
L-Sorbose	+	Ethanol	–
Sucrose	+	Glycerol	+
Maltose	+	Erythritol	+
Cellobiose	+	Ribitol	+
Trehalose	+	Galactitol	+
Lactose	+	D-Mannitol	+
Melibiose	v	D-Glucitol	+
Raffinose	v	α-Methyl-D-glucoside	v
Melezitose	–	Salicin	+
Inulin	v	D-Gluconate	n
Soluble starch	+	DL-Lactate	–
D-Xylose	+	Succinate	+
L-Arabinose	+	Citrate	v
D-Arabinose	+	Inositol	v
D-Ribose	+	Hexadecane	n
L-Rhamnose	v	Nitrate	–
D-Glucosamine	+	Vitamin-free	–

Additional assimilation tests and other growth characteristics:

Growth at 37°C –
 Co-Q: Not determined.
 Mol% G+C: Not determined.

Origin of the strain studied: CBS 521.75, from moldy plaster, Marvanová, Czechoslovakia.

Type strain: CBS 521.75.

Comments: Physiological characteristics are often difficult to judge because of formation of hyphal clumps. Primary conidia are borne on long, tapering pedicels which are formed singly or in small groups at the apex of conidiophores.

61.3. *Blastobotrys capitulata* de Hoog, Rantio-Lehtimäki & M.Th. Smith (1985)

Growth on 4% malt extract/0.5% yeast extract agar:

After 10 days at 20–22°C, colonies are 5 mm in diameter, snow-white, dry, and evenly farinose. Budding cells are absent; hyphae are hyaline and 2.5–3.5 µm wide. Conidia are sessile and produced in dense clusters at the apex of poorly differentiated cells. Primary conidia are obovoidal, 5 × 10 µm, and bear 1–2 sterile, flexuose setae 0.5 µm wide and up to 200 µm long. Secondary conidia are synchronously produced in dense packets on primary conidia; they are hydrophobic, globose and 2.5–3.5 µm in diameter. Similar conidia are produced alongside the hyphae (Fig. 204).

Fermentation:

Glucose	+	Lactose	–
Galactose	+	Raffinose	–
Sucrose	–	Trehalose	v
Maltose	v		

Assimilation:

Glucose	+	<i>N</i> -Acetyl-D-glucosamine	n
Galactose	+	Methanol	n
L-Sorbose	+	Ethanol	+
Sucrose	v	Glycerol	+
Maltose	v	Erythritol	+
Cellobiose	+	Ribitol	+
Trehalose	+	Galactitol	+
Lactose	v	D-Mannitol	+
Melibiose	–	D-Glucitol	+
Raffinose	v	α-Methyl-D-glucoside	–
Melezitose	–	Salicin	+
Inulin	v	D-Gluconate	n
Soluble starch	+	DL-Lactate	–
D-Xylose	+	Succinate	+
L-Arabinose	+	Citrate	v
D-Arabinose	v	Inositol	+
D-Ribose	+	Hexadecane	n
L-Rhamnose	+	Nitrate	–
D-Glucosamine	+	Vitamin-free	–

Additional assimilation tests and other growth characteristics:

Growth at 37°C +
 Co-Q: Not determined.
 Mol% G+C: Not determined.

Origin of the strain studied: CBS 287.82, from rotting *Euphorbia ingens*, van der Walt, South Africa; from straw.

Type strain: CBS 287.82.

Comments: The closely aggregated, sessile primary conidia that bear very thin, flexuose, sterile setae are characteristic of this species.

Fig. 204. *B. capitulata*, CBS 287.82. Conidiophores with terminal groups of primary conidia bearing secondary conidia, primary conidia with secondary conidia and setae, and sessile conidia on hyphae. MEYA, 22°C, 10 days.

61.4. *Blastobotrys elegans* de Hoog, Rantio-Lehtimäki & M.Th. Smith (1985)

Growth on 4% malt extract/0.5% yeast extract agar: After 10 days at 20–22°C, colonies are 3–5 mm in diameter, cerebriform, whitish and in later stages with snow-white, farinose patches. Budding cells are mostly absent; hyphae are hyaline, 2–3 µm wide. Conidia are formed on loose apical clusters of cylindrical denticles, that are up to 3 µm long. Primary conidia are subglobose, (2.8–4.2) µm wide, without setae and densely crowded with globose, synchronously formed secondary conidia that are (1.8–3.4) µm in diameter (Fig. 205).

Fermentation: absent.

Fig. 205. *B. elegans*, CBS 530.83. Conidiophores with and without clusters of primary conidia which bear secondary conidia; denticles remain after detachment. MEYA, 22°C, 10 days.

Assimilation:

Glucose	+	N-Acetyl-D-glucosamine	n
Galactose	+	Methanol	n
L-Sorbose	v	Ethanol	+
Sucrose	–	Glycerol	+
Maltose	+	Erythritol	+
Cellobiose	+	Ribitol	+
Trehalose	+	Galactitol	v
Lactose	+	D-Mannitol	+
Melibiose	–	D-Glucitol	+
Raffinose	–	α-Methyl-D-glucoside	–
Melezitose	–	Salicin	v
Inulin	v	D-Gluconate	n
Soluble starch	v	DL-Lactate	–
D-Xylose	+	Succinate	+
L-Arabinose	v	Citrate	v
D-Arabinose	–	Inositol	–
D-Ribose	+	Hexadecane	n
L-Rhamnose	–	Nitrate	–
D-Glucosamine	v	Vitamin-free	–

Additional assimilation tests and other growth characteristics:

Growth at 37°C –
Co-Q: Not determined.
Mol% G+C: Not determined.

Origin of the strain studied: CBS 530.83, from house air, Rantio-Lehtimäki, Finland.

Type strain: CBS 530.83.

Comments: The species is recognizable by the absence of yeastlike growth and by a grape-like arrangement of conidia which do not easily separate.

61.5. *Blastobotrys gigas* de Hoog, Rantio-Lehtimäki & M.Th. Smith (1985)

See under teleomorph: *Stephanoascus farinosus* de Hoog, Rantio-Lehtimäki & M.Th. Smith: p. 401.

61.6. *Blastobotrys nivea* von Klopotek (1967)

Growth on 4% malt extract/0.5% yeast extract agar: After 10 days at 20–22°C, colonies are 14 mm in diameter, dry, farinose, somewhat folded, snow-white and consist of compact mycelium; budding cells are absent. Hyphae are hyaline and (2–3) µm wide. Conidiophores are ascending, up to 230 µm high and the apical parts have distant geniculations with cylindrical denticles at the edges. Primary conidia are globose, (2.5–4.5) µm wide, without setae, and synchronously produce globose, densely crowded secondary conidia that are (2.0–2.5) µm in diameter (Fig. 206).

Fermentation:

Glucose	+	Lactose	–
Galactose	+	Raffinose	–
Sucrose	–	Trehalose	+
Maltose	+		

Fig. 206. *B. nivea*, CBS 163.67. Conidiophores with primary conidia bearing secondary conidia. MEYA, 22°C, 10 days.

Assimilation:

Glucose	+	<i>N</i> -Acetyl-D-glucosamine	n
Galactose	+	Methanol	n
L-Sorbose	+	Ethanol	+
Sucrose	v	Glycerol	+
Maltose	+	Erythritol	+
Cellobiose	+	Ribitol	+
Trehalose	+	Galactitol	+
Lactose	+	D-Mannitol	+
Melibiose	+	D-Glucitol	+
Raffinose	-	α -Methyl-D-glucoside	v
Melezitose	-	Salicin	+
Inulin	v	D-Gluconate	n
Soluble starch	+	DL-Lactate	-
D-Xylose	+	Succinate	+
L-Arabinose	+	Citrate	+
D-Arabinose	+	Inositol	+
D-Ribose	+	Hexadecane	n
L-Rhamnose	-	Nitrate	-
D-Glucosamine	+	Vitamin-free	-

Additional assimilation tests and other growth characteristics:

Growth at 37°C +
 Co-Q: Not determined.
 Mol% G+C: Not determined.

Origin of the strain studied: CBS 163.67 (ATCC 18420), from compost, Germany, von Klopotek.

Type strain: CBS 163.67.

Comments: Physiological characteristics are often difficult to judge because of formation of hyphal clumps. Morphologically, the species is recognized by slender conidiophores with a long geniculate rachis. Conidia are borne on widely spaced cylindrical denticles.

61.7. *Blastobotrys proliferans* Marvanová (1976)

Synonym:

Blastobotrys navarrensis Sesma & C. Ramírez (1978)

Growth on 4% malt extract/0.5% yeast extract agar:

After 10 days at 20–22°C, the colonies are 10 mm in diameter, dry, thinly hairy, soft and snow-white; budding cells are absent. Hyphae are hyaline, and (1.5–2.5) μ m wide. Conidiophores are ascending, up to 80 μ m long, and barely different from the remaining hyphae; apically, they produce 1–3 pedicels up to 5 μ m long bearing conidia. Primary conidia are pear-shaped, about (3.0–4.5) \times (4.5–8.0) μ m, contain a refractive granular body, and bear a seta which again produces 1–3 similar conidia at its apex. The primary conidia synchronously produce densely crowded globose secondary conidia that are 1.5–2.5 μ m in diameter (Fig. 207).

Fermentation:

Glucose	+	Lactose	-
Galactose	+	Raffinose	+
Sucrose	+	Trehalose	v
Maltose	+		

Assimilation:

Glucose	+	<i>N</i> -Acetyl-D-glucosamine	n
Galactose	+	Methanol	n
L-Sorbose	+	Ethanol	+
Sucrose	+	Glycerol	+
Maltose	+	Erythritol	+
Cellobiose	+	Ribitol	+

Fig. 207. *B. proliferans*, CBS 522.75. Conidiophores and primary conidia bearing secondary conidia and setae, endoconidia in hyphae, and intercalary chlamydozoospores. MEYA, 22°C, 10 days.

Additional assimilation tests and other growth characteristics:

Growth at 37°C +

Co-Q: Not determined.

Mol% G + C: Not determined.

Origin of the strains studied: CBS 522.75, from a mite-infested nut, Brazil; CBS 139.77, type strain of *B. navarrensis*, from black pepper, Spain; from soil (1); from man (1); from house dust (1); from linoleum (1).

Type strain: CBS 522.75.

Comments: Key features are the primary conidia which contain granular, highly refractive bodies and the setae which bear new, similar conidia.

Comments on the genus

Budding cells are usually absent or in low abundance when present. Until recently, the genus was treated as a hyphomycete, close to the ascomycetous genus *Sporothrix* Hektoen & Perkins, from which it was distinguished

on morphological criteria. However, members of *Blastobotrys*, as well as some *Sporothrix* species, were shown to have micropores in their septa (Smith and Batenburg-van der Vegte 1985, 1986b), coenzyme Q-9 systems (Suzuki and Nakase 1986, Yamada and Smith 1985), and occasionally a *Stephanoascus* teleomorph (Smith et al. 1981, de Hoog et al. 1985). Consequently, *Blastobotrys* is maintained here for saccharomycetous fungi and treated under the yeasts, while *Sporothrix* should be reserved for anamorphs of the Ophiostomatales (de Hoog 1992).

Species delimitation in the genus has not yet been satisfactorily established. Most species are known from a single strain. The taxonomic value of morphological and physiological criteria has to be evaluated on the basis of teleomorphs and genomic data. To this end, Kurtzman and Robnett (1995) showed from nucleotide sequence analysis of 5' end large subunit rDNA that species of *Blastobotrys* are members of a clade that includes *Arxula*, *Sympodiomyces* and *Stephanoascus* (Fig. 170, p. 385).

62. *Botryozyma* Shann & M.Th. Smith

M.Th. Smith

Diagnosis of the genus

Asexual reproduction is by multilateral budding. Cells are cylindrical. Pseudohyphae are formed. Terminal pseudohyphal cells are transformed into simple or complex appressoria.

Ascospores are not formed.

Sugars are not fermented. Nitrate is not assimilated. Urease is not produced. Diazonium blue B reaction is negative.

Type species

Botryozyma nematodophila Shann & M.Th. Smith

Species accepted

Botryozyma nematodophila Shann & M.Th. Smith (1992)

Systematic discussion of the species

62.1. *Botryozyma nematodophila* Shann & M.Th. Smith (Smith et al. 1992)

Growth in glucose–yeast extract–peptone water:

After 3 days at 25°C, the cells are cylindrical, (8.0–22.5) × (2.0–5.5) μm, reproduce predominantly in the apical zone and occur in pairs and short chains, but mainly in pseudomycelial elements; fusiform cells may be present. End cells are usually transformed into simple or complex branch-like structures (appressoria), (2.0–20.0) × (1.0–2.0) μm (Fig. 208). A sediment is formed.

Fig. 208. *B. nematodophila*, CBS 7426. Budding cells, pseudohyphae and appressoria in glucose–peptone–yeast extract after 3 days at 25°C. Bar = 5 μm.

Growth on glucose–yeast extract–peptone agar:

After 3 days at 25°C, the cells are similar in shape and size as in glucose–yeast extract–peptone water. Appressorial cells are present. The streak culture is cream-colored, dull, delicately wrinkled, butyrous, and the margin slightly lobed.

Dalmau plate cultures on glucose–yeast extract–peptone agar:

After 3 days at 25°C, a well-developed pseudomycelium is formed. Fusiform cells may be present, and simple as well as complex appressoria are formed.

Fermentation: absent.

Assimilation:

Additional assimilation tests and other growth characteristics:

Starch formation	–	Growth at 37°C	+
0.1% Cycloheximide	+		

Co-Q: Not determined.

Mol% G+C: 29.5, CBS 7426; 29.7, CBS 7442 (T_m : Smith et al. 1992).

Origin of the strains studied: CBS 7426, CBS 7442, from *Panagrellus zymosiphilus* in sour rot of grapes, Italy, C. Shann.

Type strain: CBS 7426, isolated by C. Shann.

Comments on the genus

The monotypic genus *Botryozyma* was introduced by Smith et al. (1992) to accommodate two yeast isolates found along with nematodes in and on damaged grapes. According to Shann (1988), the species is a saprophyte on the nematode *Panagrellus zymosiphilus*, to which it may be attached by appressoria.

63. *Brettanomyces* Kufferath & van Laer

M.Th. Smith

Diagnosis of the genus

Asexual reproduction is either by multilateral budding or, rarely, by bipolar budding in basipetal succession on a narrow base. Cells are either spheroidal, subglobose to ellipsoidal, frequently ogival, or cylindroidal to elongate. Pseudomycelium is simple or well-developed, and branched. One-celled, non-septate mycelium may be formed.

Cultures grow slowly and are usually short-lived. Acetic acid is produced aerobically from glucose. Fermentation is usually stimulated by molecular oxygen. An extraneous vitamin source is required. Diazonium blue B reaction is negative.

The teleomorphic genus is *Dekkera*.

Type species

Brettanomyces bruxellensis Kufferath & van Laer

Species accepted

1. *Brettanomyces anomalus* Custers (1940): see *Dekkera anomala*
2. *Brettanomyces bruxellensis* Kufferath & van Laer (1921): see *Dekkera bruxellensis*
3. *Brettanomyces custersianus* van der Walt (1961)
4. *Brettanomyces naardenensis* Kolfshoten & Yarrow (1970)
5. *Brettanomyces nanus* (M.Th. Smith, Batenburg-van der Vegte & Scheffers) M.Th. Smith, Boekhout, Kurtzman & O'Donnell (1994)

63.3. *Brettanomyces custersianus* van der Walt (1961)**Synonym:**

Dekkera custersiana F.-L. Lee & S.-C. Jong (1986a)

Growth in malt extract: After 5 days at 25°C, the cells are ellipsoidal, frequently ogival and cylindroidal to elongate, (1.5–3.5) × (2.0–19.0) μm. Cells reproduce by budding, and occur singly, in pairs or in short, occasionally somewhat branched chains. Pseudomycelium is produced. A floccose sediment is formed. A thin, dull pellicle or a slight, frequently incomplete ring is sometimes present.

Growth on malt agar + 2% calcium carbonate: After 6 weeks at room temperature, the streak culture is raised, cream-colored to light brown, shiny to dull, verrucose, and crispulate or rugose. The margin is undulating to lobiform. Acetic acid production is slight.

Dalmu plate cultures on potato-, rice- and morphology agars: Pseudomycelium is abundantly produced and consists of filamentous cells with few or no blastospores. Blastospores are more abundant under anaerobic conditions, and are arranged in short chains or weakly branched verticils (Fig. 209).

Co-Q: 9 (Yamada et al. 1980, Billon-Grand 1987).

Mol% G+C: 38.9–39.3, 4 strains, CBS 4805, CBS 4806, CBS 5207, CBS 5208 (T_m : Smith et al. 1990b).

Origin of the strain studied: CBS 4805, CBS 4806, CBS 5207, CBS 5208, equipment at a Bantu beer brewery, South Africa, van der Walt.

Type strain: CBS 4805 (ATCC 34446), isolated by van der Walt.

63.4. *Brettanomyces naardenensis* Kolschoten & Yarrow (1970)**Synonym:**

Dekkera naardenensis S.-C. Jong & F.-L. Lee (1986)

Growth in malt extract: After 5 days at 25°C, the cells are predominantly cylindroidal to elongate, rarely ellipsoidal or ogival, (1.5–4.5) × (4.0–15.0–30) μm, and reproduce by budding. They occur singly, in pairs or in short chains or small clusters. Pseudomycelium is abundant. Floccose sediment is formed; occasionally a slight, incomplete ring and islets are present.

Growth on malt agar + 2% calcium carbonate: After 6 weeks at room temperature, the streak culture is rather coherent, creamish-brown to light brown, somewhat shiny to rather dull, and pulvinate to verruculose. The margin is lobate. Acetic acid production is not very pronounced.

Dalmu plate cultures on potato-, rice- and morphology agars: A ramified pseudomycelium is produced that bears few or no blastospores. Pseudomycelium is better developed under anaerobic conditions.

Mol% G+C: 42.2–43.3, 3 strains, CBS 6042, CBS 6107, CBS 6117 (T_m : Smith et al. 1990b).

Origin of the strains studied: CBS 6042, lemonade, Netherlands, G.A. Kolschoten; CBS 6040, soda water, U.S.A., D.G. Ahearn; the following were isolated by G.A. Kolschoten: CBS 6041, carbonated lemonade pH 2.7, Belgium; CBS 6043, carbonated tonic water pH 3, Netherlands; CBS 6107, carbonated lemonade pH 3.1, Norway; CBS 6115, carbonated soft drink pH 2.7, Netherlands; CBS 6117, carbonated lemonade pH 3, Denmark; CBS 6118, carbonated lemonade, Netherlands.

Type strain: CBS 6042 (ATCC 22075).

63.5. *Brettanomyces nanus* (M.Th. Smith, Batenburg-van der Vegte & Scheffers) M.Th. Smith, Boekhout, Kurtzman & O'Donnell (Boekhout et al. 1994)

Synonyms:

Brettanomyces nanus Scheffers (1966) nom. inval.

Eeniella nana M.Th. Smith, Batenburg-van der Vegte & Scheffers (1981)

Growth in glucose–yeast extract–peptone water:

After 3 days at 25°C, the cells are usually ogival to apiculate, (1.8–4.5)×(2.2–7.5)µm, seldom spheroidal or cylindrical, single, or in pairs. Pear-shaped cells are sometimes present (Fig. 210). After 1 month, sediment is formed.

Growth on malt agar + 2% calcium carbonate: After 1 month, the streak culture is white to cream-colored, smooth, and glossy; in cross-section, the colony shows a slightly raised center and a flat periphery.

Dalmau plate cultures on potato-, rice- and corn meal agars: Simple pseudohyphae consisting of short chains of cells are occasionally present.

Co-Q: 9 (Yamada et al. 1980).

Mol% G+C: 40.2–41.4, 3 strains, CBS 1945, CBS 1955, CBS 1956 (T_m : Smith et al. 1981).

Origin of the strains studied: CBS 1945, bottled beer, brewery, Kalmar, Sweden, G. Een; CBS 1955, bottled beer, brewery, Stockholm, Sweden, G. Een; CBS 1956, bottled beer, brewery, Göteborg, Sweden, G. Een.

Type strain: CBS 1945 (ATCC 48014).

Comments: *Brettanomyces nanus* was introduced by Scheffers (1966) without a Latin diagnosis. Smith et al. (1981) examined the three available isolates and found bipolar budding. On the basis of this morphological feature and the physiological property of acetic acid production, Smith et al. (1981) considered it incorrect to classify these isolates in *Brettanomyces* or in any other extant genus with bipolar budding. Therefore, they

introduced the genus *Eeniella* to accommodate these apiculate, acetic acid-producing strains. However, on the basis of partial 26S rDNA sequence data, Boekhout et al. (1994) considered *Eeniella* a synonym of *Brettanomyces* and consequently reintroduced and validated the species *B. nanus*.

Comments on the genus

For a detailed historical account of the genus *Brettanomyces*, see Custers (1940) and van der Walt (1970e, 1984c). Fiol and Billon-Grand (1978b) studied the production of intracellular oxidases, nitrite and nitrate reductases in *Brettanomyces* and *Dekkera* and discussed the relationship between the two genera. The coenzyme Q systems were studied by Yamada et al. (1980) and Billon-Grand (1987); the latter author stressed the importance of minor ubiquinones in the classification of both genera. In addition to the major component Co-Q 9, Co-Q 8 was found as a minor component in all *Brettanomyces* and *Dekkera* species. Traces of Co-Q 7 and Co-Q 6 were found

in a few species. A series of publications appeared on ascospore formation in type strains of five *Brettanomyces* species (Lee and Jong 1985, 1986a,b, Jong and Lee 1986); as a consequence, these species were reclassified in the teleomorphic genus *Dekkera*. The presence of ascospores was demonstrated by staining. However, Smith et al. (1990b) considered the hat-shaped spores to be artifacts that may have resulted from contraction of cellular cytoplasm during staining. Therefore, Smith et al. (1990b) did not accept the species *D. custersianus* and *D. naardenensis*. On the basis of DNA reassociations and enzyme comparisons, Smith et al. (1990b) accepted four species in *Brettanomyces*, two of which lack a teleomorphic state. Various studies of mtDNA (McArthur and Clark-Walker 1983, Hoeben and Clark-Walker 1986, Clark-Walker et al. 1987, Hoeben et al. 1993), rRNA (Molina et al. 1993), rDNA (Boekhout et al. 1994) and rRNA (Yamada et al. 1994d) have been performed on *Brettanomyces* and the teleomorph *Dekkera* (see *Dekkera*, Comments on the genus).

64. *Candida* Berkhout

S.A. Meyer, R.W. Payne and D. Yarrow

Diagnosis of the genus

Cells are globose, ellipsoidal, cylindroidal, or elongate, occasionally ogival, triangular or lunate. Reproduction is by holoblastic budding. Pseudohyphae and septate hyphae may be formed. The cell wall is ascomycetous and two-layered. Arthroconidia and ballistoconidia are not formed. Starch-like compounds are not produced. Diazonium blue B reaction is negative. Xylose, rhamnose and fucose are not present in cell hydrolyzates.

Type species

56. *Candida glabrosa* Komagata & Nakase (1965)
57. *Candida glucosophila* Tokuoka, Ishitani, S. Goto & Komagata (1987)
58. *Candida gropengiesseri* (F.C. Harrison) S.A. Meyer & Yarrow (1978)
59. *Candida guilliermondii* (Castellani) Berkhout (1923)
 - a. *Candida guilliermondii* (Castellani) Berkhout var. *guilliermondii* (1952): see *Pichia guilliermondii*, p. 308
 - b. *Candida guilliermondii* var. *membranifaciens* Lodder & Kreger-van Rij (1952): see *Pichia ohmeri*, p. 329
60. *Candida haemulonii* (van Uden & Kolipinski) S.A. Meyer & Yarrow (1978)
61. *Candida homilentoma* van der Walt & Nakase (1973)
62. *Candida humilis* (E.E. Nel & van der Walt) S.A. Meyer & Yarrow (1978)
63. *Candida incommunis* Y. Ohara, Nonomura & T. Yamazaki (1965)
64. *Candida inconspicua* (Lodder & Kreger-van Rij) S.A. Meyer & Yarrow (1978)
65. *Candida insectalens* (D.B. Scott, van der Walt & van der Klift) S.A. Meyer & Yarrow (1978)
66. *Candida insectamans* D.B. Scott, van der Walt & van der Klift (1972)
67. *Candida insectorum* D.B. Scott, van der Walt & van der Klift (1972)
68. *Candida intermedia* (Ciferri & Ashford) Langeron & Guerra (1938)
69. *Candida ishiwadae* Sugiyama & S. Goto (1969)
70. *Candida karawaiewii* Yarrow & S.A. Meyer (1978)
71. *Candida krissii* S. Goto & Iizuka (1974)
72. *Candida kruisii* (Kocková-Kratochvílová & Ondrušová) S.A. Meyer & Yarrow (1978)
73. *Candida krusei* (Castellani) Berkhout (1923): see *Issatchenkia orientalis*, p. 222
74. *Candida lactis-condensi* (B.W. Hammer) S.A. Meyer & Yarrow (1978)
75. *Candida laureliae* C. Ramírez & A. González (1984)
76. *Candida lipolytica* (F.C. Harrison) Diddens & Lodder (1942): see *Yarrowia lipolytica*, p. 420
77. *Candida llanquihuensis* C. Ramírez & A. González (1984)
78. *Candida lusitaniae* van Uden & do Carmo-Sousa (1959): see *Clavispora lusitaniae*, p. 148
79. *Candida lyxosophila* van der Walt, N.P. Ferreira & Steyn (1987)
80. *Candida magnoliae* (Lodder & Kreger-van Rij) S.A. Meyer & Yarrow (1978)
81. *Candida maltosa* Komagata, Nakase & Katsuya (1964)
82. *Candida maris* (van Uden & Zobell) S.A. Meyer & Yarrow (1978)
83. *Candida maritima* (Siepmann) van Uden & H.R. Buckley ex S.A. Meyer & Ahearn (1983)
84. *Candida melibiosica* H.R. Buckley & van Uden (1968)
85. *Candida membranifaciens* (Lodder & Kreger-van Rij) Wickerham & K.A. Burton (1954)
86. *Candida mesenterica* (A. Geiger) Diddens & Lodder (1942)
87. *Candida methanosorbosa* (Abe & Yokote) J.A. Barnett, R.W. Payne & Yarrow (1983)
88. *Candida milleri* Yarrow (1978)
89. *Candida mogii* Vidal-Leiria (1967)
90. *Candida montana* S. Goto & Oguri (1983)
91. *Candida multigemmis* (Buhagiar) S.A. Meyer & Yarrow (1978)

92. *Candida musae* (Nakase) S.A. Meyer & Yarrow (1978)
93. *Candida naeodendra* van der Walt, E. Johannsen & Nakase (1973)
94. *Candida nanaspora* Saëz & Rodrigues de Miranda (1988)
95. *Candida natalensis* van der Walt & Tscheuschner (1957)
96. *Candida nemodendra* (van der Walt, van der Klift & D.B. Scott) S.A. Meyer & Yarrow (1978)
97. *Candida nitratophila* (Shifrine & Phaff) S.A. Meyer & Yarrow (1978)
98. *Candida norvegica* (Reiersöl) S.A. Meyer & Yarrow (1978)
99. *Candida odintsovae* Bab'eva, Reshetova, Blagodatskaya & Galimova (1989)
100. *Candida oleophila* Montrocher (1967)
101. *Candida oregonensis* Phaff & do Carmo-Sousa (1962)
102. *Candida ovalis* Kumamoto & Yamamoto (1986)
103. *Candida palmioleophila* Nakase & M. Itoh (1988)
104. *Candida paludigena* Golubev & Blagodatskaya (1981)
105. *Candida parapsilosis* (Ashford) Langeron & Talice (1932)
106. *Candida pararugosa* Nakase, Komagata & Fukazawa (1978)
107. *Candida peltata* (Yarrow) S.A. Meyer & Ahearn (1983)
108. *Candida petrohuensis* C. Ramírez & A. González (1984)
109. *Candida pignaliae* (F.H. Jacob) S.A. Meyer & Yarrow (1978)
110. *Candida pini* (Lodder & Kreger-van Rij) S.A. Meyer & Yarrow (1978)
111. *Candida populi* Hagler, Mendonça-Hagler & Phaff (1989)
112. *Candida pseudointermedia* Nakase, Komagata & Fukazawa (1976)
113. *Candida pseudolambica* M.Th. Smith, Poot & Kull (1989)
114. *Candida psychrophila* (S. Goto, Sugiyama & Iizuka) S.A. Meyer & Yarrow (1978)
115. *Candida pulcherrima* (Lindner) Windisch (1940): see *Metschnikowia pulcherrima*, p. 264
116. *Candida quercitrusa* (van Uden & do Carmo-Sousa) S.A. Meyer & Phaff ex S.A. Meyer & Yarrow (1998)
117. *Candida quercuum* Nakase (1971)
118. *Candida railenensis* C. Ramírez & A. González (1984)
119. *Candida reukaufii* (Grüss) Diddens & Lodder (1942): see *Metschnikowia reukaufii*, p. 265
120. *Candida rhagii* Jurzitza, Kühlwein & Kreger-van Rij (1960)
121. *Candida rugopelliculosa* Nakase (1971)
122. *Candida rugosa* (H.W. Anderson) Diddens & Lodder (1942)
123. *Candida saitoana* Nakase & M. Suzuki (1985)
124. *Candida sake* (Saito & Oda) van Uden & H.R. Buckley ex S.A. Meyer & Ahearn (1983)
125. *Candida salmanticensis* (Santa María) van Uden & H.R. Buckley ex S.A. Meyer & Ahearn (1983)
126. *Candida santamariae* Montrocher (1967)
127. *Candida santjacobensis* C. Ramírez & A. González (1984)
128. *Candida savonica* Sonck (1974)
129. *Candida schatavii* (Kocková-Kratochvílová & Ondrušová) S.A. Meyer & Yarrow (1978)
130. *Candida sequanensis* Saëz & Rodrigues de Miranda (1984)
131. *Candida shehatae* H.R. Buckley & van Uden (1967)
 - a. *Candida shehatae* H.R. Buckley & van Uden var. *shehatae* (1990)
 - b. *Candida shehatae* var. *insectosa* Kurtzman (1990)
 - c. *Candida shehatae* var. *lignosa* Kurtzman (1990)
132. *Candida silvae* Vidal-Leiria & van Uden (1963)
133. *Candida silvanorum* van der Walt, van der Klift & D.B. Scott (1971)
134. *Candida silvatica* (van der Walt, van der Klift & D.B. Scott) S.A. Meyer & Yarrow (1978)
135. *Candida silvicultrix* van der Walt, D.B. Scott & van der Klift (1972)
136. *Candida solani* Lodder & Kreger-van Rij (1952)
137. *Candida sonorensis* (M.W. Miller, Phaff, Miranda, Heed & Starmer) S.A. Meyer & Yarrow (1978)
138. *Candida sophiae-reginae* C. Ramírez & A. González (1984)
139. *Candida sorbophila* (Nakase) S.A. Meyer & Yarrow (1978)
140. *Candida sorboxylosa* Nakase (1971)
141. *Candida spandovensis* (Henninger & Windisch) S.A. Meyer & Yarrow (1978)
142. *Candida stellata* (Kroemer & Krumbholz) S.A. Meyer & Yarrow (1978)
143. *Candida succiphila* J.-D. Lee & Komagata (1980)
144. *Candida suecica* Rodrigues de Miranda & Norkrans (1968)

145. *Candida tanzawaensis* Nakase & M. Itoh (1988)
 146. *Candida tenuis* Diddens & Lodder (1942)
 147. *Candida tepae* Grinbergs (1967)
 148. *Candida torresii* (van Uden & Zobell) S.A. Meyer & Yarrow (1978)
 149. *Candida tropicalis* (Castellani) Berkhout (1923)
 150. *Candida tsuchiyae* Nakase & M. Suzuki (1985)
 151. *Candida utilis* (Henneberg) Lodder & Kreger-van Rij (1952); see *Pichia jadinii*, p. 314
 152. *Candida vaccinii* Tokuoka, Ishitani, S. Goto & Komagata (1987)
 153. *Candida valdiviana* Grinbergs & Yarrow (1970)
 154. *Candida valida* (Leberle) van Uden & H.R. Buckley (1970); see *Pichia membranifaciens*, p. 319
 155. *Candida vanderwaltii* (Vidal-Leiria) S.A. Meyer & Yarrow (1978)
 156. *Candida vartiovaarae* (Capriotti) van Uden & H.R. Buckley ex S.A. Meyer & Ahearn (1983)
 157. *Candida versatilis* (Eichells & T.A. Bell) S.A. Meyer & Yarrow (1978)
 158. *Candida vinaria* Y. Ohara, Nonomura & Yunome ex M.Th. Smith (1973)
 159. *Candida vini* (Vallot ex Desmazières) van Uden & H.R. Buckley ex S.A. Meyer & Ahearn (1983)
 160. *Candida viswanathii* Viswanathan & H.S. Randhawa ex R.S. Sandhu & H.S. Randhawa (1962)
 161. *Candida wickerhamii* (Capriotti) S.A. Meyer & Yarrow (1978)
 162. *Candida xestobii* Yarrow & S.A. Meyer (1978)
 163. *Candida zeylanoides* (Castellani) Langeron & Guerra (1938)

Key to species

It must be noted that *C. famata* is not included in the key because it is variable in many of the tests.

1. a Nitrate growth positive → 2
 b Nitrate growth negative → 29
- 2(1). a Melezitose growth positive → 3
 b Melezitose growth negative → 13
- 3(2). a Raffinose growth positive → 4
 b Raffinose growth negative → 7
- 4(3). a Glucose fermentation positive → 5
 b Glucose fermentation negative → 6
- 5(4). a Galactose growth positive *C. valdiviana*: p. 566
 b Galactose growth negative *C. utilis*: p. 565
- 6(4). a Growth at 37°C positive *C. edax*: p. 500
 b Growth at 37°C negative *C. bertae*: p. 486
- 7(3). a Galactose growth positive → 8
 b Galactose growth negative → 10
- 8(7). a Soluble starch growth positive *C. ishiwadae*: p. 516
 b Soluble starch growth negative → 9
- 9(8). a Lactose growth positive *C. chilensis*: p. 495
 b Lactose growth negative *C. incommunis*: p. 513
- 10(7). a Soluble starch growth positive *C. ishiwadae*: p. 516
 b Soluble starch growth negative → 11
- 11(10). a L-Rhamnose growth positive *C. populi*: p. 541
 b L-Rhamnose growth negative → 12
- 12(11). a Erythritol growth positive *C. incommunis*: p. 513
 b Erythritol growth negative *C. vartiovaarae*: p. 567
- 13(2). a Erythritol growth positive → 14
 b Erythritol growth negative → 15
- 14(13). a Galactose growth positive *C. nanaspora*: p. 530
 b Galactose growth negative *C. boidinii*: p. 488
- 15(13). a Growth at 37°C positive → 16
 b Growth at 37°C negative → 20
- 16(15). a Galactose growth positive → 17
 b Galactose growth negative → 19
- 17(16). a L-Rhamnose growth positive *C. methanosorbosa*: p. 526
 b L-Rhamnose growth negative → 18
- 18(17). a Hexadecane growth positive *C. vaccinii*: p. 565
 b Hexadecane growth negative *C. magnoliae*: p. 521
- 19(16). a Cellobiose growth positive *C. berthetii*: p. 487
 b Cellobiose growth negative *C. glucosophila*: p. 510
- 20(15). a Cellobiose growth positive → 21
 b Cellobiose growth negative → 24
- 21(20). a Galactose growth positive → 22
 b Galactose growth negative → 23

22(21).	a L-Rhamnose growth positive	<i>C. wickerhamii</i> :	p. 570
	b L-Rhamnose growth negative	<i>C. versatilis</i> :	p. 567
23(21).	a Soluble starch growth positive	<i>C. ernobii</i> :	p. 501
	b Soluble starch growth negative	<i>C. norvegica</i> :	p. 532
24(20).	a Raffinose growth positive	<i>C. lactis-condensii</i> :	p. 519
	b Raffinose growth negative	→ 25		
25(24).	a L-Rhamnose growth positive	<i>C. nitratophila</i> :	p. 531
	b L-Rhamnose growth negative	→ 26		
26(25).	a Glucose fermentation positive	→ 27		
	b Glucose fermentation negative	→ 28		
27(26).	a 0.01% Cycloheximide growth positive	<i>C. pignaliae</i> :	p. 539
	b 0.01% Cycloheximide growth negative	<i>C. etchellsii</i> :	p. 502
28(26).	a 0.01% Cycloheximide growth positive	<i>C. vanderwaltii</i> :	p. 566
	b 0.01% Cycloheximide growth negative	<i>C. etchellsii</i> :	p. 502
29(1).	a Erythritol growth positive	→ 30		
	b Erythritol growth negative	→ 86		
30(29).	a 0.01% Cycloheximide growth positive	→ 31		
	b 0.01% Cycloheximide growth negative	→ 64		
31(30).	a Soluble starch growth positive	→ 32		
	b Soluble starch growth negative	→ 38		
32(31).	a Growth at 37°C positive	→ 33		
	b Growth at 37°C negative	→ 36		
33(32).	a Lactose growth positive	<i>C. blankii</i> :	p. 487
	b Lactose growth negative	→ 34		
34(33).	a Glucose fermentation positive	→ 35		
	b Glucose fermentation negative	<i>C. chiropterorum</i> :	p. 495
35(34).	a Growth at 40°C positive	<i>C. peltata</i> :	p. 538
	b Growth at 40°C negative	<i>C. homilentoma</i> :	p. 512
36(32).	a L-Rhamnose growth positive	<i>C. tenuis</i> :	p. 561
	b L-Rhamnose growth negative	→ 37		
37(36).	a DL-Lactate growth positive	<i>C. shehatae</i> var. <i>lignosa</i> :	p. 552
	b DL-Lactate growth negative	<i>C. shehatae</i> var. <i>shehatae</i> :	p. 552
38(31).	a Glucose fermentation positive	→ 39		
	b Glucose fermentation negative	→ 59		
39(38).	a Raffinose growth positive	→ 40		
	b Raffinose growth negative	→ 43		
40(39).	a Growth at 37°C positive	→ 41		
	b Growth at 37°C negative	→ 42		
41(40).	a L-Rhamnose growth positive	<i>C. insectorum</i> :	p. 515
	b L-Rhamnose growth negative	<i>C. entomophila</i> :	p. 500
42(40).	a Lactose growth positive	<i>C. tenuis</i> :	p. 561
	b Lactose growth negative	<i>C. santjacobensis</i> :	p. 550
43(39).	a Lactose growth positive	→ 44		
	b Lactose growth negative	→ 48		
44(43).	a Growth at 37°C positive	<i>C. auringiensis</i> :	p. 484
	b Growth at 37°C negative	→ 45		
45(44).	a Melezitose growth positive	→ 46		
	b Melezitose growth negative	→ 47		
46(45).	a L-Rhamnose growth positive	<i>C. tenuis</i> :	p. 561
	b L-Rhamnose growth negative	<i>C. coipomoensis</i> :	p. 496
47(45).	a Trehalose fermentation positive	<i>C. coipomoensis</i> :	p. 496
	b Trehalose fermentation negative	<i>C. ergastensis</i> :	p. 501
48(43).	a L-Rhamnose growth positive	→ 49		
	b L-Rhamnose growth negative	→ 50		
49(48).	a Galactose growth positive	<i>C. succiphila</i> :	p. 559
	b Galactose growth negative	<i>C. boidinii</i> :	p. 488
50(48).	a Galactose growth positive	→ 51		
	b Galactose growth negative	→ 54		
51(50).	a Trehalose fermentation positive	→ 52		
	b Trehalose fermentation negative	<i>C. cantarellii</i> :	p. 492
52(51).	a Galactose fermentation positive	<i>C. schatavii</i> :	p. 551
	b Galactose fermentation negative	→ 53		
53(52).	a Pellicle formation positive	<i>C. boleticola</i> :	p. 489
	b Pellicle formation negative	<i>C. laureliae</i> :	p. 519
54(50).	a Cellobiose growth positive	<i>C. ovalis</i> :	p. 535
	b Cellobiose growth negative	→ 55		

55(54).	a DL-Lactate growth positive → 56		
	b DL-Lactate growth negative → 58		
56(55).	a Trehalose fermentation positive	<i>C. llanquihuensis</i> :	p. 520
	b Trehalose fermentation negative → 57		
57(56).	a Vitamin-free growth positive	<i>C. cantarellii</i> :	p. 492
	b Vitamin-free growth negative	<i>C. boidinii</i> :	p. 488
58(55).	a Vitamin-free growth positive	<i>C. cantarellii</i> :	p. 492
	b Vitamin-free growth negative	<i>C. pini</i> :	p. 540
59(38).	a DL-Lactate growth positive → 60		
	b DL-Lactate growth negative → 62		
60(59).	a Xylitol growth positive → 61		
	b Xylitol growth negative	<i>C. lipolytica</i> :	p. 520
61(60).	a Melezitose growth positive	<i>C. tenuis</i> :	p. 561
	b Melezitose growth negative	<i>C. nemodendra</i> :	p. 531
62(59).	a Cellobiose growth positive → 61		
	b Cellobiose growth negative → 63		
63(62).	a Trehalose growth positive	<i>C. nemodendra</i> :	p. 531
	b Trehalose growth negative	<i>C. fermenticavens</i> :	p. 504
64(30).	a Vitamin-free growth positive → 65		
	b Vitamin-free growth negative → 67		
65(64).	a Soluble starch growth positive → 66		
	b Soluble starch growth negative	<i>C. rhagii</i> :	p. 545
66(65).	a Growth at 37°C positive	<i>C. silvicultrix</i> :	p. 555
	b Growth at 37°C negative	<i>C. fennica</i> :	p. 503
67(64).	a Cellobiose growth positive → 68		
	b Cellobiose growth negative → 85		
68(67).	a Galactose growth positive → 69		
	b Galactose growth negative	<i>C. mesenterica</i> :	p. 525
69(68).	a Melezitose growth positive → 70		
	b Melezitose growth negative → 83		
70(69).	a Raffinose growth positive → 71		
	b Raffinose growth negative → 77		
71(70).	a Lactose growth positive → 72		
	b Lactose growth negative → 73		
72(71).	a Growth at 37°C positive	<i>C. insectorum</i> :	p. 515
	b Growth at 37°C negative	<i>C. tenuis</i> :	p. 561
73(71).	a L-Rhamnose growth positive → 74		
	b L-Rhamnose growth negative → 76		
74(73).	a DL-Lactate growth positive	<i>C. membranifaciens</i> :	p. 525
	b DL-Lactate growth negative → 75		
75(74).	a N-Acetyl-D-glucosamine growth positive	<i>C. insectorum</i> :	p. 515
	b N-Acetyl-D-glucosamine growth negative	<i>C. silvanorum</i> :	p. 554
76(73).	a Sucrose fermentation positive	<i>C. membranifaciens</i> :	p. 525
	b Sucrose fermentation negative	<i>C. friedrichii</i> :	p. 506
77(70).	a L-Rhamnose growth positive → 78		
	b L-Rhamnose growth negative → 80		
78(77).	a Growth at 37°C positive	<i>C. naeodendra</i> :	p. 529
	b Growth at 37°C negative → 79		
79(78).	a Lactose growth positive	<i>C. tenuis</i> :	p. 561
	b Lactose growth negative	<i>C. atlantica</i> :	p. 483
80(77).	a Glucose fermentation positive → 81		
	b Glucose fermentation negative	<i>C. aaseri</i> :	p. 476
81(80).	a Growth at 37°C positive → 82		
	b Growth at 37°C negative	<i>C. atmosphaerica</i> :	p. 483
82(81).	a Trehalose fermentation positive	<i>C. diddensiae</i> :	p. 498
	b Trehalose fermentation negative	<i>C. butyri</i> :	p. 491
83(69).	a Soluble starch growth positive → 84		
	b Soluble starch growth negative	<i>C. conglobata</i> :	p. 496
84(83).	a L-Rhamnose growth positive	<i>C. dendronema</i> :	p. 498
	b L-Rhamnose growth negative	<i>C. sequanensis</i> :	p. 551
85(67).	a Glucose fermentation positive	<i>C. sophiae-reginae</i> :	p. 556
	b Glucose fermentation negative	<i>C. psychrophila</i> :	p. 542
86(29).	a Trehalose growth positive → 87		
	b Trehalose growth negative → 169		
87(86).	a Galactose growth positive → 88		
	b Galactose growth negative → 147		

- 88(87). a Cellobiose growth positive → 89
b Cellobiose growth negative → 130
- 89(88). a Glucose fermentation positive → 90
b Glucose fermentation negative → 123
- 90(89). a Melezitose growth positive → 91
b Melezitose growth negative → 116
- 91(90). a Growth at 37°C positive → 92
b Growth at 37°C negative → 98
- 92(91). a 0.01% Cycloheximide growth positive → 93
b 0.01% Cycloheximide growth negative → 96
- 93(92). a Soluble starch growth positive → 94
b Soluble starch growth negative → 95
- 94(93). a Galactose fermentation positive *C. tropicalis*: p. 563
..... *C. viswanathii*: p. 570
..... *C. fluviatilis*: p. 505
b Galactose fermentation negative *C. (Pichia) guilliermondii* var. *guilliermondii*: p. 511
- 95(93). a Raffinose growth positive *C. maltosa*: p. 522

	b Xylitol growth negative		<i>C. castellii:</i>	p. 493

Separation of *Candida* species by physiological groups

Candida is divided into physiological groups solely for convenience and ease in identification. There is no known basis of genetic relatedness for species within each of these groups. Some species appear in more than one group because of their physiological variability. There are four species not included in the Physiological Group Keys because of their particular growth characteristics. *C. austromarina* and *C. psychrophila* do not grow at 25°C, *C. famata* var. *famata* and *C. famata* var. *flarerii* have extensive physiological variability and *C. glucosophila* is osmophilic and does not grow in the usual media without additional sugar.

Key to the physiological groups:

1.	a Inositol assimilated		Group I
	b Inositol not assimilated	→ 2	
2(1).	a Nitrate assimilated		Group II
	b Nitrate not assimilated	→ 3	
3(2).	a Erythritol assimilated	→ 4	
	b Erythritol not assimilated	→ 6	
4(3).	a Raffinose assimilated		Group III
	b Raffinose not assimilated	→ 5	
5(4).	a Maltose assimilated		Group IV
	b Maltose not assimilated		Group V

- 6(3). a Growth at 40°C Group VI
 b Growth absent at 40°C → 7
- 7(6). a Raffinose assimilated → 8
 b Raffinose not assimilated → 9
- 8(7). a Cellobiose assimilated Group VII
 b Cellobiose not assimilated Group VIII
- 9(7). a Cellobiose assimilated → 10
 b Cellobiose not assimilated → 11
- 10(9). a Melezitose assimilated Group IX
 b Melezitose not assimilated Group X
- 11(9). a Trehalose assimilated Group XI
 b Trehalose not assimilated Group XII

Key to species in Group I: Growth response: inositol +. See Table 50.

1. a Nitrate assimilated → 2
 b Nitrate not assimilated → 5
- 2(1). a Erythritol assimilated → 3
 b Erythritol not assimilated *C. valdiviana*: p. 566
- 3(2). a Lactose assimilated → 4
 b Lactose not assimilated *C. incommunis*: p. 513
- 4(3). a Growth at 37°C *C. edax*: p. 500
 b Growth absent at 37°C *C. bertae*: p. 486
- 5(1). a Erythritol assimilated → 6
 b Erythritol not assimilated → 9
- 6(5). a Growth at 37°C → 7
 b Growth absent at 37°C *C. santjacobensis*: p. 550
- 7(6). a Lactose assimilated → 8
 b Lactose not assimilated *C. chiropterorum*: p. 495
- 8(7). a Rhamnose assimilated *C. blankii*: p. 487
 b Rhamnose not assimilated *C. auringiensis*: p. 484
- 9(5). a Lactose assimilated *C. paludigena*: p. 536
 b Lactose not assimilated *C. castrensis*: p. 493

Table 50

Key characters of Group I *Candida* species with the following primary growth response: **inositol +**

Species	Assimilation					Growth at 37°C
	Lactose	Raffinose	L-Rhamnose	Erythritol	Nitrate	
<i>Candida auringiensis</i>	+	–	–	+	–	+
<i>C. bertae</i>	+	+	+	+	+	–
<i>C. blankii</i>	+	v	+	+	–	+
<i>C. castrensis</i>	–	–	–	–	–	–
<i>C. chiropterorum</i>	–	+	+	+	–	+
<i>C. edax</i>	+	+	+	+	+	+
<i>C. incommunis</i>	–	–	–	+	+	v
<i>C. paludigena</i>	+	v	–	–	–	–
<i>C. santjacobensis</i>	–	+	v	+	–	–
<i>C. valdiviana</i>	v	+	–	–	+	–

Key to species in Group II: Growth response: inositol –, nitrate +. See Table 51.

1. a Erythritol assimilated → 2
 b Erythritol not assimilated → 5
- 2(1). a Sucrose assimilated → 3
 b Sucrose not assimilated → 4
- 3(2). a Lactose assimilated *C. chilensis*: p. 495
 b Lactose not assimilated *C. ishiwadae*: p. 516
- 4(2). a Galactose assimilated *C. nanaspora*: p. 530
 b Galactose not assimilated *C. boidinii*: p. 488
- 5(1). a Melezitose assimilated → 6
 b Melezitose not assimilated → 8
- 6(5). a Growth at 37°C *C. utilis*: p. 565
 b Growth absent at 37°C → 7

7(6).	a	Growth present with 0.01% cycloheximide	<i>C. populi</i> :	p. 541
	b	Growth absent with 0.01% cycloheximide	<i>C. vartiovaarae</i> :	p. 567
8(5).	a	L-Rhamnose assimilated → 9			
	b	L-Rhamnose not assimilated → 13			
9(8).	a	Sucrose assimilated	<i>C. ernobii</i> :	p. 501
	b	Sucrose not assimilated → 10			
10(9).	a	Galactose assimilated → 11			
	b	Galactose not assimilated	<i>C. norvegica</i> :	p. 532
11(10).	a	Growth at 37°C	<i>C. methanosorbosa</i> :	p. 526
	b	Growth absent at 37°C → 12			
12(11).	a	Cellobiose assimilated	<i>C. wickerhamii</i> :	p. 570
	b	Cellobiose not assimilated	<i>C. nitratophila</i> :	p. 531

^a *C. bombicola* is the only sucrose-positive yeast in this group. *C. maris* is the only L-rhamnose-positive yeast in this group.

^b Abbreviations: Gal, galactose; Xy, D-xylose; NAG, N-acetyl-D-glucosamine; Gly, glycerol; Lact, DL-lactate.

^c Abbreviations: VF, in vitamin-free medium; 50%G, on 50% (w/w) glucose–yeast extract agar; 0.01%, with 0.01% cycloheximide.

Systematic discussion of the species

64.1. *Candida aaseri* Dietrichson ex van Uden & H.R. Buckley (1970)

Synonym:

Azymocandida aaseri (Dietrichson) Novák & Zsolt (1961)

Growth in glucose–yeast extract–peptone broth: After 3 days at 25°C, the cells are elongate, (2.5–3.0) × (7.0–15.0) µm, in chains and clusters. A thin powdery pellicle may be present.

Dalmau plate culture on corn meal agar: After 7 days at 25°C, primitive pseudohyphae are present and consist of branched chains of elongate, sometimes rather curved cells. Aerobic growth is cream-colored, dull, soft and mostly smooth.

Fermentation: absent.

Assimilation:

Glucose	+	N-Acetyl-D-glucosamine	+
Galactose	+	Methanol	–
L-Sorbose	l	Ethanol	+
Sucrose	+	Glycerol	+
Maltose	+	Erythritol	+
Cellobiose	+	Ribitol	+
Trehalose	+	Galactitol	–
Lactose	+/l	D-Mannitol	+
Melibiose	–	D-Glucitol	+
Raffinose	–	α-Methyl-D-glucoside	+
Melezitose	l	Salicin	+
Inulin	–	D-Gluconate	l
Soluble starch	–	D,L-Lactate	–
D-Xylose	+	Succinate	+
L-Arabinose	+	Citrate	+
D-Arabinose	–	Inositol	–
D-Ribose	+	Hexadecane	–
L-Rhamnose	–	Nitrate	–
D-Glucosamine	–	Vitamin-free	–

Additional assimilation tests and other growth characteristics:

2-Keto-D-gluconate	–	L-Lysine	+
5-Keto-D-gluconate	n	Ethylamine	–
Saccharate	n	D-Glucosamine (N) ¹	+
D-Glucuronate	–	50% Glucose	–
Xylitol	+	10% NaCl/5% glucose	n
L-Arabinitol	+	Starch formation	–

Propane 1,2 diol	–	Biotin-free	–
Butane 2,3 diol	–	Pyridoxine-free	+
Nitrite	–	0.01% Cycloheximide	–
Cadaverine	+	Growth at 37°C	+
Creatinine	–	Growth at 40°C	–

¹ Utilization of D-glucosamine as a source of nitrogen.

Co-Q: 9 (Shin et al. 1996).

Mol% G+C: 37.1, CBS 1913 (T_m : Meyer and Phaff 1972).

Origin of the strain studied: CBS 1913, sputum, Norway.

Type strain: CBS 1913.

Comments: Kurtzman and Robnett (1997) found *C. aaseri* and *C. butyri* to have identical sequences in a 600-nucleotide region at the 5' end of large subunit (26S) rDNA, thus indicating the two taxa to be conspecific.

64.2. *Candida albicans* (Robin) Berkhout (1923)

Synonyms:

Oidium albicans Robin (1853)
Saccharomyces albicans (Robin) Reess (1877)
Monilia albicans Plaut (1887)
Dermatium albicans (Robin) Laurent (1889)
Monilia albicans (Robin) Zopf (1890)
Endomyces albicans (Robin) Vuillemin (1898)
Parasaccharomyces albicans (Robin) Froilano de Mello (Froilano de Mello and Gonzaga Fernandes 1918)

Growth in glucose–yeast extract–peptone broth:

After 3 days at 25°C, the cells are globose to ovoidal, (3.5–6.0)×(4.0–8.0)µm, single, in pairs, chains and clusters (Fig. 211).

Dalmu plate culture on corn meal agar: After 7 days at 25°C, well-differentiated, branched pseudohyphae with chains or clusters of blastoconidia and septate hyphae are

present. Pseudohyphae of the "Mycotorula" type are often observed – grape-like clusters of blastoconidia occurring along the pseudohyphal chains. Chlamydoconidia are usually present. A few strains fail to form pseudohyphae when first isolated, however, most of them demonstrate this ability after being maintained in culture. Aerobic growth is white to cream-colored, glistening, usually butyrous, soft, and smooth; sometimes growth is membranous.

Co-Q: 9 (Yamada and Kondo 1972a).

Mol% G+C: 34.9, CSAV 29-31-1; 35.1, CBS 2712; 35.7, CBS 1905; 36.9, CBS 1899 (*T_m*: Stenderup and Bak 1968); 34.4–35.4, 7 strains (Nakase and Komagata 1971f); 35.9–37.3, 4 strains (*T_m*: Meyer and Phaff 1972); 34.3–35.6; 15 strains (*T_m*: Meyer et al. 1984); 32.6–34.2, 34 strains (*T_m*: Kamiyama et al. 1989); 35.6, 35.9, 2 strains (*T_m*: Su and Meyer 1991).

Origin of the strains studied: CBS 562, skin infection (Mackinnon 1936); CBS 1894, soil, New Zealand; CBS 1899, skin, received as *C. truncata* (Vanbreuseghem 1948); CBS 1905, type of *Monilia stellatoidea*; CBS 1912, from sputum, type of *C. langeroni*; CBS 1918, probably human, N.F. Conant; CBS 1949, type of *C. clausenii* and *Syringospora clausenii*; CBS 2316, CBS 2689,

Fig. 211. *C. albicans*, CBS 562. After 3 days in glucose–yeast extract–peptone broth at 25°C. Bar = 5 µm.

interdigital mycosis, type of *Myceloblastanion gruetzii*; CBS 2691, pharyngitis, received as *Saccharomyces tumefaciens-albus*; CBS 2693, nail; CBS 2694, unknown; CBS 2695, sprue, authentic strain of *Monilia psilosis*; CBS 2697, sputum, type of *Mycotoruloides triadis*; CBS 2703, tonsillo-pharyngitis, type of *C. mycotoruloides*; CBS 2707, blastomycosis, type of *Monilia alvarezsotoi*; CBS 2711, sputum, type of *Monilia richmondii*; CBS 2721, unknown; CBS 2738, child's mouth; CBS 2740, from leaf; CBS 2770, unknown; CBS 2990, sputum; CBS 5137, sputum, type of *Syringospora stellatoidea*; CBS 5982, serotype A; CBS 5983, serotype B; CBS 5990, vagina; CBS 6073, sputum; CBS 6431, bronchomycosis; CBS 6552, pharynx of *Cephalopus dorsalis*, type of *C. nouvelii*; CBS 6589, vagina; CBS 6910, urine.

Type strain: CBS 562, neotype, designated by Didens and Lodder (1942).

Comments: *C. albicans* is the most studied of all *Candida* species. The essence of much of the research is to ascertain the opportunistic or pathogenic aspects of this species, the ways to deal with the microbe/patient relationship and the epidemiology. A significant number of *C. albicans* strains are isolated routinely from clinical sources. The degree of variability has been reported repeatedly using various techniques. The terms 'typical' and 'atypical' frequently appear in publications. Besides the usual morphological and physiological characterizations as described above, *C. albicans* has been studied with numerous molecular biological techniques to determine strain identity and strain variability: restriction fragment length polymorphisms (RFLPs), karyotypes, DNA probes, randomly amplified polymorphic DNA (RAPD) analysis, nuclear DNA reassociation, mitochondrial DNA RFLPs, size and mol% G+C, protein electrophoretic profiles, as well as the phylogenetically determining criterion, ribosomal RNA gene sequences.

The conspecificity of *C. albicans* and *C. stellatoidea* was established by DNA reassociation (Meyer 1979), supported by other studies (immunoelectrophoretic analysis, Montrocher 1980) and confirmed by additional

DNA reassociation studies (Kamiyama et al. 1989). Nevertheless, Kwon-Chung et al. (1988) showed two distinct karyotype profiles for strains of *C. stellatoidea*. They were designated type I and type II. Mahrous et al. (1990) demonstrated that phenotypically diverse strains of *C. albicans*, whose identification was verified by DNA reassociation, had varying karyotypes. Sullivan et al. (1995) showed that the nucleotide sequences of the V3 region of the ribosomal RNA genes of *C. stellatoidea* type I and type II are identical and differed from five other strains of *C. albicans* at one or two nucleotide positions.

Sullivan et al. (1995) described *C. dubliniensis*, a new species isolated from sixty HIV-infected and three HIV negative persons, that closely resembles *C. albicans*. *C. dubliniensis* is germ tube positive and produces chlamydospores in abundance. It is serotype A and its physiological profile shows few differences compared with four reference strains (*C. albicans* serotype A and serotype B; *C. stellatoidea* type I and type II). Several molecular biological techniques (DNA fingerprinting, DNA probing, RAPD analysis, karyotyping, rRNA gene sequencing) were employed to compare strains of this species with *C. albicans* reference strains. The results showed that the strains of *C. dubliniensis* were distinct from the *C. albicans* strains. The most convincing evidence that *C. dubliniensis* is distinct from *C. albicans* is the number of nucleotide differences (13–15) in the ribosomal RNA gene sequences. However, Sullivan et al. (1995) did not compare their strains with strains representing the many synonyms of *C. albicans*, so it is possible that the species may be found to be synonymous with an earlier described species.

64.3. *Candida amapae* Morais, Rosa, S.A. Meyer, Mendonça-Hagler & Hagler (1995)

The following description is taken from the original description (Morais et al. 1995).

Growth in malt extract: After 3 days at 25°C, the cells are large and globose to elongate. After four weeks, a sediment and a thick ring are present.

Growth on malt extract agar: After 3 days, cells are pleomorphic and cylindrical to elongate. Well-developed, moderately branched pseudohyphae are also present. The streak culture is dry, white, cottony, rough with a smooth center and an irregular fringed margin. After 10 days, the growth is off-white, smooth and with a rugose lobate margin that is fringed with pseudomycelium.

Dalmau plate culture on corn meal agar: After 5 days at 25°C, abundant pseudohyphae are present. After 10–20 days, rare true hyphae are observed.

Fermentation: absent.

Assimilation:

Glucose	+	<i>N</i> -Acetyl-D-glucosamine	n
Galactose	–	Methanol	–
L-Sorbose	+	Ethanol	–
Sucrose	–	Glycerol	–

Ethylamine	–	Growth at 37°C	–
50% Glucose	–		
10% NaCl	–		
Starch formation	–		

Co-Q: Not determined.

Mol% G+C: 38.8, CBS 7872 (T_m : Morais et al. 1995).

Origin of the strains studied: CBS 7872 (type strain) and 13 other strains, fallen fruit of *Parahancornia amapa*, Mocambo forest, Belem, Para, Brazil.

Type strain: CBS 7872.

Comments: Morais et al. (1995) studied 14 strains of this species. Only one strain grew on succinate, citrate and glucosamine. This species is very similar to *C. sorboxylosa* and also to species of *Issatchenkia*. What differentiates *C. amapae* from these yeasts is its absolute requirement for the sulfur-containing amino acids methionine and cysteine.

64.4. *Candida anatomiae* (Zwillenberg) S.A. Meyer & Yarrow (Yarrow and Meyer 1978)

Synonym:

Torulopsis anatomiae Zwillenberg (1966)

Growth in glucose-yeast extract-peptone broth:

After 3 days at 25°C, the cells are globose to short-oval, (3.0–5.0) × (3.0–7.0) μ m, single, in pairs and short chains.

Dalmau plate culture on corn meal agar: After 7 days at 25°C, primitive pseudohyphae of short chains of cells are sometimes present. Aerobic growth is white to cream-colored, soft, glistening, smooth and entire.

¹ Utilization of D-glucosamine as a source of nitrogen.

Co-Q: Not determined.

Mol% G+C: 42.0, CBS 8184 (*T_m*: O'Neill and Meyer, unpublished data).

Origin of the strains studied: CBS 8184, from rotten *Drimys winteri*, Chile.

Type strain: CBS 8184.

Comments: Kurtzman and Robnett (1997) found *C. petrohuensis*, *C. ancudensis* and *C. drimydis* to have identical sequences in a 600-nucleotide region at the 5' end of large

subunit (26S) rDNA, thus indicating the three taxa to be conspecific.

64.6. *Candida antillancae* C. Ramírez & A. González (1984a)

Synonym:

Candida bondarzewiae C. Ramírez & A. González (1984a)

Growth in glucose–yeast extract–peptone broth:

After 3 days at 20°C, the cells are ovoidal, (3.0–4.5) × (3.5–10.0) μm, single, in pairs and small groups (Fig. 213).

Dalmou plate culture on corn meal agar: After 7 days at 22°C, primitive to well-developed pseudohyphae are evident. Aerobic growth is white to cream-colored, butyrous, soft and entire.

Fermentation: absent.

¹ Utilization of D-glucosamine as a source of nitrogen.

Co-Q: Not determined.

Mol% G+C: 39.0, CBS 8171 (*T_m*: Meyer, unpublished data).

Origin of the strains studied: CBS 8170, CBS 8171 (type strain, *C. bondarzewiae*) rotten wood, Chile.

Type strain: CBS 8170.

Fig. 213. *C. antillancae*, CBS 8171. After 3 days in glucose–yeast extract–peptone broth at 20°C. Bar = 5 μm.

Comments: The strains examined grow poorly at 25°C, therefore, most tests were incubated at 17–20°C. Dalmou plate cultures were incubated at 22°C. Some assimilation responses differ from those in the original descriptions of *C. antillancae* and *C. bondarzewiae*. Primarily, latent growth was evident in galactose, sucrose, cellobiose, salicin and lactic acid for *C. antillancae* and latent growth on cellobiose, salicin, arbutin and mannitol was noted for the strain of *C. bondarzewiae*, as well as positive responses on glycerol. These two yeasts are nearly identical in the tested morphological and physiological properties. In addition, Kurtzman and Robnett (1997) found *C. antillancae*, *C. bondarzewiae* and *C. tepae* to have identical sequences in a 600-nucleotide region at the 5' end of large subunit (26S) rDNA, thus indicating the three taxa to be conspecific.

64.7. *Candida apicola* (Hajsig) S.A. Meyer & Yarrow (Yarrow and Meyer 1978)

Synonyms:

Torulopsis apicola Hajsig (1958)

Torulopsis bacillaris (Kroemer & Krumbholz) Lodder var. *obesa*

Y. Ohara, Nonomura & Yunome (1960a)

Growth in glucose–yeast extract–peptone broth:

After 3 days at 25°C, the cells are spherical to ovoidal, (1.5–2.5) × (3.0–4.0) μm, and occur singly and in pairs.

Dalmou plate culture on corn meal agar: After 14 days at 25°C, pseudohyphae are not present. Aerobic growth is yellowish to cream-colored, glistening, soft, smooth and entire.

Fermentation:

Co-Q: 9 (F.-L. Lee et al. 1993).

Mol% G+C: 46.3, CBS 2868 (*T_m*: Stenderup et al. 1972); 44.3, CBS 2868 (HPLC: F.-L. Lee et al. 1993).

Origin of the strains studied: CBS 1887, CBS 1888, CBS 1889, pickled cucumbers, U.S.A.; CBS 2868, 2869, bee's gut; CBS 4078, grape must, type of *Torulopsis bacillaris* var. *obesa*; CBS 4353, sugar.

Type strain: CBS 2868.

64.8. *Candida apis* (Lavie ex van Uden & Vidal-Leiria) S.A. Meyer & Yarrow (Yarrow and Meyer 1978)

Synonyms:

Paratorulopsis apis (Lavie) Novák & Zsolt (1961)

Torulopsis apis Lavie ex van Uden & Vidal-Leiria (1970)

Growth in glucose–yeast extract–peptone broth:

After 3 days at 25°C, the cells are globose to ovoidal, (2.0–4.0)×(3.0–7.0) μm, single, in pairs and short chains (Fig. 214).

Dalmau plate culture on corn meal agar: After 14 days at 25°C, primitive pseudohyphae of short chains of cells are sometimes present. Aerobic growth is cream-colored to beige, soft, smooth and entire.

Fermentation: absent.

Fig. 214. *C. apis*, CBS 2674. After 3 days in glucose–yeast extract–peptone broth at 25°C. Bar = 5 μm.

¹ Utilization of D-glucosamine as a source of nitrogen.

Co-Q: 9 (F.-L. Lee et al. 1993).

Mol% G+C: 48.8, CBS 2674 (BD: Stenderup et al. 1972); 45.6, CBS 2674 (HPLC: F.-L. Lee et al. 1993).

Origin of the strain studied: CBS 2674, from bees.

Type strain: CBS 2674.

Comments: This species no longer has the variety *galacta*. F.-L. Lee et al. (1993) found that the mol% G+C contents of *C. apis* var. *apis* and *C. apis* var. *galacta* differed by 5.6% and Co-Q also differed, 9 and 8, respectively. DNA reassociation confirmed the lack of

relatedness between these two organisms. These investigators recognized *C. apis* var. *galacta* as the distinct species, *C. galacta*.

64.9. *Candida atlantica* (Siepmann) S.A. Meyer & Simione ex S.A. Meyer & Yarrow (1998)

Synonyms:

Trichosporon atlanticum Siepmann (Siepmann and Höhnik 1962)

Candida atlantica (Siepmann) S.A. Meyer & Simione (1978)

nom. inval.

Growth in glucose–yeast extract–peptone broth:

After 3 days at 25°C, the cells are globose to ovoidal, (2.5–5.0) × (2.5–6.0) μm, and single, in pairs, short chains and small clusters.

Dalmay plate culture on corn meal agar: After 7 days at 25°C, primitive to well-developed pseudohyphae are formed. Aerobic growth is cream-colored, somewhat glistening and soft with some ‘craters’ in the central area of the streak. The margin is entire.

Fermentation:

Glucose	w/–	Lactose	–
Galactose	–	Raffinose	–
Sucrose	–	Trehalose	–
Maltose	–		

Assimilation:

¹ Utilization of D-glucosamine as a source of nitrogen.

Co-Q: Not determined.

Mol% G + C: 35.8, CBS 5263 (*T_m*: Meyer et al. 1984).

Origin of the strain studied: CBS 5263, shrimp eggs from the North Atlantic Ocean.

Type strain: CBS 5263.

64.10. *Candida atmosphaerica* Santa María (1959c)

Growth in glucose–yeast extract–peptone broth:

After 3 days at 25°C, the cells are ovoidal to cylindrical, (1.5–3.0) × (3–12) μm, single, in pairs and chains.

Dalmay plate culture on corn meal agar: After 7 days at 25°C, well-developed pseudohyphae of long, branched chains of cells, usually with few blastoconidia, are present. Aerobic growth is white to cream-colored, soft, smooth and butyrous.

Fermentation:

Glucose	s	Lactose	–
Galactose	–/s	Raffinose	–
Sucrose	–/s	Trehalose	s
Maltose	–/s		

Assimilation:

Glucose	+	<i>N</i> -Acetyl-D-glucosamine	+

Butane 2, 3 diol	–	Pyridoxine-free	+
Nitrite	–	0.01% Cycloheximide	–
Cadaverine	+	Growth at 30°C	+
Creatinine	–	Growth at 35°C	–

¹ Utilization of D-glucosamine as a source of nitrogen.

Co-Q: 9 (Yamada and Kondo 1972a).

Mol% G + C: 39.0, 38.4, CBS 4547 (*T_m*: Meyer and Phaff 1972, HPLC: C.-F. Lee et al. 1993, respectively), 39.7, CSAV 29-50-1 (*T_m*: Stenderup and Bak 1968); 38.8, AJ 5107 (*T_m*: Nakase and Komagata 1971f).

Origin of the strains studied: CBS 4547, atmosphere; CBS 7170, fruiting body of a fungus (*Tyromyces ptychogaster*) on a fallen tree trunk.

Type strain: CBS 4547.

Comments: Triangular to clover-leaf shaped cells may

be found on some media. DNA reassociation experiments confirmed that this species was not a synonym of *C. diddensiae* (Meyer and Simone 1978). C.-F. Lee et al. (1993) showed insignificant DNA relatedness between *C. atmosphaerica* and *C. dendronema* and between *C. atmosphaerica* and *C. terebra*.

64.11. *Candida aurangiensis* Santa María (1978)

Growth in glucose–yeast extract–peptone broth: After 3 days at 25°C, the cells are ovoidal, (2.5–4.0) × (3.0–5.0) μm, single and in pairs. Some cells may be teardrop-shaped.

Dalmau plate culture on corn meal agar: After 7 days at 25°C, primitive to well-developed pseudohyphae are present. Aerobic growth is white, creamy, smooth and glistening. The margin is mostly entire with an occasional tuft of mycelial growth.

Fermentation:

Creatinine	–		

¹ Utilization of D-glucosamine as a source of nitrogen.

Co-Q: Not determined.

Mol% G+C: 39.0, 2 strains (*T_m*: Meyer et al. 1984).

Origin of the strains studied: CBS 6179, 6588, Antarctic Ocean.

Type strain: CBS 6179.

Comments: All tests reported here were conducted at 15–17°C. The maximum temperature for growth of this species is 18–21°C. Kurtzman and Robnett (1997) found *C. sake* and *C. austromarina* to have identical sequences in a 600-nucleotide region at the 5' end of large subunit (26S) rDNA, indicating the two taxa to be conspecific.

64.13. *Candida azyma* (van der Walt, E. Johannsen & Yarrow) S.A. Meyer & Yarrow (Yarrow and Meyer 1978)

Synonym:

Torulopsis azyma van der Walt, E. Johannsen & Yarrow (1978)

Growth in glucose–yeast extract–peptone broth:

After 3 days at 25°C, the cells are ovoidal to long ovoidal, (2.0–4.0)×(5.0–9.0)µm, single, in pairs or short chains (Fig. 215).

Dalmou plate culture on corn meal agar: After 14 days at 25°C, pseudohyphae, if present, consist of branched chains of ovoid cells. Aerobic growth is slightly beige to cream-colored, smooth and shiny. The margin may be smooth to undulating.

Fermentation: absent.

Assimilation:

Glucose	+	<i>N</i> -Acetyl-D-glucosamine	–
Galactose	+	Methanol	–
L-Sorbose	+	Ethanol	+
Sucrose	+	Glycerol	+

Co-Q: Not determined.

Mol% G+C: 43.7, 44.4, CBS 8169; 43.9, 43.4, CBS 8168 (*T_m*: M.Th. Smith, personal communication; *T_m*: Tengku Zainal Mulok 1988, respectively).

Origin of the strains studied: CBS 8169, CBS 8168, rotten wood in Chile.

Type strain: CBS 8169.

Comments: At the time Ramírez and González (1984c) described *C. bertae*, they also described *C. bertae* var. *chiloensis*. The variety *chiloensis* was distinguished from the variety *bertae* on the basis of trehalose assimilation and the inability to utilize glycerol, ribitol, and salicin. We found that both varieties assimilate glycerol, ribitol and salicin, either well or latently. They differ in the assimilation of maltose and trehalose. The strain designated *C. bertae* var. *chiloensis* grows well on maltose and trehalose, in contrast to the variety *bertae* which grows only latently or not at all. Other differences from the original description include the assimilation of L-sorbose, lactose, melezitose, D-ribose, and D-arabinose. Tengku Zainal Mulok (1988) found 97.6% DNA relatedness for these yeasts. We feel there are insufficient differences to warrant varietal status for the strain designated *C. bertae* var. *chiloensis*.

64.16. *Candida berthetii* Boidin, Pignal, Mermier & Arpin (1963)

Growth in glucose-yeast extract-peptone broth: After 3 days at 25°C, the cells are globose to subglobose, (4.0–6.0) × (4.5–6.5) μm, single and in pairs. A dry pellicle is present.

Dalmau plate culture on corn meal agar: After 7 days at 25°C, short densely branched pseudohyphae usually with verticils of globose blastoconidia are present. Aerobic growth is off-white to cream-colored, soft, mostly smooth and the margin entire.

Type strain: CBS 5452.

64.17. *Candida blankii* H.R. Buckley & van Uden (1968)**Synonym:**

Candida hydrocarbofumarica K. Yamada, Furukawa & Nakahara ex C. Ramirez (1974)

Growth in glucose-yeast extract-peptone broth: After 3 days at 25°C, the cells are spheroidal to ovoidal to elongate, (2.0–5.0) × (2.0–13.0) μm, and occur singly, in pairs and short chains.

Dalmau plate culture on corn meal agar: After 7 days at 25°C, pseudohyphae consist of branched chains of cells with blastoconidia formed in verticils. True hyphae may be present. Aerobic growth is white to cream-colored, soft, and smooth to wrinkled.

¹ Utilization of D-glucosamine as a source of nitrogen.

Co-Q: 7 (J.-D. Lee and Komagata 1980a, Lin et al. 1995).

Mol% G + C: 30.5, AJ 4778, 32.4, AJ 4939 (*T_m*: Nakase and Komagata 1971f), 33.0, CBS 2428 (*T_m*: Meyer and Phaff 1972); 31.0, CBS 2428 & CBS 8051, 30.8, CBS 8030 (HPLC: C.-F. Lee et al. 1994b); 34.6, CBS 7299 (*T_m*: Kumamoto et al. 1986); 35.6, CBS 8030 (*T_m*: Trotsenko et al. 1974); 31.0–32.9, 19 strains (HPLC: Lin et al. 1995).

Origin of the strains studied: CBS 2428, tanning fluid; CBS 2429, soil; CBS 3092, olives (type strain of *C. olivarium*); CBS 5325, sea water; CBS 5777, wine (type strain of *C. koshuensis*); CBS 6056, ginger ale, U.S.A.; CBS 6202, floor of hospital ward in Finland; CBS 6295, soil; CBS 6368, washed soft-drink bottles; CBS 6990, tepache in Mexico (type strain of *C. queretana*); CBS 7299, slimy mud in Japan (type strain of *C. ooitensis*); CBS 8051 (NRRL Y-8025), 8052 (NRRL Y-8023), unknown; CBS 8106, soil; CBS 8251, soil (type strain of *C. silvicola* var. *melibiosica*); CBS 8030, soil, (type strain of *C. methylica*).

Type strain: CBS 2428.

Comments: *C. methylica* was added to the list of synonyms because of the significant DNA hybridization with the type strain of *C. boidinii* (C.-F. Lee et al. 1994b). The type strain of *C. methylica* assimilates rhamnose and not ribose whereas all other strains of *C. boidinii* assimilate ribose and not rhamnose. Kurtzman (personal communication) found the ribosomal RNA gene sequences to be identical for the type strains of *C. ooitensis* and *C. boidinii*. Their morphological and physiological properties are nearly the same with the exception of nitrate utilization. This means that the type strain of *C. ooitensis* is the only strain presently included in *C. boidinii* that is nitrate negative. Interestingly, *C. ooitensis* does assimilate nitrite. J.-D. Lee and Komagata (1983) compared the electrophoretic patterns of enzymes of *C. boidinii* strains and showed the presence of two distinct groups. Lin et al. (1996) employed several molecular and chemical techniques to examine nineteen strains of *C. boidinii* and found a high degree of genetic heterogeneity. The strains clustered into two groups according to their different electrophoretic enzyme patterns and profiles of the restriction digests of the rDNA spacer region. They also found a unique chromosomal banding pattern for each strain.

64.19. *Candida boleticola* Nakase (1971b)**Synonym:***Candida ralunensis* C. Ramírez & A. González (1984f)**Growth in glucose–yeast extract–peptone broth:**

After 5 days at 25°C, the cells are ovoidal to elongate, (2.5–5.0) × (5.0–10.0) μm, and occur singly, in pairs and short chains (Fig. 217). The type strain forms a thin pellicle.

Dalmau plate culture on corn meal agar: After 5 days at 25°C, well-developed pseudohyphae consisting of branched chains of cylindroidal cells with small verticils of ovoidal blastoconidia are present. Aerobic growth is off-white to cream-colored, dry, wrinkled, dull and with a fringed margin.

Fermentation:

Glucose	+	Lactose	–
Galactose	–	Raffinose	–
Sucrose	–	Trehalose	+
Maltose	–		

Assimilation:

¹ Utilization of D-glucosamine as a source of nitrogen.

Co-Q: Not determined.

Mol% G + C: 43.2–44.1, 3 strains (T_m : Nakase 1971b); 44.4, CBS 6420; 43.6, CBS 8179 (T_m : Meyer, unpublished data).

Origin of the strains studied: CBS 6420, from the fruiting body of the fungus *Astraeus hygrometricus*; CBS 8179, type strain of *C. ralunensis*, rotten trunk of *Laurelia sempervirens*, Chile.

Fig. 217. *C. boleticola*, CBS 6420. After 3 days in glucose–yeast extract–peptone broth at 25°C. Bar = 5 μm.

Type strain: CBS 6420.

Comments: Kurtzman and Robnett (1997) found *C. laureliae* and *C. ralunensis* to have identical sequences in a 600-nucleotide region at the 5' end of large subunit (26S) rDNA and to differ by only one nucleotide from *C. boleticola*, thus indicating the three taxa to be conspecific. *C. boleticola* assimilates L-sorbose, D-arabinose, D-ribose, D-glucosamine, and D-gluconate, grows on high osmotic pressure media (50% glucose and 10% NaCl/5% glucose) and grows at 35°C; *C. ralunensis* does not assimilate these compounds and is unable to grow on high osmotic pressure media and at 30°C.

64.20. *Candida bombi* Montrocher (1967)**Growth in glucose–yeast extract–peptone broth:**

After 3 days at 25°C, the cells are ovoidal, (2.0–4.0) × (4.0–6.0) μm, single, in pairs and small groups (Fig. 218).

Dalmau plate culture on corn meal agar: After 7 days at 25°C, pseudohyphae may be sparse or consist of branched chains of cells, sometimes with verticils of blastopores. Aerobic growth is cream-colored to light tan, smooth and soft with an entire to slightly irregular margin.

Fig. 218. *C. bombi*, CBS 5836. After 3 days in glucose–yeast extract–peptone broth at 25°C. Bar = 5 μm.

Co-Q: Not determined.

Mol% G+C: 31.5, CBS 6796 (*T_m*: Meyer et al. 1984).

Origin of the strain studied: CBS 6796, tree fern, Buin.

Type strain: CBS 6796.

64.23. *Candida butyri* Nakase (1971b)

Growth in glucose–yeast extract–peptone broth: After 3 days at 25°C, the cells are subglobose, ovoidal to elongate, (3.6–5.7)×(3.6–7.2) µm, and occur singly, in pairs, clusters and chains. Pseudohyphae may be present.

Dalmay plate culture on corn meal agar: After 3 days at 25°C, abundant pseudohyphae consist of ramified chains of cells bearing groups of blastoconidia in verticils. Aerobic growth is white to cream-colored, shiny, smooth with some wrinkled areas and soft. The border is fringed.

Mol% G+C: 34.4, 34.9, 2 strains (*T_m*: Nakase 1971b); 36.1, CBS 2226 (*T_m*: von Arx 1979a).

Origin of the strains studied: CBS 2226, abscess at site of penicillin injection; CBS 6421, butter.

Type strain: CBS 6421.

Comments: Kurtzman and Robnett (1997) found *C. aaseri* and *C. butyri* to have identical sequences in

a 600-nucleotide region at the 5' end of large subunit (26S) rDNA, indicating the two taxa to be conspecific.

64.24. *Candida cantarellii* (van der Walt & van Kerken) S.A. Meyer & Yarrow (Yarrow and Meyer 1978)

Synonyms:

Torulopsis cantarellii van der Walt & van Kerken (1961b)

Torulopsis vinacea Ohara, Nonomura & Yamazaki (1964)

Growth in glucose-yeast extract-peptone broth:

After 3 days at 25°C, the cells are subglobose to ellipsoidal, (3.0–4.0) × (4.0–8.0) µm, single, in pairs and small groups.

Dalmou plate culture on corn meal agar: After 14 days at 25°C, pseudohyphae are not present. Aerobic growth is cream-colored, soft, dull and wrinkled.

Fermentation:

¹ Utilization of D-glucosamine as a source of nitrogen.

Co-Q: 9 (Yamada and Kondo 1972a).

Mol% G+C: 41.9, CBS 4878 (BD: Meyer et al. 1984).

Origin of the strains studied: CBS 4878, grape must in South Africa; CBS 5383, CBS 5445, CBS 5654, grape must in Japan.

Type strain: CBS 4878.

64.25. *Candida caseinolytica* Phaff, Starmer, Lachance & Ganter (1994)

This species was not included in our studies because of the time of its publication. Therefore, the description here is taken from the original description (Phaff et al. 1994).

Growth in YM broth: After 3 days at 30°C, the cells are ovoidal to short cylindroidal, (1.3–2.5) × (2.5–5.0) µm, and occur singly, in pairs or in short chains.

Growth on YM agar: After 3 days, the streak culture is white, smooth, glossy, butyrous, convex and slow growing.

Dalmou plate culture on corn meal agar: After 10 days, no pseudohyphae or true hyphae are produced.

Fermentation: absent.

Assimilation:

Glucose	+	<i>N</i> -Acetyl-D-glucosamine	–
Galactose	+	Methanol	–
L-Sorbose	–/l	Ethanol	+

¹ Utilization of D-glucosamine as a source of nitrogen.

Co-Q: Not determined.

Mol% G+C: 46.4–47.4, 8 strains; 46.9, type strain (BD: Phaff et al. 1994).

Origin of the strains studied: Cacti (*Opuntia* spp. and *Stenocereus* spp.) in Arizona, Texas, Mexico, Hawaii, and Argentina (36 strains); *Myrtillocactus cochal*, Mexico (2); *Drosophila mojavensis* in Mexico (1).

Type strain: CBS 7781 from *Opuntia phaeacantha*, Santa Rita Mountains, Arizona.

Comments: This species was isolated from necrotic tissues of various cactus species in various locations. Its unique property is its exceptionally strong ability to hydrolyze casein at pH 6.5. In addition, the cells are very small. The type strain was described as having the ability to assimilate xylose, gluconate, glucono- δ -lactone, sorbose (latently) and to grow at 42° and 45°C.

64.26. *Candida castellii* (Capriotti) S.A. Meyer & Yarrow (Yarrow and Meyer 1978)

Synonym:

Torulopsis castellii Capriotti (1961d)

Growth in glucose–yeast extract–peptone broth: After 3 days at 25°C, the cells are ovoidal to cylindrical, (2.0–3.0)×(3.0–7.0) μ m, single and in pairs (Fig. 220).

Dalmou plate culture on corn meal agar: After 14 days at 25°C, no pseudohyphae are present. Aerobic growth is white to cream-colored, soft, smooth, glistening and entire.

Fermentation:

Glucose	+	Lactose	–
Galactose	–	Raffinose	–
Sucrose	–	Trehalose	–
Maltose	–		

Assimilation:

Glucose	+	<i>N</i> -Acetyl-D-glucosamine	–
Galactose	–	Methanol	–

Creatinine	–	Growth at 40°C	–

¹ Utilization of D-glucosamine as a source of nitrogen.

Co-Q: Not determined.

Mol% G+C: 43.3, CBS 4332 (*T_m*: Meyer et al. 1984).

Fig. 220. *C. castellii*, CBS 4232. After 3 days in glucose–yeast extract–peptone broth at 25°C. Bar = 5 μ m.

Origin of the strain studied: CBS 4332, soil, Finland.

Type strain: CBS 4332.

Comments: *Candida castellii* closely resembles *C. glabrata* but can be distinguished from it by requiring inositol but not pyridoxine as a vitamin for growth.

64.27. *Candida castrensis* C. Ramírez & A. González (1984a)

Growth in glucose–yeast extract–peptone broth:

After 3 days at 20°C, the cells are elongate, (1.5–2.5)×(6.0–15.0) μ m, single and in pairs (Fig. 221).

Dalmou plate culture on corn meal agar: After 7 days at 22°C, pseudohyphae consist of branched chains of elongate cells with pyriform blastoconidia; septate hyphae are also present. Aerobic growth is white, dull, and smooth with a mycelial border.

Fermentation: absent.

Fig. 221. *C. castrensis*, CBS 8172. After 3 days in glucose–yeast extract–peptone broth at 20°C. Bar = 5 µm.

Assimilation:

Glucose	+	<i>N</i> -Acetyl-D-glucosamine	+
Galactose	l	Methanol	–
L-Sorbose	l	Ethanol	+

¹ Utilization of D-glucosamine as a source of nitrogen.

Co-Q: Not determined.

Mol% G + C: 41.7, CBS 8172 (*T_m*: Meyer, unpublished data).

Origin of the strain studied: CBS 8172, from rotten wood, Chile.

Type strain: CBS 8172.

Comments: The strain examined grows poorly at 25°C, consequently the assimilation test cultures were incubated at 20°C. Kurtzman and Robnett (1997) found *C. paludigena* and *C. castrensis* to differ by only two nucleotides in a 600-nucleotide region at the 5' end of

large subunit (26S) rDNA, indicating the two taxa to be conspecific.

64.28. *Candida catenulata* Diddens & Lodder (1942)

Synonyms:

Blastodendron brumptii Guerra (1935)

Candida brumptii (Guerra) Langeron & Guerra (1938)

Mycotorula brumptii (Guerra) Krasil'nikov (1954c)

Candida ravautii Langeron & Guerra (1938)

Growth in glucose–yeast extract–peptone broth:

After 3 days at 25°C, the cells are ovoidal to cylindrical, (1.5–4.5) × (4–12) µm, single, in pairs and chains (Fig. 222).

Dalmau plate culture on corn meal agar: After 7 days at 25°C, pseudohyphae consist of chains of ovoidal or cylindrical cells, and sometimes bear small verticils of ovoidal blastoconidia. Aerobic growth is grayish to cream-colored, somewhat dull, soft and wrinkled.

Fermentation:

¹ Utilization of D-glucosamine as a source of nitrogen.

Co-Q: 9 (Yamada and Kondo 1972a).

Mol% G + C: 54.5, CBS 565; 54.1, CBS 564 (*T_m*: Stenderup and Bak 1968); 53.2, C-140 (Langeron #495); 53.2, CBS 1904; 53.4, UCD-FS&T 60-60 (*T_m*: Meyer and Phaff 1972); 53.2, 54.4, IFO 0745 (CBS 565); 54.4, IFO 0744 (CBS 1904) (*T_m*: Nakase and Komagata 1971f).

Origin of the strains studied: CBS 564, case of perleche (*C. brumptii*); CBS 565, from dysentery patient; CBS 1904, hyperkeratinic foot (*C. ravautii*); CBS 2014, chicken's gut; CBS 2743; CBS 6145, skin; CBS 6174, mastitis milk; CBS 6824; CBS 7135, CBS 7230, soil.

Type strain: CBS 565.

Comments: The conspecificity of *C. catenulata*, *C. brumptii* and *C. ravautii* was established by DNA reassociation experiments (Simione and Meyer 1978).

64.29. *Candida chilensis* Grinbergs & Yarrow (1970a)

Growth in glucose–yeast extract–peptone broth: After 3 days at 25°C, the cells are short ovoidal to elongate, (3.6–5.8) × (4.3–7.2) μm, single, in pairs and small groups. After one month a creeping pellicle is present and the cell suspension is mucoid.

Dalmau plate culture on corn meal agar: After 7 days at 25°C, branched chains of cylindrical cells give a wavy appearance. A few to many subglobose to ovoidal blastoconidia appear individually or in clusters. Some septate hyphae are evident. Aerobic growth is cream-colored to beige, shiny, smooth and butyrous. The margin is entire to slightly fringed.

¹ Utilization of D-glucosamine as a source of nitrogen.

Co-Q: Not determined.

Mol% G + C: 32.0, CBS 8178 (*T_m*: Meyer, unpublished data).

Origin of the strain studied: CBS 8178, rotten wood, Chile.

Type strain: CBS 8178.

64.32. *Candida conglobata* (Redaelli) van Uden & H.R. Buckley ex S.A. Meyer & Ahearn (1983)**Synonyms:**

Cryptococcus conglobatus (Redaelli) Pollacci & Nannizzi (Nannizzi 1934)

Torulopsis conglobata Redaelli (1925)

Candida conglobata (Redaelli) van Uden & H.R. Buckley (1970) nom. inval.

Growth in glucose–yeast extract–peptone broth: After 3 days at 25°C, the cells are ovoidal to cylindrical, (3.0–5.0) × (5.0–20.0) μ m, single and in chains.

Dalmou plate culture on corn meal agar: Pseudohyphae consist of long, branched chains of cylindrical cells, usually with few blastoconidia. Aerobic growth is cream-colored and delicately wrinkled.

Fermentation:

Glucose	+	Lactose	–
Galactose	s	Raffinose	–
Sucrose	–	Trehalose	s

64.33. *Candida cylindracea* K. Yamada & Machida ex S.A. Meyer & Yarrow (1998)

Synonym:

Candida cylindracea K. Yamada & Machida (1962) nom. inval.

Growth in glucose–yeast extract–peptone broth: After 3 days at 25°C, the cells are elongate, (2.0–5.0) × (4.0–12.0) μ m, in pairs and chains. Growth is predominantly pseudomycelial with very few single cells present. A thick wrinkled pellicle is present.

Dalmou plate culture on corn meal agar: After 7 days at 25°C, pseudohyphae consist of elongate cells with little branching and few blastoconidia. A wavy appearance is evident. Aerobic growth is white, smooth and lacy, crater-like and heavily fringed with mycelium.

Fermentation:

Glucose	s	Lactose	-
Galactose	-	Raffinose	-

¹ Utilization of D-glucosamine as a source of nitrogen.

Co-Q: Not determined.

Mol% G+C: 62.7, CBS 6330 (T_m : Meyer and Yarrow 1998).

Origin of the strain studied: CBS 6330, soil.

Type strain: CBS 6330.

Comments: This species, which was previously placed in synonymy with *Candida zeylanoides*, has been restored because of the significant difference of mol% G+C. In addition, the rRNA sequence comparison of these two species supports this separation (Kurtzman, personal communication).

64.34. *Candida dendrica* (van der Walt, van der Klift & D.B. Scott) S.A. Meyer & Yarrow (Yarrow and Meyer 1978)

Synonym:

Torulopsis dendrica van der Walt, van der Klift & D.B. Scott (van der Walt et al. 1971b)

Growth in glucose–yeast extract–peptone broth: After 3 days at 25°C, the cells are subglobose to short-ovoidal, some cylindrical, (2.0–5.5) × (3.0–6.5) μ m, and occur singly, in pairs, short chains and clusters.

Dalmou plate culture on corn meal agar: After 14 days at 25°C, pseudohyphae are not present. Aerobic growth is smooth, shiny, cream-colored with an entire to somewhat irregular margin.

Fermentation:

Type strain: CBS 6151.

64.35. *Candida dendronema* van der Walt, van der Klift & D.B. Scott (van der Walt et al. 1971a)

Growth in glucose–yeast extract–peptone broth: After 3 days at 25°C, the cells are various shapes: globose, ovoid, elongate, teardrop, and triangular to cylindrical, (2.2–5.1) × (3.6–5.7) μ m, and occur singly, in pairs and in small clusters and short chains. Pseudohyphae are present.

Dalmou plate culture on corn meal agar: After 7 days at 25°C, well-developed pseudohyphae are present. The blastoconidia are curved, globose, triangular or teardrop shaped and arranged in grape-like clusters. Aerobic growth is off-white, dry, raised, wrinkled and with a fringed border.

Fermentation:

Glucose	+	Lactose	–

Origin of the strains studied: CBS 6270, CBS 6271, frass of beetle larvae, South Africa.

Type strain: CBS 6270.

64.36. *Candida diddensiae* (Phaff, Mrak & Williams) Fell & S.A. Meyer ex S.A. Meyer & Ahearn (1983)

Synonyms:

Trichosporon diddensiae Phaff, Mrak & Williams (1952)

Torulopsis saccharini Santa Maria (1959b)

Candida diddensiae (Phaff, Mrak & Williams) Fell & S.A. Meyer (1967) nom. inval.

Growth in glucose–yeast extract–peptone broth: After 3 days at 25°C, the cells are subglobose, pear-shaped to cylindrical, (2.3–4.6) × (2.5–5.7) μ m, and occur singly, in pairs, short chains and clusters. After one month a thin filmy pellicle and sediment are present.

Dalmou plate culture on corn meal agar: After 7 days at 25°C, pseudohyphae consist of branched chains of cylindrical cells with verticils of ovoidal blastoconidia

giving a wavy appearance. Aerobic growth is off-white to cream-colored, lacy to wrinkled with a mycelial border.

¹ Utilization of D-glucosamine as a source of nitrogen.

Co-Q: 9 (Yamada and Kondo 1972a).

Mol% G + C: 38.8; 38.3; 36.1, CBS 2214 (T_m : Meyer and Phaff 1972; T_m : Daniel 1983; HPLC: C.-F. Lee et al. 1993, respectively); 37.3, AJ 5108 (*T. saccharini*) (T_m : Nakase and Komagata 1971e).

Origin of the strains studied: CBS 2214, shrimp, USA; CBS 4514, sugar, Spain.

Type strain: CBS 2214.

Comments: DNA reassociation studies (Meyer and Simione 1978) demonstrated a high degree of relatedness between the type strain of *Torulopsis saccharini* and *C. diddensiae*. Other species (*C. atmosphaerica*, *C. polymorpha* and *Trichosporon atlanticum*) that had been considered synonyms of *C. diddensiae* (van Uden and Buckley 1970) were found to have low DNA relatedness and were restored to the species level (Meyer et al. 1984). C.-F. Lee et al. (1993) showed low DNA relatedness between *C. diddensiae* and *C. dendronema*, and *C. diddensiae* and *C. terebra*. Kurtzman and Robnett (1997) found *C. diddensiae* and *C. naeodendra* to have identical sequences in a 600-nucleotide region at the

5' end of large subunit (26S) rDNA, indicating the two taxa to be conspecific.

64.37. *Candida diversa* Y. Ohara, Nonomura & Yunome ex van Uden & H.R. Buckley (1970)

Synonyms:

Candida fimetaria Soneda var. *diversa* Ohara, Nonomura & Yunome (1960b)

Torulopsis arnaudii Capriotti & Fatichenti (1969)

Growth in glucose-yeast extract-peptone broth: After 3 days at 25°C, the cells are ovoid to short cylindrical, (1.5–4.5) × (5.0–8.0) μ m, and occur singly and in short chains.

Dalmu plate culture on corn meal agar: After 7 days at 25°C, primitive pseudohyphae consisting of branched chains of cylindrical cells with clusters of blastoconidia may be present. Aerobic growth is white, smooth, and creamy with an entire border.

¹ Utilization of D-glucosamine as a source of nitrogen.

Co-Q: 7 (Yamada and Kondo 1972a).

Mol% G + C: 34.4, AJ 4648; 34.9, AJ 5367 (T_m : Nakase and Komagata 1971f); 36.0, CBS 6102; 36.5, CBS 6103; 35.1, 36.6, CBS 4074 (T_m : Suzuki et al. 1994; BD: Meyer et al. 1984).

Origin of the strains studied: CBS 4074, grape must, Japan; CBS 6102, CBS 6103, grape must, Italy.

Type strain: CBS 4074.

Comments: Suzuki et al. (1994) described a new species, *C. stellimalicola*, that has physiological and morphological properties similar to *C. diversa*, *C. karawaiewii* and *C. silvae*. It is differentiated from *C. diversa* on its ability to assimilate D-arabinose and DL-lactic acid, its inability to assimilate ribitol and the lack of fermentation. It differs from *C. karawaiewii* by its ability to assimilate L-lysine and from *C. silvae* on a vitamin requirement. DNA reassociation, cell surface antigens and proton magnetic resonance spectra of cell wall mannans were employed to differentiate these species.

64.38. *Candida drimydis* C. Ramírez & A. González (1984j)

Growth in glucose–yeast extract–peptone broth: After 3 days at 25°C, the cells are ovoidal, (2.5–6.0) × (2.8–6.9) µm, single and in pairs. A sediment is present (Fig. 223). After 30 days a ring is present.

Dalmau plate culture on corn meal agar: After 14 days at 25°C, no pseudohyphae are present. Aerobic growth is white, smooth, and waxy with an undulating margin.

Fermentation: absent.

Assimilation:

Glucose	+	<i>N</i> -Acetyl-D-glucosamine	–

Mol% G + C: 43.4, CBS 8185 (*T_m*: Tengku Zainal Mulok 1988).

Fig. 223. *C. drimydis*, CBS 8185. After 3 days in glucose–yeast extract–peptone broth at 25°C. Bar = 5 µm.

Origin of the strain studied: CBS 8185, rotten wood (*Drimys winteri*), Chile.

Type strain: CBS 8185.

Comments: Kurtzman and Robnett (1997) found *C. petrohuensis*, *C. ancudensis* and *C. drimydis* to have identical sequences in a 600-nucleotide region at the 5' end of large subunit (26S) rDNA, thus indicating the three taxa to be conspecific.

64.39. *Candida edax* van der Walt & E.E. Nel (1968)

See *Stephanoascus smithiae*: p. 402

Comments: Giménez-Jurado et al. (1994) demonstrated *C. edax* to be the anamorph of *Stephanoascus smithiae* from mating reactions and high nuclear DNA complementarity.

64.40. *Candida entomophila* D.B. Scott, van der Walt & van der Klift (van der Walt et al. 1971a)

Growth in glucose–yeast extract–peptone broth: After 3 days at 25°C, the cells are spheroidal, ovoidal, long ovoidal, cylindrical, teardrop to somewhat triangular and occur singly, with buds, and in chains. The cell size differs in the two strains which measure (2.8–4.2) × (7.0–8.4) µm and (5.6–7.0) × (14.0–21.0) µm (Fig. 224). Spheroidal to ellipsoidal asexual endospores are formed in hyphal strands.

Dalmau plate culture on corn meal agar: After 7 days at 25°C, pseudohyphae are abundant and consist of long straight chains of cylindrical cells with little branching and often without blastoconidia. When blastoconidia are present, they are ovoidal to triangular and occur singly, in small clusters and short chains. Septate hyphae are also present. Aerobic growth is white to cream-colored, semi-shiny to dull, and smooth with wrinkled areas. The margin is fringed.

Origin of the strains studied: CBS 6159, CBS 6160, tunnels of beetles in trees, South Africa.

Type strain: CBS 6160.

64.41. *Candida ergastensis* Santa María (1971)

Growth in glucose-yeast extract-peptone broth: After 3 days at 25°C, the cells are ovoidal to elongate and cylindroidal, (2.0–4.0) × (4.5–15.0) μm, single and in chains.

Dalmau plate culture on corn meal agar: After 7 days at 25°C, pseudohyphae are abundant and consist of chains of cylindroidal cells, often long and slender, with oval blastoconidia. Septate hyphae may also be present. Aerobic growth is white to cream-colored, somewhat shiny, and folded with a fringed margin.

Fermentation:

Co-Q: Not determined.

Mol% G+C: 36.5, CBS 6248 (BD: Meyer et al. 1984).

Origin of the strain studied: CBS 6248, bark beetles (*Ergastes faber*), Spain.

Type strain: CBS 6248.

64.42. *Candida ernobii* (Lodder & Kreger-van Rij) S.A. Meyer & Yarrow (Yarrow and Meyer 1978)

Synonym:

Torulopsis ernobii Lodder & Kreger-van Rij (1952)

Growth in glucose-yeast extract-peptone broth: After 3 days at 25°C, the cells are subglobose, (3.0–5.0) × (3.0–6.0) μm, single and in pairs.

Dalmau plate culture on corn meal agar: After 14 days at 25°C, pseudohyphae are absent or consist

of short chains of cells. Aerobic growth is off-white to cream-colored, soft, smooth or slightly wrinkled.

Fermentation:

Glucose	+	Lactose	-
Galactose	-	Raffinose	-

¹ Utilization of D-glucosamine as a source of nitrogen.

Co-Q: 8 (Yamada and Kondo 1972a).

Mol% G + C: 36.1, CBS 1737 (*T_m*: Nakase and Komagata 1971e).

Origin of strain studied: CBS 1737, bark beetles (*Ernobius mollis*).

Type strain: CBS 1737.

Comments: Kurtzman and Robnett (unpublished data) found *C. ernobii* and *C. karawaiewii* to have identical sequences in a 600-nucleotide region at the 5' end of large subunit (26S) rDNA, indicating the two taxa to be conspecific. Furthermore, the sequence of *Pichia holstii* differed by only two nucleotides suggesting that it is either the teleomorph or a sibling species.

64.43. *Candida etchellsii* (Lodder & Kreger-van Rij) S.A. Meyer & Yarrow (Yarrow and Meyer 1978)

Synonyms:

Brettanomyces sphaericus Etchells & T.A. Bell (1950b)

Torulopsis citrus Recca & Mrak (1952)

Torulopsis etchellsii Lodder & Kreger-van Rij (1952)

Torulopsis halonitratophila Onishi ex van Uden & Vidal-Leiria (1970)

Candida halonitratophila (Onishi ex van Uden & Vidal-Leiria)

S.A. Meyer & Yarrow (Yarrow and Meyer 1978)

Torulopsis nodaensis Onishi (1957) nom. nud.

Candida nodaensis Yarrow & S.A. Meyer (1978)

Growth in glucose-yeast extract-peptone broth:

After 3 days at 25°C, the cells are subglobose to ovoidal, (2.0–4.0) × (3.0–5.0) μ m, single and in pairs.

Dalmu plate culture on corn meal agar: After 14 days at 25°C, pseudohyphae are not present. Aerobic growth is off-white to cream-colored, shiny or somewhat dull, and smooth with a entire margin.

Fermentation:

¹ Utilization of D-glucosamine as a source of nitrogen.

Co-Q: 9 (Yamada and Kondo 1972a).

Mol% G + C: 52.0–52.7, 4 strains (*T_m*: Nakase and Komagata 1971d); 52.4, CBS 6268 (*T_m*: Meyer et al. 1984); 53.0, CBS 3094 (*T_m*: Yarrow and Meyer 1978); 52.0, CBS 1750; 52.4, JCM 5956; 51.4, CBS 5240; 52.0, CBS 3094 (*T_m*: Suzuki et al. 1992).

Origin of the strains studied: CBS 1750, CBS 1751, fermenting cucumber brine, USA; CBS 2853, sputum, Netherlands; CBS 2854, unknown, probably of human origin; CBS 2987, concentrated lemon juice (type strain)

of *Torulopsis citrus*); CBS 3094, soy mash, Japan (type strain of *C. nodaensis*); CBS 4852, sputum; CBS 5008, sugar, Mauritius; CBS 5240, soy mash, Japan (type strain of *C. halonitratophila*); CBS 6268, soy mash, Japan; CBS 8147, sausages, Netherlands.

Type strain: CBS 1750.

Comments: Suzuki et al. (1992) did taxonomic studies of halophilic and halotolerant *Candida* species found in the ripening process of soy sauce mash. They employed several criteria: proton magnetic resonance spectra of cell wall galactomannans, DNA base composition, electrophoretic patterns of enzymes and DNA–DNA hybridization. The results demonstrated that *C. halonitratophila* and *C. nodaensis* are conspecific with *C. etchellsii*. F.-L. Lee et al. (1992) employed DNA reassociations on these same species and reported their conspecificity.

64.44. *Candida ethanolica* Rybářová, Štros & Kocková-Kratochvílová (1980)

Synonyms:

Torulopsis ethanolitolerans Rybářová, Štros & Kocková-Kratochvílová (1981)

Torulopsis ethanolitolerans Rybářová, Štros & Kocková-Kratochvílová var. *minor* Rybářová, Štros & Kocková-Kratochvílová (1981)

Growth in glucose–yeast extract–peptone broth: After 3 days at 25°C, the cells are ovoidal, (5.0–7.0) × (6.0–10.0) μm, single and in pairs. After one month, a thin pellicle is present and growth is evident on the glass surface.

Dalmau plate culture on corn meal agar: After 7 days at 25°C, pseudohyphae consist of branched chains of elongate cells. Aerobic growth is white to cream-colored, smooth to delicately wrinkled, lobed and entire.

Fermentation:

Glucose	s/–	Lactose	–
Galactose	–	Raffinose	–
Sucrose	–	Trehalose	–
Maltose	–		

Assimilation:

¹ Utilization of D-glucosamine as a source of nitrogen.

Co-Q: Not determined.

Mol% G + C: 29.3, CBS 6753 (*T_m*: Meyer, unpublished data).

Origin of the strains studied: CBS 6753 (ATCC 14927) source unknown; CBS 8041, CBS 8084 (type of *Torulopsis ethanolitolerans*); CBS 8085 (type of *Torulopsis ethanolitolerans* var. *minor*), industrial fodder yeasts from Czechoslovakia.

Type strain: CBS 8041.

Comments: Kurtzman and Robnett (unpublished data) found *C. ethanolica* and *Pichia deserticola* to differ by only two nucleotides in a 600-nucleotide region at the 5' end of large subunit (26S) rDNA, indicating the two taxa to be either conspecific or sibling species.

64.45. *Candida famata* (Harrison) S.A. Meyer & Yarrow (Yarrow and Meyer 1978)

This species has two varieties:

Candida famata (Harrison) S.A. Meyer & Yarrow (Yarrow and Meyer 1978) var. *famata* (1985)

See *Debaryomyces hansenii* var. *hansenii*: p. 161

Candida famata var. *flareri* (Ciferri & Redaelli) Nakase & Suzuki (1985b)

See *Debaryomyces hansenii* var. *fabryi*: p. 162.

Comments: Nakase and Suzuki (1985a,b) made a thorough investigation of *Debaryomyces hansenii*. Various strains of *Candida* species that at one time had been recognized as anamorphs of *D. hansenii* were included. DNA base composition, DNA reassociation, PMR spectra, isoenzymes, and serology were employed in these studies.

64.46. *Candida fennica* (Sonck & Yarrow) S.A. Meyer & Ahearn (1983)

Synonyms:

Trichosporon fennicum Sonck & Yarrow (1969)

Trichosporon melibiosaceum D.B. Scott & van der Walt (1970b)

Growth in glucose–yeast extract–peptone broth: After 3 days at 25°C, cells are globose or ovoidal to elongate, (2.2–6.5) × (2.9–6.5) μm. Pseudohyphae and true hyphae are also present. After one month the sediment is clumpy and the broth appears viscous.

Dalmau plate culture on corn meal agar: After 7 days

at 25°C, pseudohyphae and true hyphae are present. Long wavy, branched chains of cells with globose to ovoidal blastoconidia are abundant as well as true hyphae which have knobby protuberances along the hyphal strands. Aerobic growth is white to off-white, folded, wrinkled, dull, dry to powdery, with a mycelial border.

¹ Utilization of D-glucosamine as a source of nitrogen.

Co-Q: Not determined.

Mol% G + C: 45.3, type strain (BD: Meyer et al. 1984); 43.8, 2 strains (BD: Holzschu et al. 1979).

Origin of the strains studied: CBS 2161, CBS 2162, wood pulp, Sweden.

Type strain: CBS 2162.

Comments: The type strain produces hat-shaped ascospores on 5% Difco malt agar. Kurtzman (personal communication) also observed very small ascospores in the type strain. However, the ascospores were not viable. More studies need to be performed before decisions can be made about the teleomorphic stage of this organism.

64.51. *Candida friedrichii* van Uden & Windisch (1968)**Growth in glucose-yeast extract-peptone broth:**

After 3 days at 25°C, the cells are ovoidal to cylindroidal, (1.5–2.5) × (5.0–12.0) μm, single and in short chains (Fig. 227). A thin pellicle is present.

Dalmay plate culture on corn meal agar: After 7 days at 25°C, pseudohyphae consist of chains of cylindroidal cells, sometimes bearing short chains of ovoidal blastoconidia. Some pseudohyphae bear many blastoconidia whereas others have few. Aerobic growth is white to cream-colored, soft, wrinkled with a frosted appearance and with a fringed border.

Fig. 227. *C. friedrichii*, CBS 6937. After 3 days in glucose-yeast extract-peptone broth at 25°C. Bar = 5 μm.

Mol% G+C: 32.9–33.7, 2 strains (*T_m*: Meyer et al. 1984).

Origin of the strains studied: CBS 4114, D-glucitol solution, Germany; CBS 6937, cheese, France.

Type strain: CBS 4114.

64.52. *Candida fructus* (Nakase) S.A. Meyer & Yarrow (Yarrow and Meyer 1978)

Synonym:

Torulopsis fructus Nakase (1971a)

Growth in glucose–yeast extract–peptone broth:

After 3 days at 25°C, the cells are subglobose to ovoidal, (3.4–5.6)×(3.4–6.7) μ m, single and in pairs.

Dalmau plate culture on corn meal agar: After 7 days at 25°C, primitive pseudohyphae of short chains of ovoidal cells are sparsely formed. Aerobic growth is off-white, shiny, smooth and entire.

Fermentation:

Glucose	+	Lactose	–
Galactose	–	Raffinose	–
Sucrose	–	Trehalose	s
Maltose	–

¹ Utilization of D-glucosamine as a source of nitrogen.

Co-Q: Not determined.

Mol% G+C: 48.8, CBS 6380 (*T_m*: Nakase 1971b).

Origin of the strain studied: CBS 6380, banana, Japan.

Type strain: CBS 6380.

Comments: Kurtzman and Robnett (1997) found *C. fructus* and *C. musae* to have identical sequences in a 600-nucleotide region at the 5' end of large subunit (26S) rDNA, indicating the two taxa to be conspecific.

64.53. *Candida galacta* (Golubev & Bab'eva)

F.-L. Lee, C.-F. Lee, Okada, Komagata & Kozak (1993)

Synonym:

Torulopsis apis var. *galacta* Golubev & Bab'eva (1977)

Growth in glucose–yeast extract–peptone broth:

After 3 days at 25°C, the cells are spheroidal, (1.5–3.5) μ m, and occur singly, in pairs, in small chains and in clusters.

Dalmau plate culture on corn meal agar: After 14 days at 25°C, pseudohyphae are not present. Aerobic growth is white to light beige in color, smooth, creamy, soft, and entire.

Fermentation: absent.

Assimilation:

Glucose	+	<i>N</i> -Acetyl-D-glucosamine	n
Galactose	l	Methanol	–
L-Sorbose	–	Ethanol	–

¹ Utilization of D-glucosamine as a source of nitrogen.

Co-Q: 9 (Yamada and Kondo 1972a).

Mol% G+C: 42.9, 42.4, CBS 5691 (*T_m*: Nakase and Komagata 1971f; BD: Meyer et al. 1984, respectively); 41.2–43.1, 5 strains; 42.5 CBS 5691 (*T_m*: Suzuki and Nakase 1993).

Origin of the strains studied: CBS 5691, frozen cuttlefish; CBS 6715, soil.

Type strain: CBS 5691.

Comments: Suzuki and Nakase (1993) compared strains of *C. glabrosa* and *C. saitoana* as well as '*Torulopsis candida*' strains that have mol% G+C comparable to that of *C. glabrosa*. They found three groups based on DNA reassociation and electrophoretic protein profiles of eight enzymes. The three groups represented three different species, *C. glabrosa*, *C. saitoana* and a new species which they described as *C. pseudoglabrosa*. CBS 6715, listed above as a member of *C. glabrosa*, is the type strain of the new species. These investigators reported that it is difficult to separate the three species using the traditional physiological tests. They found that *C. pseudoglabrosa* does not assimilate D- and L-arabinose, ribitol, DL-glyceraldehyde and dihydroxyacetone, whereas *C. glabrosa* and *C. saitoana* assimilate the latter three compounds and differ in the assimilation of D-arabinose (*C. glabrosa*, +; *C. saitoana*, -) and L-arabinose (*C. saitoana*, +; *C. glabrosa*, -).

64.57. *Candida glucosophila* Tokuoka, Ishitani, S. Goto & Komagata (1987)

The species description presented here was taken from the original description (Tokuoka et al. 1987).

Growth in 25% (w/w) glucose-YM broth: After 3 days at 25°C, growth is very poor. After 7 days, the cells are globose to subglobose, (4.2–7.0) × (4.2–7.3) μm, and occur singly, in pairs, in short chains and in clusters. After one month only a sediment is present.

Growth on 25% (w/w) glucose-YM agar: After one month at 25°C, the growth is cream-colored, dull, dry, smooth and entire.

Slide culture on 25% glucose-corn meal agar: Pseudohyphae are not formed.

Fermentation (in media containing 10% w/v NaCl):

Glucose	+	Lactose	-
Galactose	-	Raffinose	-
Sucrose	-	Trehalose	n
Maltose	-		

Assimilation (in media containing 10% w/v NaCl):

Glucose	+	<i>N</i> -Acetyl-D-glucosamine	-
Galactose	-	Methanol	-
L-Sorbose	-	Ethanol	-
Sucrose	-	Glycerol	w
Maltose	-	Erythritol	-
Cellobiose	-	Ribitol	-
Trehalose	-	Galactitol	-
Lactose	-	D-Mannitol	-
Melibiose	-	D-Glucitol	-
Raffinose	-	α-Methyl-D-glucoside	-
Melezitose	-	Salicin	-
Inulin	-	D-Gluconate	-
Soluble starch	-	DL-Lactate	-
D-Xylose	w	Succinate	-

Creatinine	n	Growth at 42°C	-

¹ Utilization of D-glucosamine as a source of nitrogen.

Co-Q: 9 (*T_m*: Tokuoka et al. 1987).

Mol% G+C: 36.6, type strain (*T_m*: Tokuoka et al. 1987).

Origin of the strain studied: CBS 7349, brown sugar made in Taiwan.

Type strain: CBS 7349.

Comments: The osmotic requirements of this yeast make it difficult to conduct the usual morphological and physiological studies. As indicated, 10% NaCl was used in the liquid assimilation and fermentation media and 25% glucose was used in the solid media.

64.58. *Candida gropengiesseri* (Harrison) S.A. Meyer & Yarrow (Yarrow and Meyer 1978)

Synonyms:

Torula gropengiesseri Harrison (1928)

Torulopsis gropengiesseri (Harrison) Lodder (1934)

Cryptococcus gropengiesseri (Harrison) Skinner (1950)

Growth in glucose-yeast extract-peptone broth:

After 3 days at 25°C, the cells are long-ovoidal, (1.5–2.0) × (3.0–7.0) μm, single and in pairs.

Dalmiau plate culture on corn meal agar: After 14 days at 25°C, pseudohyphae are not present. Aerobic growth is off-white to cream-colored, glistening, soft, butyrous and entire.

¹ Utilization of D-glucosamine as a source of nitrogen.

Co-Q: 9 (Yamada and Kondo 1972a).

Mol% G + C: 55.7, CBS 156 (BD: Meyer et al. 1984), 57.1, CBS 156 (*T_m*: Nakase and Komagata 1971d).

Origin of the strains studied: CBS 156, cocoon of cockroach (*Periplaneta orientalis*); CBS 6387, human toe; CBS 7074, citrus product.

Type strain: CBS 156.

64.59. *Candida guilliermondii* (Castellani) Berkhout (1923)

This species has two varieties:

***Candida guilliermondii* (Castellani) Berkhout var. *guilliermondii* (1952)**

See *Pichia guilliermondii*: p. 308

***Candida guilliermondii* var. *membranifaciens* (as *membranaefaciens*) Lodder & Kreger-van Rij (1952)**

See *Pichia ohmeri*: p. 329

64.60. *Candida haemulonii* (van Uden & Kolipinski) S.A. Meyer & Yarrow (Yarrow and Meyer 1978)

Synonym:

Torulopsis haemulonii van Uden & Kolipinski (1962)

Growth in glucose–yeast extract–peptone broth:

After 3 days at 25°C, the cells are globose, ovoidal and ellipsoidal, (2.0–7.0) × (2.0–7.0) μm, single and in pairs. (Fig. 230). A ring or a thin pellicle may be present.

Fig. 230. *C. haemulonii*, CBS 5468. After 3 days in glucose–yeast extract–peptone broth at 25°C. Bar = 5 μm.

Dalmiau plate culture on corn meal agar: After 14 days at 25°C, primitive pseudohyphae are sometimes present. Aerobic growth is off-white to light beige, smooth, and butyrous with an entire border.

Fermentation:

Cadaverine	+	Growth at 37°C	+
Creatinine	–	Growth at 40°C	–

¹ Utilization of D-glucosamine as a source of nitrogen.

Co-Q: 9 (Yamada and Kondo 1972a).

Mol% G+C: 45.9–46.1, 2 strains (T_m : Nakase and Komagata 1971d); 47.8, CBS 5149 (T_m : Meyer et al. 1984); 45.4, CDC 86-041135; 46.3, CBS 5149; 47.9, CBS 7801 (T_m : Gargeya et al. 1991); 45.6–46.3, 8 strains including the type strain, 46.1 (T_m : Ribeiro 1995).

Origin of the strains studied: CBS 5149, gut of blue-striped grunt (*Haemulon sciurus*); CBS 5150, seawater, Portugal; CBS 5468, water, Florida, USA; CBS 6332, skin of captive dolphin; CBS 6590, human; CBS 8125, furniture polish.

Type strain: CBS 5149.

Comments: Lehmann et al. (1993) studied twenty-five clinical isolates that had been identified as *C. haemulonii*. These investigators used electrophoretic isoenzyme profiles, mol% G+C and DNA reassociations, as well as morphological and physiological characteristics, to examine these strains. Two distinct groups were evident and designated Group I and Group II. *C. haemulonii* type strain and eleven isolates comprised Group I. The remaining fourteen isolates made up Group II. Some physiological differences were noted between the two groups. Group I strains demonstrated negative or latent reactions on galactose, sorbose, melezitose, L-arabinose, galactitol, and α -methyl-D-glucoside, whereas the Group II strains showed positive responses on these carbon sources. Ribeiro (1995) examined the CBS strains included in *C. haemulonii* to determine if the two groups were present. DNA reassociation experiments and restriction fragment length polymorphisms showed that most of the strains were the same as the type strain (Group I) and are considered valid members of *C. haemulonii*. One strain demonstrated significant DNA reassociation with members of Group II. Group II strains will be designated a new species.

64.61. *Candida homilentoma* van der Walt & Nakase (1973)

Growth in glucose–yeast extract–peptone broth: After 3 days at 25°C, the cells are ovoidal to elongate, (2.5–3.5) × (3.0–4.5) μ m, single and in pairs (Fig. 231).

Dalmau plate culture on corn meal agar: After

Fig. 231. *C. homilentoma*, CBS 6099. After 3 days in glucose–yeast extract–peptone broth at 25°C. Bar = 5 μ m.

3 days at 25°C, pseudohyphae of long cylindrical cells and septate hyphae with few blastoconidia are present. Aerobic growth is off white, dull, and wrinkled with a mycelial border.

Fermentation:

Glucose	+	Lactose	–
Galactose	s	Raffinose	–
Sucrose	–	Trehalose	+
Maltose	s		

Assimilation:

Glucose	+	<i>N</i> -Acetyl-D-glucosamine	–

Creatinine	–	Growth at 40°C	–

¹ Utilization of D-glucosamine as a source of nitrogen.

Co-Q: Not determined.

Mol% G+C: 48.3, CBS 6099; 49.0, CBS 6312 (T_m : van der Walt and Nakase 1973).

Origin of the strains studied: CBS 6099, CBS 6312, tunnels and frass of insects infesting trees in South Africa.

Type strain: CBS 6312.

64.62. *Candida humilis* (E.E. Nel & van der Walt) S.A. Meyer & Yarrow (Yarrow and Meyer 1978)

Synonym:

Torulopsis humilis E.E. Nel & van der Walt (1968)

Growth in glucose-yeast extract-peptone broth:

After 3 days at 25°C, the cells are ovoidal, (3.0–6.0 × (5.0–8.0) μm, single and in pairs.

Dalmau plate culture on corn meal agar: After 14 days at 25°C, pseudohyphae are not present. Aerobic growth is off-white, smooth, glistening, and butyrous with an entire edge.

Fermentation:

Glucose	+	Lactose	–
Galactose	+	Raffinose	–
Sucrose	–	Trehalose	+
Maltose	–		

Assimilation:

Glucose	+	<i>N</i> -Acetyl-D-glucosamine	n
Galactose	+	Methanol	–
L-Sorbose	–	Ethanol	–/l

Additional assimilation tests and other growth characteristics:

2-Keto-D-gluconate	–	L-Lysine	–
5-Keto-D-gluconate	–	Ethylamine	–
Saccharate	n	D-Glucosamine (N) ¹	–
D-Gluconate	–	50% Glucose	–
Xylitol	–	10% NaCl/5% glucose	+
L-Arabinitol	–	Starch formation	–
Arbutin	–	Urease	–
Propane 1, 2 diol	–	Biotin-free	+
Butane 2, 3 diol	–	Pyridoxine-free	+
Nitrite	–	0.01% Cycloheximide	–
Cadaverine	–	Growth at 35°C	w
Creatinine	–	Growth at 37°C	–

¹ Utilization of D-glucosamine as a source of nitrogen.

Co-Q: Not determined.

Mol% G + C: 47.1, CBS 5658 (*T_m*: Meyer et al. 1984).

Origin of the strain studied: CBS 5658, Bantu beer.

Type strain: CBS 5658.

Comments: Kurtzman and Robnett (unpublished data)

found *C. humilis* and *C. milleri* to have identical sequences in a 600-nucleotide region at the 5' end of large subunit (26S) rDNA, indicating the two taxa to be conspecific.

64.63. *Candida incommunis* Y. Ohara, Nonomura & T. Yamazaki (1965)

Growth in glucose-yeast extract-peptone broth:

After 3 days at 25°C, the cells are elongate, cylindrical, (1.5–2.5) × (6.0–12.0) μm, single and in chains (Fig. 232).

Fig. 232. *C. incommunis*, CBS 5604. After 5 days in glucose-yeast extract-peptone broth at 25°C. Bar = 5 μm.

Dalmau plate culture on corn meal agar: After 7 days at 25°C, long pseudohyphae of branched chains of cylindrical cells are present. Aerobic growth is off-white with a wrinkled center, a smoother periphery and some pseudomycelial development at the margin.

Fermentation:

Glucose	s	Lactose	–
Galactose	–	Raffinose	–
Sucrose	s/–	Trehalose	–
Maltose	–		

Assimilation:

Glucose	+	<i>N</i> -Acetyl-D-glucosamine	–

¹ Utilization of D-glucosamine as a source of nitrogen.

Co-Q: 9 (Yamada and Kondo 1972a).

Mol% G + C: 43.7, AJ 4621; 44.4, AJ 4632; 44.4, AJ 4619 (CBS 592) (*T_m*: Nakase and Komagata 1971f).

Origin of the strains studied: CBS 572, feces; CBS 2044, washed beer bottle; CBS 2049, beer; CBS 2879, soil; CBS 5159, skin; CBS 5310, grape (*C. intermedia* var. *ethanophila*); CBS 5460, fruit.

Type strain: CBS 572.

64.69. *Candida ishiwadae* Sugiyama & S. Goto (1969)

Growth in glucose–yeast extract–peptone broth: After 3 days at 25°C, the cells are subglobose to ovoidal, (1.5–5.0) × (3.0–6.0) μ m, single and in pairs.

Dalmou plate culture on corn meal agar: After 7 days at 25°C, a few primitive pseudohyphae consisting of chains of elongated cells are present. Aerobic growth is white to slightly cream-colored, mucoid, moist, smooth and entire.

Fermentation:

Glucose	+	Lactose	–
Galactose	s/–	Raffinose	–
Sucrose	s/–	Trehalose	s
Maltose	+		

Assimilation:

Glucose	+	<i>N</i> -Acetyl-D-glucosamine	n
Galactose	-/l	Methanol	-
L-Sorbose	l	Ethanol	+
Sucrose	+	Glycerol	+
Maltose	+	Erythritol	+
Cellobiose	+	Ribitol	+
Trehalose	+	Galactitol	-/l
Lactose	-	D-Mannitol	+
Melibiose	-	D-Glucitol	+
Raffinose	-	α -Methyl-D-glucoside	+/l
Melezitose	+/l	Salicin	+
Inulin	-	D-Gluconate	+
Soluble starch	+	DL-Lactate	+/l
D-Xylose	+	Succinate	+

Butane 2,3 diol	v	Pyridoxine-free	+
Nitrite	+	0.1% Cycloheximide	+
Cadaverine	+	Growth at 35°C	+/w
Creatinine	-	Growth at 37°C	-

¹ Utilization of D-glucosamine as a source of nitrogen.

Co-Q: Not determined.

Mol% G+C: 36.7, CBS 6022 (*T_m*: Meyer et al. 1984).

Origin of the strains studied: CBS 5526, unknown; CBS 6022, soil.

Type strain: CBS 6022.

64.70. *Candida karawaiewii* Yarrow & S.A. Meyer (1978)**Synonym:**

Torulopsis karawaiewii Jurzitza (1970) nom. nud.

Growth in glucose-yeast extract-peptone broth:

After 3 days at 25°C, the cells are globose to subglobose, (2.5–5.0) × (2.5–5.0) μ m, single and in pairs.

Dalmou plate culture on corn meal agar: After 14 days at 25°C, there is no evidence of pseudohyphae. Aerobic growth is white to cream-colored, smooth, soft, butyrous and entire.

Fermentation:

Glucose	+/s	Lactose	-
Galactose	-	Raffinose	-
Sucrose	-	Trehalose	-
Maltose	-
